where i is the current flowing through the inductor. Figure 30.2 shows how these energies vary with time in this LC circuit. This figure may remind you of Figure 14.16, which showed potential energy and kinetic energy as a function of time for a mass oscillating on a spring. The resemblance is not coincidental! Much of this chapter's mathematical description of electromagnetic oscillations follows closely that developed in Chapter 14 for mechanical oscillations.

In Figure 30.2a, the capacitor is initially fully charged (with the positive charge on the bottom plate) and then connected to the circuit. At that time, the energy in the circuit is contained entirely in the

electric field of the capacitor. The capacitor begins to discharge through the inductor in Figure 30.2b. At this point, current is flowing through the inductor, which generates a magnetic field. (A green arrow or label below each circuit diagram indicates the direction and the magnitude of the instantaneous current, i.) Now part of the energy of the circuit is stored in the electric field of the capacitor and part in the magnetic field of the inductor. The current begins to level off as the inductor's increasing magnetic field induces an emf that opposes the current. In Figure 30.2c, the capacitor is completely discharged, and maximum current is flowing through the inductor. (When the magnitude of i has its maximum value, it is designated as $i_{\max}$ in the figure.) All the energy of the circuit is now stored in the magnetic field of the inductor. However, the current continues to flow, decreasing from its maximum value, which causes the magnetic field in the inductor to decrease. In Figure 30.2d, the capacitor begins to charge with the opposite polarity (positive charge on the top plate). Energy is again stored in the electric field of the capacitor, as well as in the magnetic field of the inductor.

In Figure 30.2e, the energy in the circuit is again entirely contained in the electric field of the capacitor. Note that the electric field now points in the opposite direction from the original field in Figure 30.2a. The current is zero, as is the magnetic field in the inductor. In Figure 30.2f, the capacitor begins to discharge again, producing a current flowing in the direction opposite to that in parts (b) through (d) of the figure; this current in turn creates a magnetic field in the opposite direction in the inductor. Again, part of the energy is stored in the electric field and part in the magnetic field. In Figure 30.2g, the energy is all stored in the magnetic field of the inductor, but with the magnetic field in the opposite direction from that in Figure 30.2c and with the maximum current in the opposite direction from that in Figure 30.2c. In Figure 30.2h, the capacitor begins to charge again, meaning there is energy in both the electric and magnetic fields. The state of the circuit then returns to that shown in Figure 30.2a. The circuit continues to oscillate indefinitely because there is no resistor in it, and the electric and magnetic fields together conserve energy. A real circuit with a capacitor and an inductor does not oscillate indefinitely; instead, the oscillations die away with time because of small resistances in the circuit (covered in Section 30.3) or electromagnetic radiation (covered in Chapter 31).

The charge on either capacitor plate and the current in the LC circuit vary sinusoidally, as shown in Figure 30.3, where $q_{\max}$ refers to the maximum charge on the capacitor plate that is initially positively charged (the lower plate in Figure 30.2a). The energy in the electric field depends on the square of the charge on the capacitor, and the energy in the magnetic field depends on the square of the current in the inductor. Thus, the electric energy, U_E, and the magnetic energy, U_B, vary between zero and their respective maximum values as a function of time.

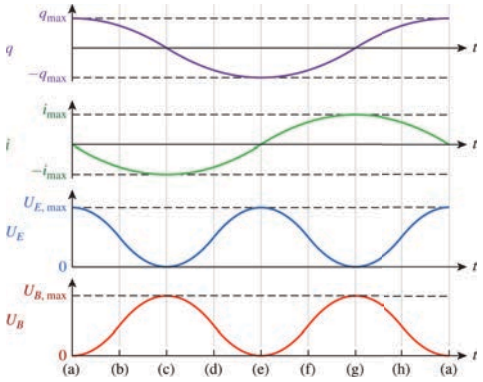

FIGURE 30.3 Variation of the charge, current, electric energy, and magnetic energy as a function of time for a simple, single-loop LC circuit. The letters along the bottom refer to the parts of Figure 30.2.

30.2 Analysis of LC Oscillations

Concept Check 30.1

Figure 30.2a shows that the charge on the capacitor in an LC circuit is largest when the current is zero. What about the potential difference across the capacitor?

a) The potential difference across the capacitor is largest when the current is the largest.

b) The potential difference across the capacitor is largest when the charge is the largest.

c) The potential difference across the capacitor does not change.

Now, let's quantify the phenomena described in the preceding section. Consider a single-loop circuit containing a capacitor of capacitance C and an inductor of inductance L, but no resistor and no resistive losses in the circuit wire, as illustrated in Figure 30.4. We can write the total energy in the circuit, U, as the sum of the electric energy in the capacitor and the magnetic energy in the inductor:

$$U = U_E + U_B.$$

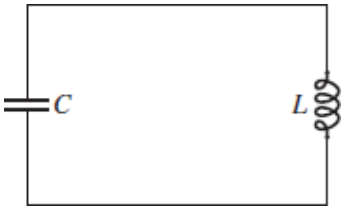

FIGURE 30.4 A single-loop LC circuit containing an inductor and a capacitor.

Using the expressions for the electric energy and the magnetic energy in terms of the charge and the current, $U_E = \frac{1}{2}\left(q^2/C\right)$ and $U_B = \frac{1}{2}Li^2$, we obtain

$$U = U_E + U_B = \frac{1}{2}\frac{q^2}{C} + \frac{1}{2}Li^2.$$

Because we have assumed zero resistance, no energy can be lost to heat, and the energy in the circuit will remain constant, because the electric field and the magnetic field together conserve energy. Thus, the derivative with respect to time of the energy in the circuit is zero:

$$\frac{dU}{dt} = \frac{d}{dt}\left(\frac{1}{2}\frac{q^2}{C} + \frac{1}{2}Li^2\right) = \frac{q}{C}\frac{dq}{dt} + Li\frac{di}{dt} = 0.$$

By definition, the current is the time derivative of the charge, $i = dq/dt$, and therefore, the time derivative of the current is the second derivative of the charge:

$$\frac{di}{dt} = \frac{d}{dt}\left(\frac{dq}{dt}\right) = \frac{d^2q}{dt^2}.$$

With this expression for di/dt, the preceding equation for the time derivative of the total energy, dU/dt, becomes

$$\frac{q}{C}\frac{dq}{dt} + L\frac{dq}{dt}\frac{d^2q}{dt^2} = \frac{dq}{dt}\left(\frac{q}{C} + L\frac{d^2q}{dt^2}\right) = 0.$$

We can rewrite this equation as

$$\frac{d^2q}{dt^2} + \frac{q}{LC} = 0. \qquad \textbf{(30.1)}$$

(We discard the solution $dq/dt = 0$ because it corresponds to the situation where there is initially no charge on the capacitor.) This differential equation has the same form as that for simple harmonic motion, which describes the position, *x,* of an object with mass m connected to a spring with spring constant *k:*

$$\frac{d^2x}{dt^2} + \frac{k}{m}x = 0.$$

We saw in Chapter 14 that the solution of this differential equation for the position as a function of time was a sinusoidal function: $x = x_{\max}\cos(\omega_0 t + \phi)$, where ϕ is a phase constant and the angular frequency, ω_0, is given by $\omega_0 = \sqrt{k/m}$.

Simply substituting q for x and $1/LC$ for k/m in the differential equation for simple harmonic motion leads to the analogous solution for equation 30.1. Thus, the charge as a function of time in an LC circuit is given by

$$q = q_{\max}\cos(\omega_0 t - \phi), \qquad \textbf{(30.2)}$$

where $q_{\max}$ is the magnitude of the maximum charge in the circuit and ϕ is the phase constant, which is determined by the initial conditions for a given situation. (Note that the convention for electromagnetic oscillations is to use a negative sign in front of ϕ.) The angular frequency is given by

$$\omega_0 = \sqrt{\frac{1}{LC}} = \frac{1}{\sqrt{LC}}. \qquad \textbf{(30.3)}$$

The current is given by the time derivative of equation 30.2:

$$i = \frac{dq}{dt} = \frac{d}{dt}(q_{\max}\cos(\omega_0 t - \phi)) = \omega_0 q_{\max}\sin(\omega_0 t - \phi).$$

Since the maximum current in the circuit is $i_{\max} = \omega_0 q_{\max}$, we get

$$i = -i_{\max} \sin(\omega_0 t - \phi). \qquad \textbf{(30.4)}$$

Equations 30.2 and 30.4 correspond to the top two curves in Figure 30.3 with $\phi = 0$. We can write expressions for the electric energy and the magnetic energy as functions of time:

$$U_E = \frac{1}{2}\frac{q^2}{C} = \frac{1}{2}\frac{\left[q_{\max}\cos(\omega_0 t - \phi)\right]^2}{C} = \frac{q_{\max}^2}{2C}\cos^2(\omega_0 t - \phi),$$

and

$$U_B = \frac{1}{2}Li^2 = \frac{L}{2}\left[-i_{\max}\sin(\omega_0 t - \phi)\right]^2 = \frac{L}{2}i_{\max}^2\sin^2(\omega_0 t - \phi).$$

Since $i_{\max} = \omega_0 q_{\max}$ and $\omega_0 = 1/\sqrt{LC}$, we can write

$$\frac{L}{2}i_{\max}^2 = \frac{L}{2}\omega_0^2 \mathrm{q}_{\max}^2 = \frac{q_{\max}^2}{2C}.$$

Thus, we can express the magnetic energy as a function of time as follows:

$$U_B = \frac{q_{\max}^2}{2C}\sin^2(\omega_0 t - \phi).$$

Note that both the electric energy and the magnetic energy have a maximum value equal to $q_{\max}^2/(2C)$ and a minimum of zero.

We can obtain an expression for the total energy in the circuit, *U,* by summing the electric and magnetic energies and then using the trigonometric identity $\sin^2\theta + \cos^2\theta = 1$:

$$U = U_E + U_B = \frac{q_{\max}^2}{2C}\cos^2(\omega_0 t - \phi) + \frac{q_{\max}^2}{2C}\sin^2(\omega_0 t - \phi)$$
$$= \frac{q_{\max}^2}{2C}\left[\sin^2(\omega_0 t - \phi) + \cos^2(\omega_0 t - \phi)\right]$$
$$= \frac{q_{\max}^2}{2C} = \frac{L}{2} i_{\max}^2.$$

Thus, the total energy in the circuit remains constant with time and is proportional to the square of the original charge put on the capacitor.

Concept Check 30.2

In Figure 30.3, suppose $t = 0$ at point (c). What is the phase constant in this case? (Define a clockwise current as positive.)

a) 0

b) $\pi/2$

c) π

d) $3\pi/2$

e) none of the above

EXAMPLE 30.1 Characteristics of an LC Circuit

A circuit contains a capacitor, with $C = 1.50\ \mu\text{F}$, and an inductor, with $L = 3.50\ \text{mH}$ (Figure 30.4). The capacitor is fully charged using a 12.0-V battery and is then connected to the circuit.

PROBLEMS

What is the angular frequency of the circuit? What is the total energy in the circuit? What is the charge on the capacitor after $t = 2.50\ \text{s}$?

SOLUTIONS

The angular frequency of the circuit is given by

$$\omega_0 = \frac{1}{\sqrt{LC}} = \frac{1}{\sqrt{\left(3.50 \cdot 10^{-3}\ \text{H}\right)\left(1.50 \cdot 10^{-6}\ \text{F}\right)}} = 1.38 \cdot 10$$

The total energy in the circuit is

$$U = \frac{q_{\text{max}}^2}{2C}.$$

The maximum charge on the capacitor is

$$\begin{aligned} q_{\text{max}} &= CV_{\text{emf}} = \left(1.50 \cdot 10^{-6}\ \text{F}\right)\left(12.0\ \text{V}\right) \\ &= 1.80 \cdot 10^{-5}\ \text{C}. \end{aligned}$$

Thus, we can calculate the initial energy stored in the electric field of the capacitor, which is the same as the total energy in the circuit:

$$U = \frac{q_{\text{max}}^2}{2C} = \frac{\left(1.80 \cdot 10^{-5}\ \text{C}\right)^2}{2\left(1.50 \cdot 10^{-6}\ \text{F}\right)} = 1.80 \cdot 10^{-4}\ \text{J}.$$

The charge on the capacitor as a function of time is given by

$$q = q_{\text{max}} \cos(\omega_0 t - \phi).$$

To determine the constant ϕ, we remember that $q = q_{\max}$ at $t = 0$, so

$$q(0) = q_{\max} = q_{\max} \cos\left[(\omega_0)(0) - \phi\right] = q_{\max} \cos(-\phi) = q_{\max}$$

Thus, we see that $\phi = 0$, and we can write the charge as a function of time as follows:

$$q = q_{\max} \cos \omega_0 t.$$

Putting in the values $q_{\max} = 1.80 \cdot 10^{-5}\ \text{C}, \omega_0 = 1.38 \cdot 10^{4}\ \text{rad/s}$, and $t = 2.50\ \text{s}$, we get

$$q = (1.80 \cdot 10^{-5}\ \text{C}) \cos[(1.38 \cdot 10^{4}\ \text{rad/s})(2.50\ \text{s})] = 1.20 \cdot 10$$

Self-Test Opportunity 30.1

The frequency of oscillation of an LC circuit is 200.0 kHz. At $t = 0$, the capacitor has its maximum positive charge on the lower plate. Decide whether each of the following statements is true or false.

a) At $t = 2.50$ μs, the charge on the lower plate has its maximum negative value.

b) At $t = 5.00$ μs, the current in the circuit is at its maximum value.

c) At $t = 2.50$ μs, the energy in the circuit is stored completely in the inductor.

d) At $t = 1.25$ μs, half the energy in the circuit is stored in the capacitor and half the energy is stored in the inductor.

30.3 Damped Oscillations in an RLC Circuit

Now let's consider a single-loop circuit that has a capacitor and an inductor but also a resistor—an **RLC circuit,** as shown in Figure 30.5. We saw in the preceding section that the energy of a circuit with a capacitor and an inductor remains constant and that the energy is transformed from electric to magnetic and back again with no losses. However, if a resistor is present in the circuit, the current flow produces ohmic losses, which show up as thermal energy. Thus, the energy of the circuit decreases because of these losses. The rate of energy loss is given by

$$\frac{dU}{dt} = -i^2 R.$$

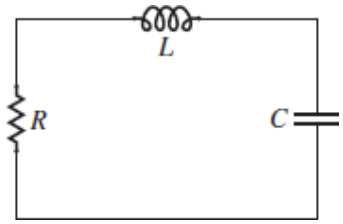

FIGURE 30.5 A single-loop RLC circuit containing a resistor, an inductor, and a capacitor.

We can rewrite the change in the energy in the circuit as a function of time:

$$\frac{dU}{dt} = \frac{q}{C}\frac{dq}{dt} + Li\frac{di}{dt} = -i^2 R.$$

Again, since $i = dq/dt$ and $di/dt = d^2q/dt^2$, we can write

$$\frac{q}{C}\frac{dq}{dt} + Li\frac{di}{dt} + i^2R = \frac{q}{C}\frac{dq}{dt} + L\frac{dq}{dt}\frac{d^2q}{dt^2} + \left(\frac{dq}{dt}\right)^2 R = 0,$$

or

$$\frac{d^2q}{dt^2} + \frac{R}{L}\frac{dq}{dt} + \frac{1}{LC}q = 0. \qquad \textbf{(30.5)}$$

The solution of this differential equation (for small damping, meaning sufficiently small values of the resistance) is

$$q = q_{\max}e^{-Rt/2L}\cos\omega t, \qquad \textbf{(30.6)}$$

where

$$\omega = \sqrt{\omega_0^2 - \left(\frac{R}{2L}\right)^2} \qquad \textbf{(30.7)}$$

and $\omega_0 = 1/\sqrt{LC}$.

Self-Test Opportunity 30.2

Compare equation 30.5 for the charge on the capacitor as a function of time to the differential equation for the position of a mass on a spring presented in Chapter 14: $\frac{d^2x}{dt} + \frac{b}{m}\frac{dx}{dt} + \frac{k}{m}x = 0$. Which quantity in the RLC circuit plays the role of the mass *m*, which that of the spring constant *k*, and which that of the damping constant *b*?

Concept Check 30.3

What is the condition for small damping that needs to be fulfilled for equation 30.6 to be a solution for equation 30.5? (*Hint:* You can find this by analogy with the damped oscillation of a mass on a spring, for which the differential equation is $\frac{d^2x}{dt^2} + \frac{b}{m}\frac{dx}{dt} + \frac{k}{m}x = 0$ and the condition for small damping is $b < 2\sqrt{mk}$. Alternatively, you can use dimensional analysis.)

a) $R < 2\sqrt{L/C}$

b) $R < \sqrt{2C/L}$

c) $R < \sqrt{2LC}$

The calculus used in arriving at the solution in equation 30.6 is not shown. You can verify that the solution satisfies equation 30.5 by straightforward substitution from equations 30.6 and 30.7 into 30.5. You can also refer back to Chapter 14, where it was shown that the equation of motion for a weakly damped (or underdamped) mechanical oscillator has a similar solution. Chapter 14 also covered overdamped and critically damped oscillations.

If the capacitor in the single-loop RLC circuit of Figure 30.5 is charged and then connected in the circuit, the charge on the capacitor will vary sinusoidally with time while decreasing in amplitude (Figure 30.6). Taking the derivative of equation 30.6 shows that the current, $i = dq/dt$, has an amplitude that is damped at the same rate that the charge is damped and that this amplitude also varies sinusoidally with time. After some time, no current remains in the circuit.

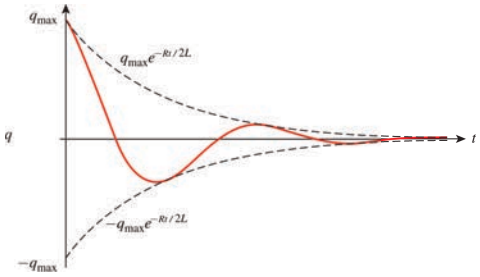

FIGURE 30.6 Graph of the charge on the capacitor as a function of time in a circuit containing a capacitor, an inductor, and a resistor.

We can analyze the energy in the circuit as a function of time by calculating the energy stored in the electric field of the capacitor:

$$U_E = \frac{1}{2}\frac{q^2}{C} = \frac{q_{\max}^2}{2C}e^{-Rt/L}\cos^2\omega t.$$

Thus, U_E and U_B both decrease exponentially in time, and therefore so does the total energy in the circuit, $U_E + U_B$.

30.4 Driven AC Circuits

So far, we have been studying circuits that contain a source of constant emf or that start with a constant charge and contain energy that then oscillates between electric and magnetic fields. However, many interesting effects occur in a circuit in which the current oscillates continuously. Let's investigate some of these effects, starting with a time-varying source of emf and then considering in turn a resistor, a capacitor, and an inductor connected to this source.

Alternating Driving emf

A source of emf can be capable of producing a time-varying voltage, as opposed to the sources of constant emf considered in previous chapters. We'll assume that the source of time-varying emf provides a sinusoidal voltage as a function of time, the *driving emf,* given by

$$V_{\text{emf}} = V_{\max} \sin \omega t, \tag{30.8}$$

where ω is the angular frequency of the emf and $V_{\max}$ is the maximum amplitude or value of the emf.

The current induced in a circuit containing a source of time-varying emf will also vary sinusoidally with time. This time-varying current is called **alternating current (AC).** However, the alternating current may not always remain in phase with the time-varying emf. The current, i, as a function of time is given by

$$i = I \sin(\omega t - \phi), \tag{30.9}$$

where I is the amplitude of the current and the angular frequency of the time-varying current is the same as that of the driving emf, but the phase constant ϕ is not zero. Note that, as is the convention, the phase constant is preceded by a negative sign.

Circuit with a Resistor

Let's begin our analysis of RLC circuits with alternating current by considering a circuit containing only a resistor and a source of time-varying emf (Figure 30.7). Applying Kirchhoff's Loop Rule to this circuit, we obtain

$$V_{\text{emf}} - v_R = 0,$$

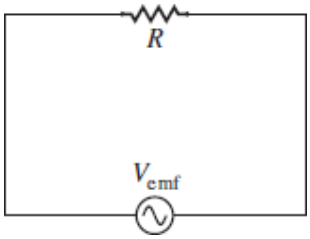

FIGURE 30.7
Single-loop circuit with a resistor and a source of time-varying emf.

where v_R is the voltage drop across the resistor. Substituting v_R for V_{emf} in equation 30.8, we get

$$v_R = V_{\max} \sin \omega t = V_R \sin \omega t,$$

where V_R is the maximum voltage drop across the resistor. Note that the voltage as a function of time is represented by a lowercase v and the amplitude of the voltage with uppercase V. According to Ohm's Law, $V = iR$, so we can write

$$i_R = \frac{v_R}{R} = \frac{V_R}{R} \sin \omega t = I_R \sin \omega t. \qquad \textbf{(30.10)}$$

Thus, the current amplitude and the voltage amplitude are related as follows:

$$V_R = I_R R. \qquad \textbf{(30.11)}$$

Figure 30.8a shows the voltage across the resistor and the current through it as functions of time. The time-varying current can be represented by a phasor, $\vec{I}_R$, and the time-varying voltage by a phasor, $\vec{V}_R$ (Figure 30.8b). A **phasor** is a counterclockwise-rotating vector (with its tail fixed at the origin) whose projection on the vertical axis represents the sinusoidal variation of the particular quantity in time. The angular velocity of the phasors in Figure 30.8b is ω of equation 30.10. The current flowing through the resistor and the voltage across the resistor are in phase, which means that the phase difference between the current and the voltage is zero.

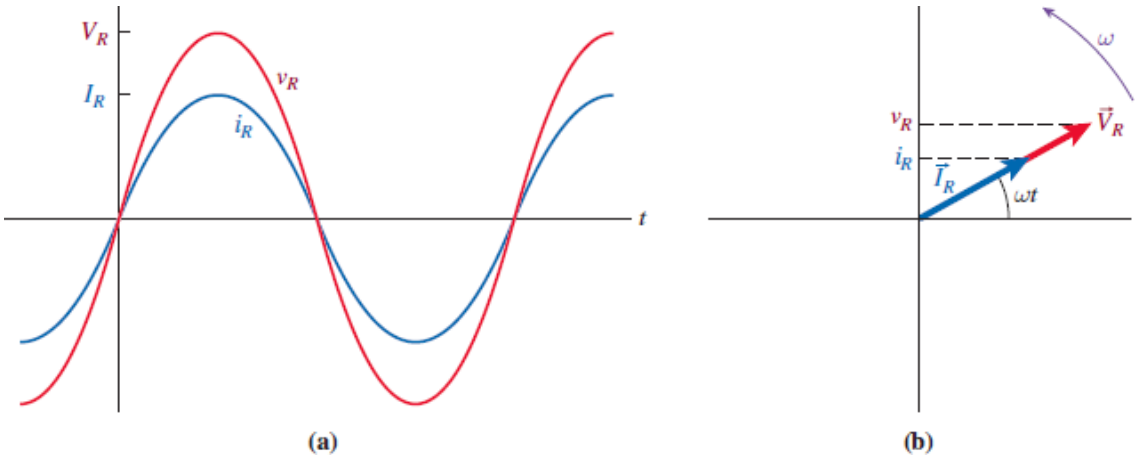

FIGURE 30.8 Alternating voltage and current for a single-loop circuit containing a source of time-varying emf and a resistor: (a) voltage and current as functions of time; (b) phasors representing voltage and current, showing that they are in phase.

Circuit with a Capacitor

Now let's examine a circuit that contains a capacitor and a source of time-varying emf (Figure 30.9). The voltage across the capacitor is given by Kirchhoff's Loop Rule,

$$V_{\text{emf}} - v_C = 0,$$

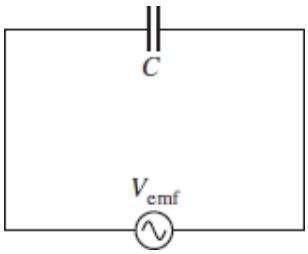

FIGURE 30.9
Single-loop circuit with a capacitor and a source of time-varying emf.

where v_C is the voltage drop across the capacitor. Thus, we have

$$v_C = V_{\max} \sin \omega t = V_C \sin \omega t,$$

where V_C is the maximum voltage across the capacitor. Since $q = CV$ for a capacitor, we can write

$$q = Cv_C = CV_C \sin \omega t.$$

However, we want an expression for the current (rather than the charge) as a function of time. Therefore, we take the derivative with respect to time of the preceding equation:

$$i_C = \frac{dq}{dt} = \frac{d(CV_C \sin \omega t)}{dt} = \omega C V_C \cos \omega t.$$

This equation can be written in a form comparable to that of equation 30.10 by defining a quantity that is similar to resistance, called the **capacitive reactance,** X_C:

$$X_C = \frac{1}{\omega C}. \tag{30.12}$$

This definition allows us to express the current, i_C, as

$$i_C = \frac{V_C}{X_C}\cos \omega t,$$

or, with $I_C = V_C/X_C$, as

$$i_C = I_C \cos \omega t.$$

We can use $\cos\theta = \sin(\theta + \pi/2)$ to express this result in a form analogous to that of equation 30.10:

$$i_C = I_C \sin(\omega t + \pi/2). \tag{30.13}$$

This expression for the current flowing in a circuit with only a capacitor is similar to the expression for the current flowing in a circuit with only a resistor, except that current and voltage are out of phase by $\pi/2$ rad (90°). Figure 30.10a shows the voltage and the current as functions of time.

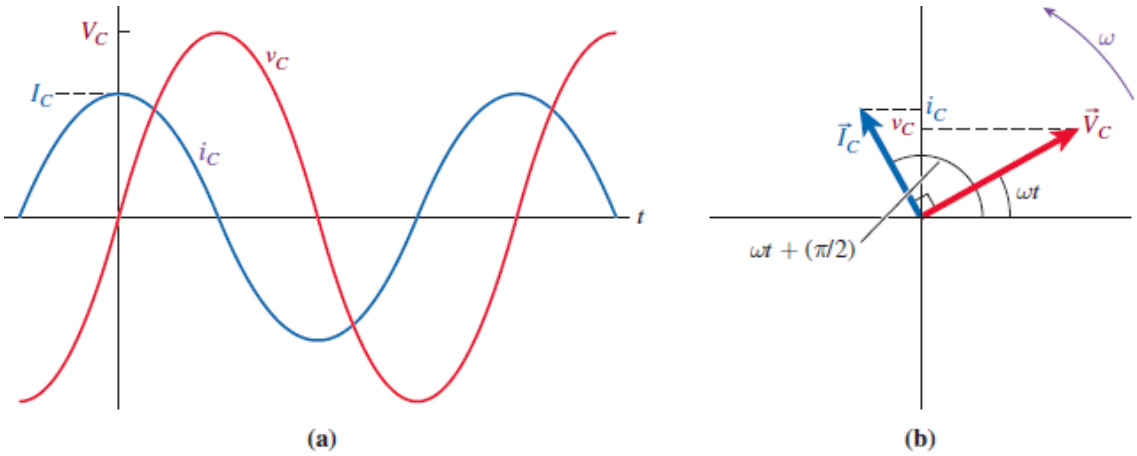

FIGURE 30.10 Alternating voltage and current for a single-loop circuit containing a source of time-varying emf and a capacitor: (a) voltage and current as functions of time; (b) phasors representing voltage and current, showing that they are out of phase by $\pi/2$ rad (90°).

Concept Check 30.4

A circuit containing a capacitor (Figure 30.9) has a source of time-varying emf that provides a voltage given by $v_C = V_C \sin\omega t$. What is the current, i_C, through the capacitor when the potential difference across it is largest $(v_C = V_{max})$?

a) $i_C = 0$

b) $i_C = +I_{max}$

c) $i_C = -I_{max}$

The corresponding phasors, $\vec{I}_C$ and $\vec{V}_C$, shown in Figure 30.10b, indicate that *for a circuit with only a capacitor, the current leads the voltage*. The amplitude of the voltage across the capacitor and the amplitude of the current through the capacitor are related by

$$V_C = I_C X_C. \tag{30.14}$$

This equation resembles Ohm's Law with the capacitive reactance replacing the resistance. One major difference between the capacitive reactance and the resistance is that the capacitive reactance depends on the angular frequency of the time-varying emf.

Circuit with an Inductor

Now let's consider a circuit with a source of time-varying emf and an inductor (Figure 30.11). We again apply Kirchhoff's Loop Rule to this circuit to obtain the voltage across the inductor:

$$v_L = V_{\max} \sin \omega t = V_L \sin \omega t,$$

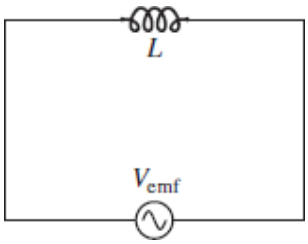

FIGURE 30.11
Single-loop circuit with an inductor and a source of time-varying emf.

where V_L is the maximum voltage across the inductor. A changing current in an inductor induces an emf given by

$$v_L = L \frac{di_L}{dt}.$$

Note that for positive di/dt the voltage drop across the inductor is positive because the direction of current is the direction of decreasing potential. Thus, we can write

$$L \frac{di_L}{dt} = V_L \sin \omega t,$$

or

$$\frac{di_L}{dt} = \frac{V_L}{L} \sin \omega t.$$

We are interested in the current rather than its time derivative, so we integrate the preceding equation:

$$i_L = \int \frac{di_L}{dt} dt = \int \frac{V_L}{L} \sin \omega t \, dt = -\frac{V_L}{\omega L} \cos \omega t.$$

Here we set the constant of integration to zero because we are not interested in solutions that contain both an oscillating and a constant current. The **inductive reactance,** which, like the capacitive reactance, is similar to resistance, is defined as

$$X_L = \omega L. \tag{30.15}$$

Using the inductive reactance, we can express i_L as

$$i_L = -\frac{V_L}{X_L} \cos\ \omega t = -I_L\ \cos\ \omega t,$$

where I_L is the maximum current. Thus,

$$V_L = I_L X_L,$$

which again resembles Ohm's Law except that the inductive reactance depends on the angular frequency of the time-varying emf.

Because $-\cos\theta = \sin(\theta - \pi/2)$, we can rewrite $i_L = -I_L \cos \omega t$ as follows:

$$i_L = I_L \sin(\omega t - \pi/2). \tag{30.16}$$

Thus, the current flowing in a circuit with an inductor and a source of time-varying emf is out of phase with the voltage by $-\pi/2$ rad. Figure 30.12a shows voltage and current as functions of time. The corresponding phasors, $\vec{I_L}$ and $\vec{V_L}$, are shown in Figure 30.12b, which shows that *for a circuit with an inductor, the voltage leads the current*.

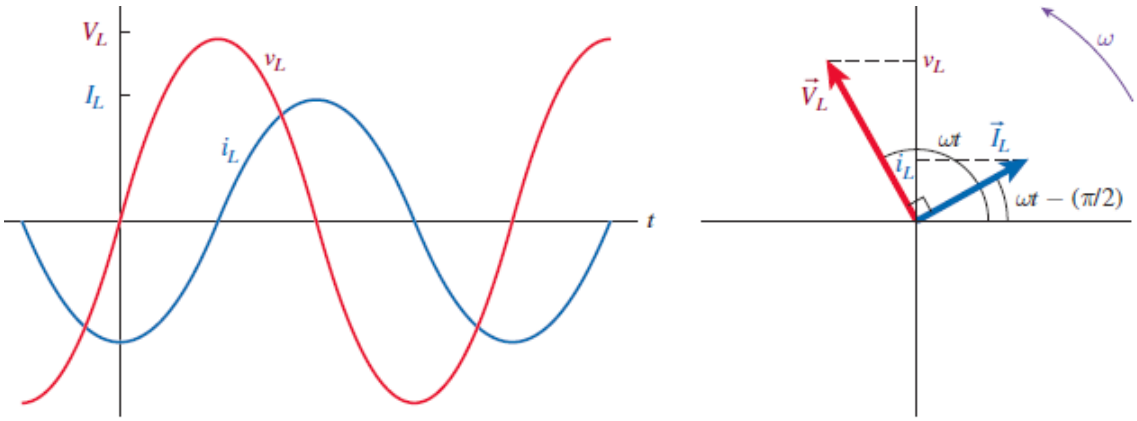

FIGURE 30.12 Alternating voltage and current for a single-loop circuit containing a source of time-varying emf and an inductor: (a) voltage and current as functions of time; (b) phasors representing voltage and current, showing that they are out of phase by $-\pi/2 \text{ rad } (-90^\circ)$.

30.5 Series RLC Circuit

Now we're ready to consider a single-loop circuit that has all three circuit elements, along with a source of time-varying emf (Figure 30.13). We will not present a full mathematical analysis of this RLC circuit but will use phasors to analyze the important aspects.

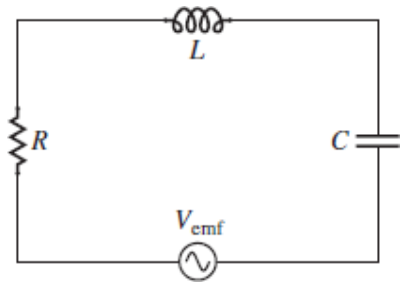

FIGURE 30.13 A single-loop circuit containing a source of time-varying emf, a resistor, an inductor, and a capacitor.

The time-varying current in the simple RLC circuit can be described by a phasor, $\vec{I}_m$ (Figure 30.14). The projection of $\vec{I}_m$ on the vertical axis represents the current i flowing in the circuit as a function of time, t, where the angle of the phasor is given by $\omega t - \phi$ such that

$$i = I_m \sin(\omega t - \phi).$$

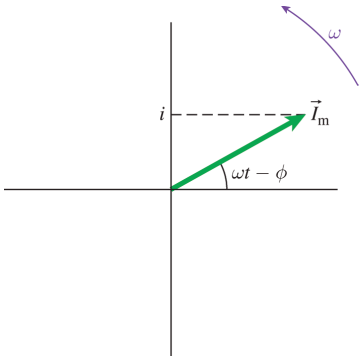

FIGURE 30.14
Phasor $\overrightarrow{I}_{\mathrm{m}}$ representing the current *i* flowing in an RLC circuit.

The current i and the voltages across the circuit components have different phases with respect to the time-varying emf, as we saw in the previous section:

- *For the resistor,* the voltage v_R and the current i are in phase with each other, and the voltage phasor, $\overrightarrow{V}_R$, is in phase with $\overrightarrow{I}_{\mathrm{m}}$.
- *For the capacitor,* the current i leads the voltage v_C by $\pi/2$ rad (90°), so the voltage phasor, $\overrightarrow{V}_C$, has an angle that is $\pi/2$ rad (90°), less than the angles of $\overrightarrow{I}_{\mathrm{m}}$ and $\overrightarrow{V}_R$.
- *For the inductor,* the current i lags behind the voltage v_L by $\pi/2$ rad (90°), so the voltage phasor, $\overrightarrow{V}_L$, has an angle that is $\pi/2$ rad (90°) greater than the angles of $\overrightarrow{I}_{\mathrm{m}}$ and $\overrightarrow{V}_R$.

The voltage phasors for the RLC circuit are shown in Figure 30.15. The instantaneous voltage across each component is represented by the projection of the respective phasor on the vertical axis.

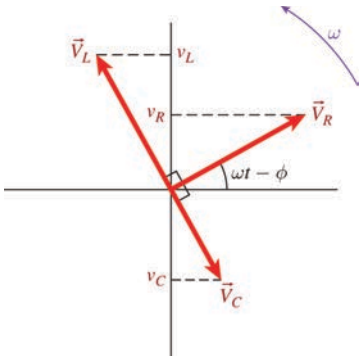

FIGURE 30.15
Voltage phasors for an RLC series circuit. The phasor $\overrightarrow{V}_R$ is in phase with the phasor $\overrightarrow{I}_m$ representing the current in the circuit.

The total voltage drop across all components, V, is given by

$$V = v_R + v_C + v_L. \qquad \textbf{(30.17)}$$

The total voltage, V, can be thought of as the projection on the vertical axis of the phasor $\overrightarrow{V}_{\mathrm{m}}$, representing the time-varying emf in the circuit (Figure 30.16). The phasors in Figure 30.15 rotate together, so equation 30.17 holds at any time. The voltage phasors must sum as vectors to match $\overrightarrow{V}_{\mathrm{m}}$ in order to satisfy equation 30.17 at all times. This vector sum is shown in Figure 30.16. In this figure, the sum of the two phasors $\overrightarrow{V}_L$ and $\overrightarrow{V}_C$ has been replaced with $\overrightarrow{V}_L + \overrightarrow{V}_C$ The vector sum of $\overrightarrow{V}_L + \overrightarrow{V}_C$ and $\overrightarrow{V}_R$ must equal $\overrightarrow{V}_{\mathrm{m}}$. Thus, we can write

$$V_{\mathrm{m}}^2 = V_R^2 + (VL - V_C)^2, \qquad \textbf{(30.18)}$$

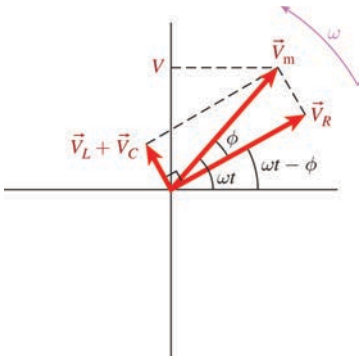

FIGURE 30.16 Sum of the voltage phasors in an RLC series circuit.

because the vectors $\vec{V}_L$ and $\vec{V}_C$ always point in opposite directions, and $\vec{V}_\mathrm{m}$ is perpendicular to both. Now we can substitute our previously derived expressions for V_R, V_L, and V_C into equation 30.18, taking the amplitude of the current in all three components to be I_m because they are connected in series:

$$V_\mathrm{m}^2 = (I_\mathrm{m}R)^2 + (I_\mathrm{m}X_L - I_\mathrm{m}X_C)^2.$$

We can then solve for the amplitude of the current in the circuit:

$$I_\mathrm{m} = \frac{V_\mathrm{m}}{\sqrt{R^2 + (X_L - X_C)^2}}.$$

The denominator of the term on the right-hand side is called the **impedance,** Z:

$$Z = \sqrt{R^2 + (X_L - X_C)^2}. \qquad \textbf{(30.19)}$$

The impedance of a circuit depends on the frequency of the time-varying emf. This time dependence is expressed explicitly when substitutions are made for the capacitive reactance, X_C, and the inductive reactance, X_L:

$$Z = \sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}. \tag{30.20}$$

The impedance of an AC circuit has the unit ohm (Ω), just like the resistance in a DC circuit. We can then write

$$I_{\mathrm{m}} = \frac{V_{\mathrm{m}}}{\sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}} = \frac{V_{\mathrm{m}}}{Z}. \tag{30.21}$$

The current flowing in an AC circuit depends on the difference between the inductive reactance and the capacitive reactance and is called the *total reactance*. The phase constant, ϕ, can be expressed in terms of this difference. The phase constant is defined as the phase difference between the voltage phasors $\overrightarrow{V}_R$ and $\overrightarrow{V}_{\mathrm{m}}$ depicted in Figure 30.16. Thus, we can express the phase constant as

$$\phi = \tan^{-1}\left(\frac{V_L - V_C}{V_R}\right).$$

Since $V_L = X_L I_{\mathrm{m}}$, $V_C = X_C I_{\mathrm{m}}$, and $V_R = R I_{\mathrm{m}}$, this can be rewritten as follows:

$$\phi = \tan^{-1}\left(\frac{X_L - X_C}{R}\right).$$

Using $X_C = 1/\omega C$ and $X_C = \omega L$, we can then obtain the frequency dependence of the phase constant:

$$\phi = \tan^{-1}\left(\frac{\omega L - (\omega C)^{-1}}{R}\right). \tag{30.22}$$

The current in the RLC circuit can now be written as

$$i = I_m \sin(\omega t - \phi), \tag{30.23}$$

where I_{m} is the magnitude of the phasor $\vec{I}_{\text{m}}$. The voltage across all the components in the circuit is given by the time-varying source of emf:

$$V = V_{\text{emf}}(t) = V_{\text{m}} \sin \omega t, \tag{30.24}$$

where V_{m} is the magnitude of the phasor $\vec{V}_{\text{m}}$.

Concept Check 30.5

A circuit like that shown in Figure 30.13 containing a capacitor, an inductor, and a resistor connected in series with a source of time-varying emf has $V_{\text{emf}} = V_{\text{m}} sin\omega t$. At a point in time when V_{emf} is increasing, how is the current in the circuit behaving?

a) The current is increasing.

b) The current is decreasing.

c) The current is not changing.

d) The current may be increasing or decreasing.

Thus, three conditions are possible for an AC circuit containing a resistor, a capacitor, and an inductor connected in series:

- For $X_L > X_C$, ϕ is positive, and the current in the circuit lags behind the voltage in the circuit. This circuit is similar to a circuit with only an inductor, except that the phase constant is not necessarily $\pi/2$ rad (90°), as illustrated in Figure 30.17a.

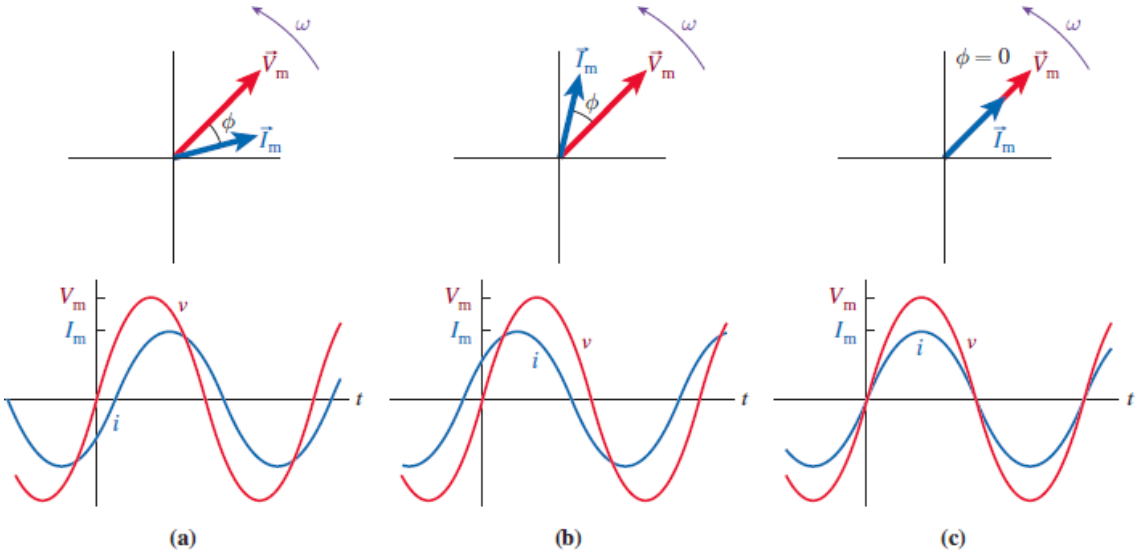

FIGURE 30.17 Current and voltage as functions of time for an RLC circuit with: (a) $X_L > X_C$; (b) $X_L < X_C$; (c) $X_L = X_C$.

- For $X_L < X_C$, ϕ is negative, and the current in the circuit leads the voltage in the circuit. This circuit is similar to a circuit with only a capacitor, except that the phase constant is not necessarily $-\pi/2$ rad (-90°), as illustrated in Figure 30.17b.
- For $X_L = X_C$, ϕ is zero, and the current in the circuit is in phase with the voltage in the circuit. This circuit is similar to a circuit with only a resistance, as illustrated in Figure 30.17c. When $\phi = 0$, the circuit is said to be in **resonance.**

The current amplitude, I_m, in the series RLC circuit depends on the frequency of the time-varying emf, as well as on L and C. Inspection of equation 30.21 shows that the maximum current occurs when

$$\omega L - \frac{1}{\omega C} = 0,$$

which corresponds to $\phi = 0$ and $X_L = X_C$. The angular frequency, ω_0, at which the maximum current occurs, called the **resonant angular frequency,** is

$$\omega_0 = \frac{1}{\sqrt{LC}}.$$

Self-Test Opportunity 30.3

Consider a series RLC circuit like the one shown in Figure 30.13. The circuit is driven at an angular frequency ω by the time-varying emf. The resonant angular frequency is ω_0. Decide whether each of the following statements is true or false.

a) If $\omega = \omega_0$, the voltage and the current are in phase.

b) If $\omega < \omega_0$, the voltage lags behind the current.

c) If $\omega > \omega_0$, then $X_C > X_L$.

A Practical Example

Now let's look at a real circuit (Figure 30.18). The diagram for this circuit is shown in Figure 30.13. The circuit has a source of time-varying emf with $V_{\mathrm{m}} = 7.5\ \mathrm{V}$ and also has $L = 8.2\ \mathrm{mH}, C = 100\ \mu\mathrm{F}$, and $R = 10\ \Omega$. The maximum current, I_{m}, was measured as a function of the ratio of the angular frequency of the time-varying emf to the resonant angular frequency, ω/ω_0 (Figure 30.19). Red circles indicate the results of the measurements. The maximum value of the current occurs, as expected, at the resonant angular frequency. However, with $R = 10\ \Omega$, the relationship between I_{m} and ω/ω_0, given by equation 30.21, results in the green curve, which does not reproduce the measured results. To better describe the current, we must remember that in a real circuit, the inductor has a resistance, even at the resonant frequency. The black curve in Figure 30.19 corresponds to equation 30.21 with $R = 15.4\ \Omega$.

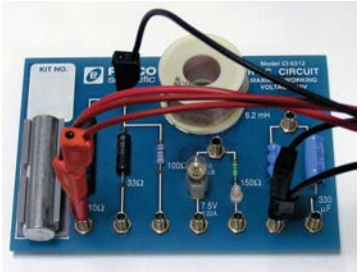

FIGURE 30.18 Real series circuit containing an 8.2-mH inductor, a 10-Ω resistor, and a 100-μF capacitor.

W. Bauer and G. D. Westfall

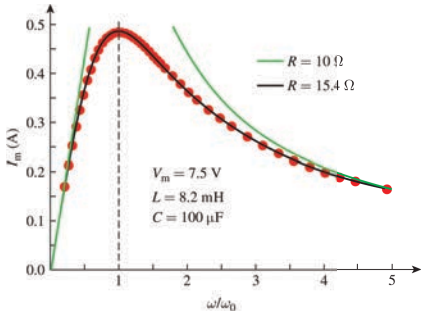

FIGURE 30.19 Graph of the maximum current, I_m, versus the ratio of the angular frequency, ω, of the time-varying emf to the resonance frequency, ω_0, for an RLC circuit. Red dots represent measurements. The text explains the green and black curves.

The resonant behavior of an RLC circuit resembles the response of a damped mechanical oscillator (Chapter 14). Figure 30.20 shows the calculated maximum current, I_m, as a function of the ratio of the angular frequency of the time-varying emf to the resonant angular frequency, ω/ω_0, for a series RLC circuit with $V_m = 7.5\ \text{V}, L = 8.2\ \text{mH}, C = 100\ \mu\text{F}$, and three different resistances. You can see that as the resistance is lowered, the maximum current at the resonant angular frequency increases, producing a more pronounced peak.

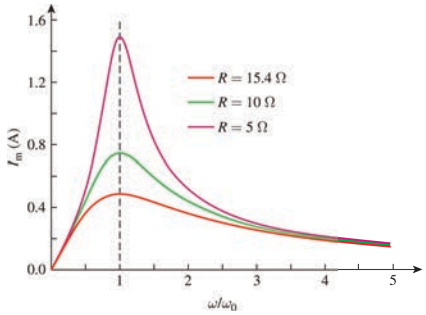

FIGURE 30.20 Graph of the maximum current, I_m, versus the ratio of the angular frequency, ω, of the time-varying emf to the resonance frequency, ω_0, for three series RLC circuits, with $L = 8.2\ \text{mH}$, $C = 100\ \mu\text{F}$, and three different resistances.

EXAMPLE 30.2 Characterizing an RLC Circuit

Suppose an RLC series circuit like the one shown in Figure 30.13 has $R = 91.0\Omega, C = 6.00\ \mu\text{F}$, and $L = 60.0\ \text{mH}$. The source of time-varying emf has an angular frequency of $\omega = 64.0\ \text{rad/s}$.

PROBLEM

What is the impedance of this circuit?

SOLUTION

Normally, we would solve this problem by obtaining an expression for the impedance in terms of the quantities provided. However, instead we'll calculate several intermediate numerical answers to gain insight into the characteristics of this circuit.

The impedance is given by $Z = \sqrt{R^2 + (X_L - X_C)^2}$. To see which of the quantities on the right-hand side has the greatest impact on the impedance, we calculate the quantities individually. The inductive reactance is

$$X_L = \omega L = (64.0\ \text{rad/s})\left(60.0 \cdot 10^{-3}\ \text{H}\right) = 3.84\ \Omega.$$

The capacitive reactance is

$$X_C = \frac{1}{\omega C} = \frac{1}{(64.0\ \text{rad/s})(60.0 \cdot 10^{-6}\ \text{H})} = 2.60\ \text{k}\Omega.$$

We see that the impedance of this circuit is dominated by the capacitive reactance at the given value of the angular frequency. This type of circuit is called *capacitive*.

Putting in our results for the capacitive and inductive reactances, we calculate the impedance:

$$Z = \sqrt{R^2 + (X_L - X_C)^2} = \sqrt{(91.0\ \Omega)^2 + \left(3.84\ \Omega - 2.60 \cdot \right.$$

That is, the inductive reactance and the resistance are completely negligible within rounding error. For comparison, the impedance

of this circuit when it is in resonance is

$$Z = \sqrt{R^2 + (X_L - X_C)^2} = \sqrt{(91.0\ \Omega)^2 + 0} = 91.0\ \Omega.$$

This result implies that the circuit as described in the problem statement is far from resonance, which is consistent with the very different values we obtained for the capacitive and inductive reactances. (Remember that at resonance these two reactances have the same value!)

Self-Test Opportunity 30.4

Consider a series RLC circuit like the one shown in Figure 30.13. Decide whether each of the following statements is true or false.

a) The current through the resistor is the same as the current through the inductor at all times.

b) In an ideal scenario, energy is dissipated in the resistor but not in the capacitor or in the inductor.

c) The voltage drop across the resistor is the same as the voltage drop across the inductor at all times.

Frequency Filters

We have been analyzing circuits that have a time-varying emf with a single frequency. However, many applications involve time-varying emfs that reflect a superposition of many frequencies. In some situations, certain frequencies need to be filtered out of this kind of circuit. (Series RLC circuits can be used as frequency filters.) One example of such a circuit can be found in DSL (digital subscriber line) filters for making connections to the Internet over a household telephone line. Despite the wide availability of broadband Internet connections, DSL lines still exist in the United States in the third decade of the 21st century, mainly in rural areas. This highlights the digital divide in this country, with vastly different access to online resources, depending on where you live. A typical DSL filter is shown in Figure 30.21.

FIGURE 30.21 A typical band-pass filter for phones connected to a household circuit that has a DSL Internet connection.

Mark Dierker/McGraw Hill

A DSL Internet connection operates at high frequencies and is connected to a household's regular phone line. The high operating frequency of the DSL connection causes noise on the phones in the house. Therefore, a **band-pass filter** is normally installed on all the phones in the house to filter out the high-frequency noise created by the DSL Internet connection. Frequency filters can be designed to pass low frequencies and block high frequencies (*low-pass filter*) or to pass high frequencies and block low frequencies (*high-pass filter*). A low-pass filter can be combined with a high-pass filter to allow a range of

frequencies to pass (*band-pass filter*) and block the frequencies outside that range.

Figure 30.22 shows two examples of a low-pass filter, where V_{in} is a time-varying emf with many frequencies. A low-pass filter is essentially a voltage divider. Part of the original voltage passes through the circuit, while part goes to ground. For the RC version of the low-pass filter, shown in Figure 30.22a, low frequencies essentially have an open circuit, while high frequencies are preferentially sent to ground. Thus, only signals with low frequencies will pass through the filter. This behavior makes sense because current going to ground must pass through a capacitor that essentially blocks the flow of current for low frequencies because the capacitor plates are charging, while rapidly changing current does not allow charge to build up on the plates of the capacitor, allowing current to flow. For the RL version, shown in Figure 30.22b, low frequencies easily pass through the inductor while high frequencies are blocked. This effect arises because the self-induced emf in an inductor opposes rapid changes in current, effectively blocking current through the inductor at high frequencies, while a slow change in current produces a much smaller opposing emf, allowing current to flow.

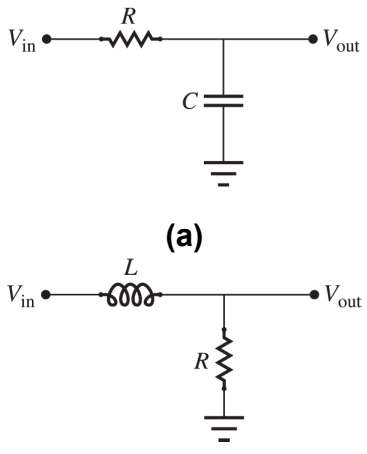

FIGURE 30.22 Two low-pass filters: (a) RC version; (b) RL version.

To quantify the performance of the low-pass filter in Figure 30.22a, we define the input section of the circuit to be the resistor and the capacitor. The impedance of this section is $Z_{\text{in}} = \sqrt{R^2 + X_C^2}$. The

impedance of the output section is just $Z_{\text{out}} = X_C$. The ratio of the emf into the filter and the emf emerging from the filter is

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{Z_{\text{out}}}{Z_{\text{in}}}. \tag{30.25}$$

The ratio of the emfs can then be written as

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{X_C}{\sqrt{R^2 + X_C^2}} = \frac{1}{\sqrt{\left(\frac{R}{X_C}\right)^2 + 1}} = \frac{1}{\sqrt{1 + \omega^2 R^2 C^2}}.$$

For the RL version of the low-pass filter, shown in Figure 30.22b, $Z_{\text{in}} = \sqrt{R^2 + X_L^2}$ and $Z_{\text{out}} = R$, allowing us to write

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{R}{\sqrt{R^2 + X_L^2}} = \frac{1}{\sqrt{1 + (\omega^2 L^2 / R^2)}}. \tag{30.27}$$

The *breakpoint frequency,* ω_{B}, between the responses to low and high frequencies is the frequency at which the ratio $V_{\text{out}}/V_{\text{in}}$ is $1/\sqrt{2} = 0.707$. At that frequency for the RC version, we have

$$\frac{1}{\sqrt{1 + \omega_{\text{B}}^2 R^2 C^2}} = \frac{1}{\sqrt{2}},$$

from which we can solve for the breakpoint frequency:

$$\omega_{\mathrm{B}} = \frac{1}{RC}. \tag{30.28}$$

For the RL version of the low-pass filter, the breakpoint frequency is obtained from equation 30.27:

$$\omega_{\mathrm{B}} = \frac{R}{L}. \tag{30.29}$$

Figure 30.23 shows two examples of a high-pass filter. A high-pass filter is also a voltage divider. For the RC version of the high-pass filter, shown in Figure 30.23a, signals with low frequencies cannot pass the capacitor while signals with high frequencies pass through easily. This behavior makes sense because the signal must pass through a capacitor that essentially blocks the flow of current for low frequencies because the capacitor plates are charging, while rapidly changing current does not allow charge to build up on the plates of the capacitor, allowing current to flow. For the RL version, shown in Figure 30.23b, signals with low frequency have essentially an open circuit to ground, while signals with high frequencies are blocked from reaching ground. Thus, only signals with high frequencies will be passed through the filter. This effect arises because the self-induced emf in an inductor opposes rapid changes in current, effectively blocking current through the inductor at high frequencies, while a slow change in current produces a much smaller opposing emf, allowing current to flow.

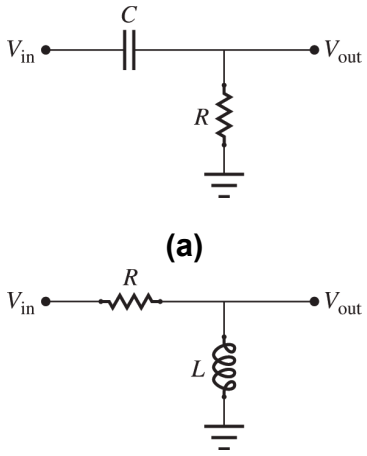

FIGURE 30.23 Two high-pass filters: (a) RC version; (b) RL version.

For the RC version of the high-pass filter in Figure 30.23a, the impedance of the input section is $Z_{\text{in}} = \sqrt{R^2 + X_C^2}$, while the impedance of the output section is $Z_{\text{out}} = R$. The ratio of the output emf to the input emf is then

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{R}{\sqrt{R^2 + X_C^2}} = \frac{1}{\sqrt{1 + X_C^2/R^2}} = \frac{1}{\sqrt{1 + \dfrac{1}{\omega^2 R^2 C^2}}}.$$

For the RL version of the high-pass filter shown in Figure 30.23b, the ratio of the output emf to the input emf is

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{X_L}{\sqrt{R^2 + X_L^2}} \frac{1}{\sqrt{\dfrac{R^2}{X_L^2} + 1}} \frac{1}{\sqrt{1 + \dfrac{R^2}{\omega^2 L^2}}}. \quad \textbf{(30.31)}$$

For these high-pass filters, as the frequency increases, the ratio of output emf to input emf approaches 1, while for low frequencies, the

ratio of output emf to input emf goes to zero. The breakpoint frequencies for the high-pass filters are the same as for the low-pass filters: $\omega_B = 1/(RC)$ for the RC version and $\omega_B = R/L$ for the RL version.

An example of a band-pass filter is shown in Figure 30.24. The band-pass filter consists of a high-pass filter in series with a low-pass filter. Thus, both high and low frequencies are suppressed, and a narrow band of frequencies is allowed to pass through the filter.

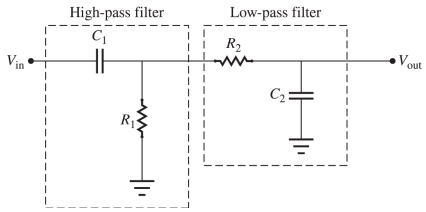

FIGURE 30.24 A band-pass filter consisting of a high-pass filter connected in series with a low-pass filter.

Figure 30.25 shows the frequency response of a low-pass filter and a high-pass filter with $R = 50.0\ \Omega$ and $C = 20.0\ \text{mF}$. For this combination of resistance and capacitance, the breakpoint frequency is

$$\omega_B = \frac{1}{RC} = \frac{1}{(50.0\ \Omega)(20.0 \cdot 10^{-3}\ \text{F})} = 1.00\ \text{rad/s}.$$

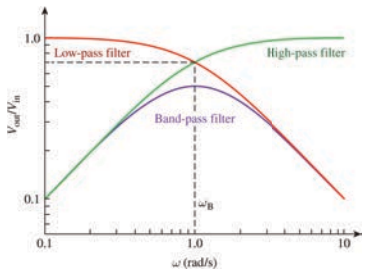

FIGURE 30.25 The frequency response of a low-pass filter, a high-pass filter, and a band-pass filter.

Also shown in Figure 30.25 is the frequency response of a band-pass filter with $R_1 = R_2 = 50.0\ \Omega$ and $C_1 = C_2 = 20.0\ \text{mF}$.

Concept Check 30.6

The frequency response for a band-pass filter plotted in Figure 30.25 is the _____ of the frequency responses for the low-pass and high-pass filters.

a) sum

b) product

c) difference

d) ratio

e) It is none of the above.

EXAMPLE 30.3 Crossover Circuit for Audio Speakers

One way to improve the performance of an audio system is to send high frequencies to a small speaker called a *tweeter* and low frequencies to a large speaker called a *woofer*. Figure 30.26 shows a simple crossover circuit that preferentially passes high frequencies to a tweeter and low frequencies to a woofer. The crossover circuit consists of an RC high-pass filter and an RL low-pass filter connected in parallel to the output of the audio amplifier. The speakers act as resistors, as shown in Figure 30.26. The capacitance and the resistance of this crossover circuit are $C = 10.0\ \mu\text{F}$ and $L = 10.0\ \text{mH}$. The speakers each have a resistance of $R = 8.00\ \Omega$.

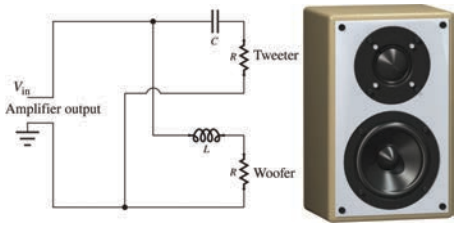

FIGURE 30.26 Crossover circuit for audio speakers.

PROBLEM

What is the crossover frequency for this crossover circuit?

SOLUTION

We can use equation 30.27 for the response of the RL low-pass filter and equation 30.30 for the response of the RC high-pass filter and equate the two responses:

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{R}{\sqrt{R^2 + X_L^2}} = \frac{R}{\sqrt{R^2 + X_C^2}}.$$

Thus, the responses of the low-pass filter and the high-pass filter are the same when

$$X_L = X_C. \tag{i}$$

We can rewrite equation (i) as

$$\omega_{\text{crossover}} L = \frac{1}{\omega_{\text{crossover}} C},$$

where $\omega_{\text{crossover}}$ is the crossover angular frequency. Thus, the crossover angular frequency is

$$\omega_{\text{crossover}} = \frac{1}{\sqrt{LC}}.$$

We want to determine the crossover frequency, and since $f = \omega/2\pi$, we have

$$f_{\text{crossover}} = \frac{\omega_{\text{crossover}}}{2\pi} = \frac{1}{2\pi\sqrt{LC}}.$$

Putting in the numerical values, we get

$$f_{\text{crossover}} = \frac{1}{2\pi\sqrt{LC}} = \frac{1}{2\pi\sqrt{(10.0\ \text{mH})(10.0\ \mu\text{F})}} = 503.\ \text{Hz}$$

Figure 30.27 shows the response of the crossover circuit as a function of frequency. The low-pass response and the high-pass response cross at $f_{\text{crossover}} = 503.\ \text{Hz}$, sending higher frequencies predominantly to the tweeter and lower frequencies predominantly to the woofer.

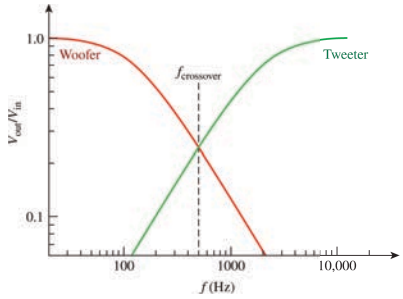

FIGURE 30.27 The response of the crossover circuit as a function of frequency.

This simple crossover circuit would not produce ideal audio performance over a broad range of frequencies and speaker designs. More sophisticated crossover circuits that have better performance deal with mid-range frequencies as well.

30.6 Energy and Power in AC Circuits

When an RLC circuit is in operation, some of the energy in the circuit is stored in the electric field of the capacitor, some of the energy is stored in the magnetic field of the inductor, and some energy is dissipated in the form of heat in the resistor. In most applications, we are interested in the steady-state behavior of the circuit, behavior that occurs after initial (transient) effects die out. (A full mathematical analysis would also account for the transient effects, which die out exponentially in a way similar to that described by equation 30.6 for a single-loop RLC circuit with no emf source.) The sum of the energy stored in the capacitor and the inductor does not change in the steady state, as we saw in Section 30.2. Therefore, the energy transferred from the source of emf to the circuit is transferred to the resistor.

The rate at which energy is dissipated in the resistor is the power, *P,* given by

$$P = i^2 R = [I \sin(\omega t - \phi)]^2 R = I^2 R \sin^2(\omega t - \phi), \textbf{(30.32)}$$

where the alternating current, *i,* is given by equation 30.9. We can express the average power, $\langle P \rangle$, using the fact that the average value of $\sin^2(\omega t - \phi)$ over a full oscillation is $\frac{1}{2}$:

$$\langle P \rangle = \frac{1}{2} I^2 R = \left(\frac{I}{\sqrt{2}} \right)^2 R.$$

In calculations of power and energy, it is common to use the **root-mean-square (rms) current,** I_{rms}. (In general, *root-mean-square,* or *rms,* means the square root of the mean of the square of the specific quantity.) From equation 30.32, we have $i^2 = [I \sin(\omega t - \phi)]^2$, and

the mean (or average) of i^2 is $I^2/2$. Thus, $I_{\text{rms}} = I/\sqrt{2}$. We can then write the average power as

$$\langle P \rangle = I_{\text{rms}}^2 R. \tag{30.33}$$

In a similar way, we can define the root-mean-square values of other time-varying quantities, such as the voltage:

$$V_{\text{rms}} = \frac{V_{\text{m}}}{\sqrt{2}}. \tag{30.34}$$

The current and voltage values normally quoted for alternating currents and measured by AC ammeters and voltmeters are I_{rms} and V_{rms}. For example, wall sockets in the United States provide $V_{\text{rms}} = 110\ \text{V}$, which corresponds to a maximum voltage of $\sqrt{2}(110\ \text{V}) \approx 156\ \text{V}$.

We can rewrite equation 30.21 in terms of root-mean-square values by multiplying both sides of the equation by $1/\sqrt{2}$:

$$I_{\text{rms}} = \frac{V_{\text{rms}}}{Z} = \frac{V_{\text{rms}}}{\sqrt{R^2 + \left(\omega L - \dfrac{1}{\omega C}\right)^2}}. \tag{30.35}$$

This form is used most often to describe the characteristics of AC circuits.

We can describe the average power dissipated in an AC circuit in a different way by starting with equation 30.33:

$$\langle P \rangle = I_{\text{rms}}^2 R = \frac{V_{\text{rms}}}{Z} I_{\text{rms}} R = I_{\text{rms}} V_{\text{rms}} \frac{R}{Z}. \tag{30.36}$$

From Figure 30.16, we see that the cosine of the phase constant is equal to the ratio of the maximum value of the voltage across the

resistor to the maximum value of the time-varying emf:

$$\cos\phi = \frac{V_{\mathrm{R}}}{V_{\mathrm{m}}} = \frac{IR}{IZ} = \frac{R}{Z}. \tag{30.37}$$

We can thus rewrite equation 30.36 as follows:

$$\langle P \rangle = I_{\mathrm{rms}} V_{\mathrm{rms}} \cos\phi. \tag{30.38}$$

This expression gives the average power dissipated in an AC circuit, where the term $\cos\phi$ is called the **power factor.** You can see that for $\phi = 0$, maximum power is dissipated in the circuit; that is, the maximum power is dissipated in an AC circuit when the frequency of the time-varying emf matches the resonant frequency of the circuit.

We can combine equations 30.19, 30.35, and 30.36 to obtain an expression for the average power as a function of the angular frequency, the inductance, the resistance, and the resonant frequency:

$$\langle P \rangle = I_{\mathrm{rms}} V_{\mathrm{rms}} \frac{R}{Z} = \frac{V_{\mathrm{rms}}}{\sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}} V_{\mathrm{rms}} \frac{R}{\sqrt{R^2 + \left(\omega L\right.}}$$

or simply

$$\langle P \rangle = \frac{V_{\mathrm{rms}}^2 R}{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}.$$

Since $\omega_0 = 1/\sqrt{LC}$, we can write $C = 1/\left(L\omega_0^2\right)$, and thus, we find for the average power for a series RLC circuit in terms of the angular frequency:

$$\langle P \rangle = \frac{V_{\text{rms}}^2 R}{R^2 + \left(\omega L - \dfrac{L\omega_0^2}{\omega}\right)^2} = \frac{V_{\text{rms}}^2 R\omega^2}{R^2\omega^2 + L^2\left(\omega^2 - \omega_0^2\right)^2}. \quad \textbf{(30.}$$

Typically all voltages, currents, and powers in AC circuits are specified as root-mean-square values. For example, the typical 110-V AC wall circuit has $V_{\text{rms}} = 110\ \text{V}$, and the ubiquitous 1000-W hair dryer uses $P_{\text{rms}} = 1000\ \text{W}$.

SOLVED PROBLEM 30.1 Voltage Drop across an Inductor

A series RLC circuit has a source of time-varying emf that supplies $V_{\text{rms}} = 170.0\ \text{V}$, a resistance $R = 820.0\ \Omega$, an inductance $L = 30.0\ \text{mH}$, and a capacitance $C = 0.290\ \text{mF}$. The circuit is operating at its resonant frequency.

PROBLEM

What is the root-mean-square voltage drop across the inductor?

SOLUTION

THINK

At the resonant frequency, the impedance of the circuit is equal to the resistance. We can calculate the root-mean-square current in the circuit. The voltage drop across the inductor is then the product of the root-mean-square current in the circuit and the inductive reactance.

SKETCH

A diagram of the series RLC circuit is shown in Figure 30.28.

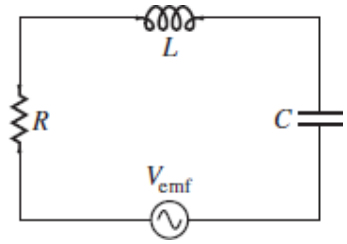

FIGURE 30.28
A series RLC circuit.

RESEARCH

At resonance, the impedance of the circuit is

$$Z = \sqrt{R^2 + (X_L - X_C)^2} = R.$$

At resonance, the root-mean-square current, I_{rms}, in the circuit is given by

$$V_{\text{rms}} = I_{\text{rms}} R.$$

The root-mean-square voltage drop across the inductor, V_L, at resonance is

$$V_L = I_{\text{rms}} X_L,$$

where the inductive reactance X_L is defined as

$$X_L = \omega L$$

and ω is the angular frequency at which the circuit is operating. The resonant angular frequency, ω_0, of the circuit is

$$\omega_0 = \frac{1}{\sqrt{LC}}.$$

SIMPLIFY

Combining all these equations gives us the voltage drop across the inductor at resonance:

$$V_L = \left(\frac{V_{\text{rms}}}{R}\right)(\omega_0 L) = \frac{L V_{\text{rms}}}{R}\frac{1}{\sqrt{LC}} = \frac{V_{\text{rms}}}{R}\sqrt{\frac{L}{C}}.$$

CALCULATE

Putting in the numerical values gives us

$$V_L = \frac{170.0\ \text{V}}{820.0\ \Omega}\sqrt{\frac{30.0 \cdot 10^{-3}\ \text{H}}{0.290 \cdot 10^{-3}\ \text{F}}} = 2.10861\ \text{V}.$$

ROUND

We report our result to three significant figures:

$$V_L = 2.11 \text{ V}.$$

DOUBLE-CHECK

The root-mean-square voltage drop across the capacitor is

$$V_C = \left(\frac{V_{\text{rms}}}{R}\right)\left(\frac{1}{\omega_0 C}\right) = \frac{V_{\text{rms}}}{RC}\sqrt{LC} = \left(\frac{V_{\text{rms}}}{R}\right)\sqrt{\frac{L}{C}},$$

which is the same as the root-mean-square voltage drop across the inductor. At resonance, the instantaneous voltage drop across the inductor is the negative of the voltage drop across the capacitor. Thus, the rms voltage across the capacitor should be the same as the rms voltage across the inductor. Thus, our result seems reasonable.

SOLVED PROBLEM 30.2 Power Dissipated in an RLC Circuit

A series RLC circuit has a source of emf providing $V_{\text{rms}} = 120.0$ V at a frequency $f = 50.0$ Hz, as well as an inductor, $L = 0.500$ H, a capacitor, $C = 3.30\ \mu\text{F}$, and a resistor, $R = 276.\ \Omega$.

PROBLEM

What is the average power dissipated in the circuit?

SOLUTION

THINK

The average power dissipated in the circuit is the root-mean-square current times the root-mean-square voltage, but it depends on the angular frequency of the source of emf. The current in the circuit can be found using the impedance.

SKETCH

A diagram of a series RLC circuit is shown in Figure 30.28.

RESEARCH

The angular frequency, ω, of the source of emf is

$$\omega = 2\pi f.$$

The impedance, Z, of the circuit is

$$Z = \sqrt{R^2 (X_L - X_C)^2},$$

where the inductive reactance is given by

$$X_L = \omega L$$

and the capacitive reactance is given by

$$X_C = \frac{1}{\omega C}.$$

We can find the root-mean-square current, I_{rms}, in the circuit using the relationship

$$V_{\text{rms}} = I_{\text{rms}} Z.$$

The average power dissipated in the circuit, $\langle P \rangle$, is given by

$$\langle P \rangle = I_{\text{rms}} V_{\text{rms}} \cos\phi,$$

where ϕ is the phase constant between the voltage and the current in the circuit:

$$\phi = \tan^{-1}\left(\frac{X_L - X_C}{R}\right).$$

SIMPLIFY

We can combine all these equations to obtain an expression for the average power dissipated in the circuit:

$$\langle P \rangle = \frac{V_{\text{rms}}}{Z} V_{\text{rms}} \cos\phi \frac{V_{\text{rms}}^2}{\sqrt{R^2 + (X_L - X_C)^2}} \cos\phi.$$

CALCULATE

First, we calculate the inductive reactance:

$$X_L = \omega L = 2\pi f L = 2\pi(50.0 \text{ Hz})(0.500 \text{ H}) = 157.1\ \Omega.$$

Next, we calculate the capacitive reactance:

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi f C} = \frac{1}{2\pi(50.0 \text{ Hz})(3.30 \cdot 10^{-6} \text{ F})} = 964.6$$

The phase constant is then

$$\phi = \tan^{-1}\left(\frac{X_L - X_C}{R}\right) = \tan^{-1}\left(\frac{157.1\ \Omega - 964.6\ \Omega}{276\ \Omega}\right) = -$$

We now calculate the average power dissipated in the circuit:

$$\langle P \rangle = \frac{(120.0\ \text{V})^2}{\sqrt{(276\ \Omega)^2 + (157.1\ \Omega - 964.6\ \Omega)^2}} \cos(-1.241\ \text{rad})$$

ROUND

We report our result to three significant figures:

$$\langle P \rangle = 5.46\ \text{W}.$$

DOUBLE-CHECK

To double-check our result, we can calculate the power that would be dissipated in the circuit if it were operating at the resonant frequency. At the resonant frequency, the maximum power is dissipated in the circuit, and the impedance of the circuit is equal to the resistance of the resistor. Thus, the maximum average power is

$$\langle P \rangle_{\text{max}} = \frac{V_{\text{rms}}^2}{R} = \frac{(120.0\ \text{V})^2}{276\ \Omega} = 52.2\ \text{W}.$$

Our result for the power dissipated at $f = 50.0$ Hz is lower than the maximum average power, so it seems plausible.

Quality Factor

The **quality factor,** Q, of a series RLC circuit is defined as

$$Q = \frac{\omega_0 L}{R} = \frac{1}{R}\sqrt{\frac{L}{C}}. \tag{30.40}$$

The quality factor is the ratio of total energy stored in the system divided by the energy dissipated per cycle of the oscillation. This is the same definition used for mechanical oscillators in Chapter 14. For a series RLC circuit, the quality factor characterizes the selectivity of the circuit. The higher the value of Q, the more selective the circuit, that is, the more precisely a given frequency can be isolated (as in an AM radio receiver, discussed next). The lower the value of Q, the less selective the circuit becomes.

AM Radio Receiver

Let's look at a typical example of a selective series RLC circuit, an AM radio receiver. An AM radio receiver can be constructed using a series RLC circuit in which the time-varying emf is supplied by an antenna that picks up transmissions from a distant radio station broadcasting at a given frequency and converts those transmissions to voltage, as illustrated in Figure 30.29.

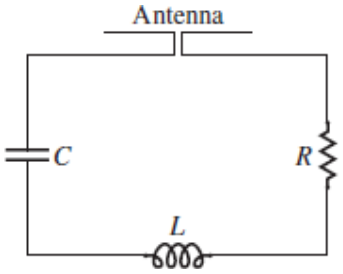

FIGURE 30.29 A series RLC circuit with the source of time-varying emf replaced by an antenna. This circuit can function as an AM radio receiver.

Figure 30.30 is a plot of the average power as a function of the frequency of the signal received on the antenna for the circuit shown in Figure 30.29, assuming that $R = 0.09111\ \Omega, L = 5.000\ \mu\text{H}, C = 6.693\ \text{nF}$, and $V_{\text{rms}} = 3.500\ \text{mV}$. The resonant angular frequency for this circuit is

$$\omega_0 = \frac{1}{\sqrt{LC}} = \frac{1}{\sqrt{\left(5.000 \cdot 10^{-6}\ \text{H}\right)\left(6.693 \cdot 10^{-9}\ \text{F}\right)}} = 5.465 \cdot 10$$

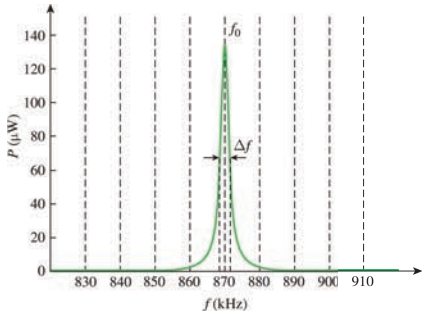

FIGURE 30.30 Power response of a series RLC circuit functioning as an AM radio receiver. The label Δ*f* indicates the *full width at half maximum,* or the difference between the frequencies where the power has half the value that it has at its maximum value, at frequency f_0.

which corresponds to a resonant frequency of

$$f_0 = \frac{\omega_0}{2\pi} = \frac{5.466 \cdot 10^6 \text{ rad/s}}{2\pi} = 870.0 \text{ kHz}.$$

Concept Check 30.7

WiFi networks are installed in most coffee shops and many residences to provide access to the Internet. The most common WiFi standard is known as 802.11 g, which supports communication rates of up to 54 megabits per second. Wireless networks in the United States and Canada that follow this standard use a frequency around 2.4 GHz, in 14 different channels in the band between 2.401 GHz and 2.495 GHz. Each channel has a full width at half maximum of 22 MHz. What is the quality factor of these WiFi networks?

a) 0.1

b) 9.9

c) 33

d) 109

e) 300

The quality factor for this circuit is

$$Q = \frac{\omega_0 L}{R} = \frac{\left(5.466 \cdot 10^6 \text{ rad/s}\right)\left(5.000 \cdot 10^{-6} \text{ H}\right)}{0.09111\ \Omega} = 300.0$$

A method for determining the approximate quality factor of a series RLC circuit uses the formula

$$Q = \frac{\omega_0}{\Delta\omega} = \frac{f_0}{\Delta f},$$

where $\Delta\omega$ and Δf are the full widths at half maximum for the angular frequency and the frequency, respectively, on the power response curve. The higher the value of Q, the narrower the power response to frequency. In Figure 30.30, $\Delta f = 2.9$ kHz, which gives a quality factor of

$$Q = \frac{f_0}{\Delta f} = \frac{870.0 \text{ kHz}}{2.9 \text{ kHz}} = 300.0.$$

This is the same result obtained using the formula that defines the quality factor in equation 30.40. Note that these two formulas for the quality factor have the same results only for high Q!

The alternative formula for the quality factor of a series RLC circuit is similar to the expression given in Chapter 14 for the quality of a weakly damped mechanical oscillator, $Q \approx \frac{\omega_0}{2\omega_\gamma}$, where ω_0 is the resonant angular frequency and ω_γ is the damping angular frequency.

In Figure 30.30, the frequencies of adjacent channels in the AM radio band are indicated by the vertical dashed lines located 10 kHz apart. The response of the series RLC circuit allows the AM receiver to tune in one station and exclude the adjacent channels.

SOLVED PROBLEM 30.3 Unknown Inductance in an RL Circuit

Consider a series RL circuit with a source of time-varying emf. In this circuit, $V_{\text{rms}} = 33.0$ V. with $f = 7.10$ kHz and $R = 83.0\ \Omega$. A current $I_{\text{rms}} = 0.158$ A flows in the circuit.

PROBLEM

What is the magnitude of the inductance, L?

SOLUTION

THINK

The specified voltage and current are implicitly root-mean-square values. We can relate the voltage and current through the impedance of the circuit. The impedance of this circuit depends on the resistance and the inductance, as well as the frequency of the source of emf.

SKETCH

A diagram of the circuit is shown in Figure 30.31.

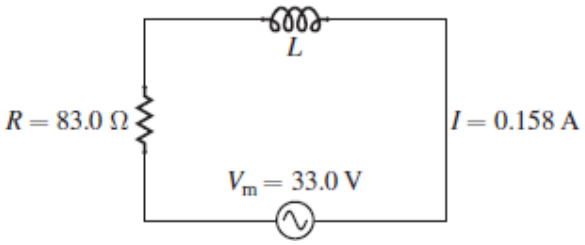

FIGURE 30.31 A series RL circuit.

RESEARCH

We can relate the time-varying emf, V_{m}, and the impedance Z in the circuit:

$$V_{\text{m}} = IZ. \qquad \text{(i)}$$

The impedance is given by

$$Z = \sqrt{R^2 + (X_L - X_C)^2} = \sqrt{R^2 + X_L^2}, \qquad \text{(ii)}$$

where R is the resistance, X_L is the inductive reactance, and X_C is the capacitive reactance, which is zero. The angular frequency, ω, of the circuit is given by

$$\omega = 2\pi f,$$

where f is the frequency. We can express the inductive reactance as

$$X_L = \omega L. \qquad \text{(iii)}$$

SIMPLIFY

We can combine equations (i), (ii), and (iii) to obtain

$$Z^2 = R^2 + X_L^2 = \left(\frac{V_\text{m}}{I}\right)^2 R^2 + (\omega L)^2. \qquad \text{(iv)}$$

Rearranging equation (iv) gives

$$\omega L = \sqrt{\frac{V_m^2}{I^2} - R^2}.$$

And, finally, we find the unknown inductance:

$$L = \frac{1}{2\pi f}\sqrt{\frac{V_\text{m}^2}{I^2} - R^2}.$$

CALCULATE

Putting in the numerical values gives us

$$L = \frac{1}{2\pi\left(7.10 \cdot 10^3\ \mathrm{s}^{-1}\right)}\sqrt{\frac{(33.0\ \mathrm{V})^2}{(0.158\ \mathrm{A})^2} - (83.0\ \Omega)^2} = 0.0042$$

ROUND

We report our result to three significant figures:

$$L = 4.30 \cdot 10^{-3}\ \mathrm{H} = 4.30\ \mathrm{mH}.$$

DOUBLE-CHECK

To double-check our result for the inductance, we first calculate the inductive reactance:

$$X_L = 2\pi f L = 2\pi\left(7.10 \cdot 10^3\ \mathrm{s}^{-1}\right)\left(4.30 \cdot 10^{-3}\ \mathrm{H}\right) = 192.\ \Omega.$$

The impedance of the circuit is then

$$Z = \sqrt{R^2 + X_L^2} = \sqrt{(83.0\ \Omega)^2 + (192\ \Omega)^2} = 209.\ \Omega.$$

We use this value of Z to calculate a value of V_m:

$$V_\mathrm{m} = IZ = (0.158\ \mathrm{A})(209.\ \Omega) = 33.0\ \mathrm{V},$$

which agrees with the value specified in the problem statement. Thus, our result is consistent.

Concept Check 30.8

In the series RL circuit in Solved Problem 30.3, what is the magnitude of the phase difference between the time-varying emf and the current in the circuit?

a) 30.0°

b) 45.0°

c) 66.6°

d) 75.0°

e) 90.0°

Self-Test Opportunity 30.5

You might argue that power companies should simply reduce the resistance in their transmission lines to avoid the substantial power losses. Typical wires for electric power transmission lines are finger-thick. How big would they need to be to reduce the resistance by a factor of 100, assuming that all other parameters (material used, length) remain the same? (*Hint:* Consult Section 25.3.)

30.7 Transformers

This section discusses the root-mean-square values of currents and voltages, rather than the maximum or instantaneous values. The result obtained for the power is always the average power when root-mean-square values are used. This practice is the convention normally followed by scientists, engineers, and electricians dealing with AC circuits.

In an AC circuit that has only a resistor, the phase constant is zero. Thus, we can express the power as

$$P = IV. \tag{30.41}$$

For a given power delivered to a circuit, the application dictates the choice of high current or high voltage. For example, to provide enough power to operate a computer or a vacuum cleaner, using a high voltage might be dangerous. The design of electric generators is complicated by the use of high voltages. Therefore, in these devices, lower voltages and higher currents are advantageous.

However, the transmission of electric power requires the opposite condition. The power dissipated in a transmission line is given by $P = I^2R$. Thus, the power lost in a line, like those in Figure 30.32a is proportional to the square of the current in the line. As an example, consider a power plant that produces 500. MW of power. If the power is transmitted at 350. kV, the current in the power lines will be

$$I = \frac{P}{V} = \frac{500.\ \text{MW}}{350.\ \text{kV}} = \frac{5.00 \cdot 10^8\ \text{W}}{3.50 \cdot 10^5\ \text{V}} = 1.43\ \text{kA}.$$

(a)

(b)

FIGURE 30.32 (a) High-voltage power lines; (b) transformers for residential power lines.

a: Malcolm Fife/age fotostock; **b:** W. Bauer and G. D. Westfall

If the total resistance of the power lines is 50. Ω, the power lost in the transmission lines is

$$P = I^2R = (1.43\ \text{kA})^2(50.0\ \Omega) = 102.\ \text{MW},$$

or about 20% of the generated power. A similar calculation would show that transmitting the power at 200. kV instead of 350. kV would increase the power loss by a factor of 3.1. Thus, approximately 60% of the power generated would be lost in transmission. This is why the transmission of electric power is always done at the highest possible voltage.

The ability to change voltage allows electric power to be generated and used at low, safe voltages but transmitted at the highest practical voltage. Alternating currents and voltages are transformed from high to low values by a device called, appropriately, a **transformer.** A transformer that takes voltages from lower to higher values is called a *step-up transformer;* a transformer that takes voltages from higher to lower values is called a *step-down transformer*. Transformers are the main components of, for example, your cell phone charger (Figure 30.33) and the power supply for your MP3 player, your laptop, and pretty much every other consumer electronics device. Most of these devices require voltages of 12 V or less, but the grid delivers 110 V to outlets in the United States, necessitating the transformers that clutter your desk drawers.

FIGURE 30.33 A transformer (black rectangle with yellow core) is the main component of a cell phone charger. (The charger also includes a rectifier, described in Section 30.8.)

W. Bauer and G. D. Westfall

A transformer consists of two sets of coils wrapped around an iron core (Figure 30.34). The primary coil, with N_P turns, is connected to a source of emf described by

$$V_{\text{emf}} = V_{\max} \sin \omega t.$$

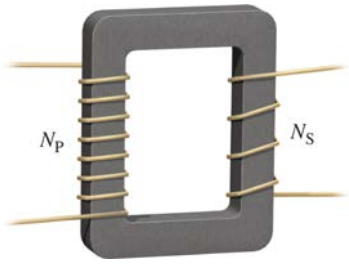

FIGURE 30.34
Transformer with N_P primary windings and N_S secondary windings.

We'll assume that the primary coil acts as an inductor. The primary circuit has the current and voltage out of phase by $\pi/2$ rad (90°), so the power factor, $\cos\phi$, is zero. Thus, the source of emf is not delivering any power to the transformer if only the primary coil is connected. In other words, if the secondary coil is not connected to a closed circuit, the transformer does not draw any power. For example, your cell phone charger does not draw power if it is plugged into the wall socket but the other end is not connected to the cell phone. (This statement is not absolutely true; there is finite resistance in the wires in the primary coil, which this description is neglecting.)

The secondary coil of a transformer has N_S turns. The time-varying emf in the primary coil induces a time-varying magnetic field in the iron core. This core passes through the secondary coil. Thus, a time-varying voltage is induced in the secondary coil, as described by Faraday's Law of Induction:

$$V_{\text{emf}} = -N\frac{d\Phi_B}{dt},$$

where N is the number of turns and Φ_B is the magnetic flux. Because of the iron core, both the primary and secondary coils experience the same changing magnetic flux. Thus,

$$V_S = -N_S\frac{d\Phi_B}{dt}$$

and

$$V_{\mathrm{P}} = -N_{\mathrm{P}} \frac{d\Phi_B}{dt},$$

where V_{S} and V_{P} are the voltages across the secondary and primary windings, respectively. Dividing the first of these two equations by the other and rearranging gives

$$\frac{V_{\mathrm{P}}}{N_{\mathrm{P}}} = \frac{V_{\mathrm{S}}}{N_{\mathrm{S}}},$$

or

$$V_{\mathrm{S}} = V_{\mathrm{P}} \frac{N_{\mathrm{S}}}{N_{\mathrm{P}}}. \qquad \textbf{(30.42)}$$

The transformer changes the voltage of the primary circuit to a secondary voltage, given by the ratio of the number turns in the secondary coil divided by the number of turns in the primary coil.

If a resistor, *R,* is connected across the secondary windings, a current, I_{S}, will begin to flow through the secondary coil. The power in the secondary circuit is then $P_{\mathrm{S}} = I_{\mathrm{S}} V_{\mathrm{S}}$. This current induces a time-varying magnetic field that induces a voltage in the primary coil, so that the emf source then produces enough current, I_{P}, to maintain the original voltage. This current, I_{P}, is in phase with the voltage because of the resistor, so power can be transmitted to the transformer. Energy conservation requires that the power delivered to the primary coil be transferred to the secondary coil, so we can write

$$P_{\mathrm{P}} = I_{\mathrm{P}} V_{\mathrm{P}} = P_{\mathrm{S}} = I_{\mathrm{S}} V_{\mathrm{S}}.$$

Using equation 30.42, we can express the current in the secondary circuit as

$$I_{\mathrm{S}} = I_{\mathrm{P}} \frac{V_{\mathrm{P}}}{V_{\mathrm{S}}} = I_{\mathrm{p}} \frac{N_{\mathrm{P}}}{N_{\mathrm{S}}}. \qquad \textbf{(30.43)}$$

The current in the secondary circuit is equal to the current in the primary circuit multiplied by the ratio of the number of primary turns divided by the number of secondary turns.

When the secondary circuit begins to draw current, current must be supplied to the primary circuit. Since $V_S = I_S R$ in the secondary circuit, we can use equations 30.42 and 30.43 to write

$$I_P = \frac{N_S}{N_P} I_S = \frac{N_S}{N_P} \frac{V_S}{R} = \frac{N_S}{N_P} \left(V_P \frac{N_S}{N_P} \right) \frac{1}{R} = \left(\frac{N_S}{N_P} \right)^2 \frac{V_P}{R}.$$

The effective resistance of the primary circuit can be expressed in terms of $V_P = I_P R_P$, so that the effective resistance is

$$R_P = \frac{V_P}{I_P} = V_P \left(\frac{N_P}{N_S} \right)^2 \frac{R}{V_P} = \left(\frac{N_P}{N_S} \right)^2 R. \qquad \textbf{(30.45)}$$

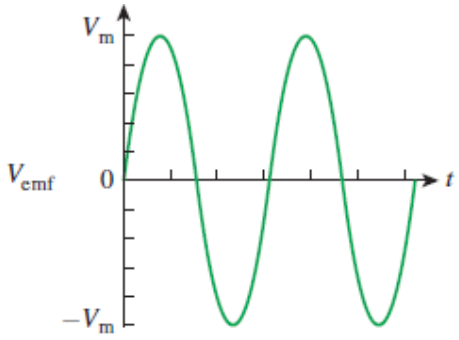
Note that we have assumed that there are no losses in the transformer, that the primary coil is only an inductor, that there are no losses in magnetic flux between the primary and secondary coils, and that the secondary circuit has the only resistance. Real transformers do have some losses. Part of these losses result from the fact that the alternating magnetic fields from the coils induce eddy currents in the iron core of the transformer. To counter this effect, transformer cores are constructed by laminating layers of metal to inhibit the formation of eddy currents. Modern transformers can transform voltages with very little loss.

Another application of transformers is **impedance matching.** The power transfer between a source of emf and a device that uses power is at a maximum when the impedance is the same in both. Often, the source of emf and the intended device do not have the same impedance. A common example is a stereo amplifier and its speakers. Usually, the amplifier has high impedance and the speakers have low impedance. A transformer placed between the amplifier and the speakers can help match the impedances of the devices, producing a more efficient power transfer.

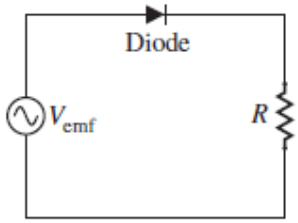
30.8 Rectifiers

Many electronic devices require direct current rather than alternating current. However, many common sources of electrical power provide alternating current. Therefore, this current must be converted to direct current to operate electronic equipment. A **rectifier** is a device that converts alternating current to direct current. Most rectifiers use an electronic component that was described in Section 25.8—the diode. A diode is designed to allow current to flow in one direction and not in the other direction. The symbol for a diode is , and the direction of the arrowhead signifies the direction in which the diode will conduct current.

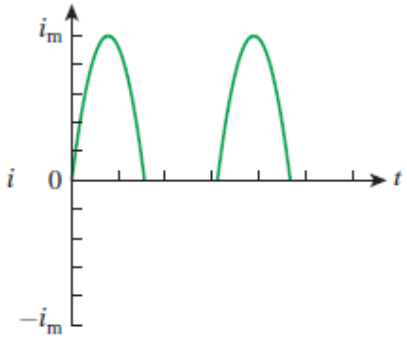
Let's start with a simple circuit containing a source of time-varying emf, a resistor, and a diode, as shown in Figure 30.35b. The voltage provided by the source of emf is alternately positive and negative, as shown in Figure 30.35a. Note that both ends of the source of emf are connected simultaneously so that when one end produces a positive voltage, the other end produces a negative voltage. The circuit in Figure 30.35b produces current in the resistor that indeed flows in only one direction. However, the circuit blocks half the current, as illustrated in Figure 30.35c. Thus, this type of circuit is often termed a **halfwave rectifier.**



(a)



(b)



(c)

FIGURE 30.35
Circuit containing a source of time-varying emf, a resistor, and a diode, forming a halfwave rectifier: (a) the emf as a function of time; (b) the circuit diagram; (c) the current flowing through the circuit as a function of time.

To allow all the current to flow in one direction, the type of circuit shown in Figure 30.36 is employed. Again the voltage alternates between positive and negative, as shown in Figure 30.36a. Two equivalent circuit diagrams are shown in Figure 30.36b and Figure 30.36c. All the current in the resistor flows in one direction, as illustrated in Figure 30.36d. This type of circuit is called a **fullwave rectifier.**

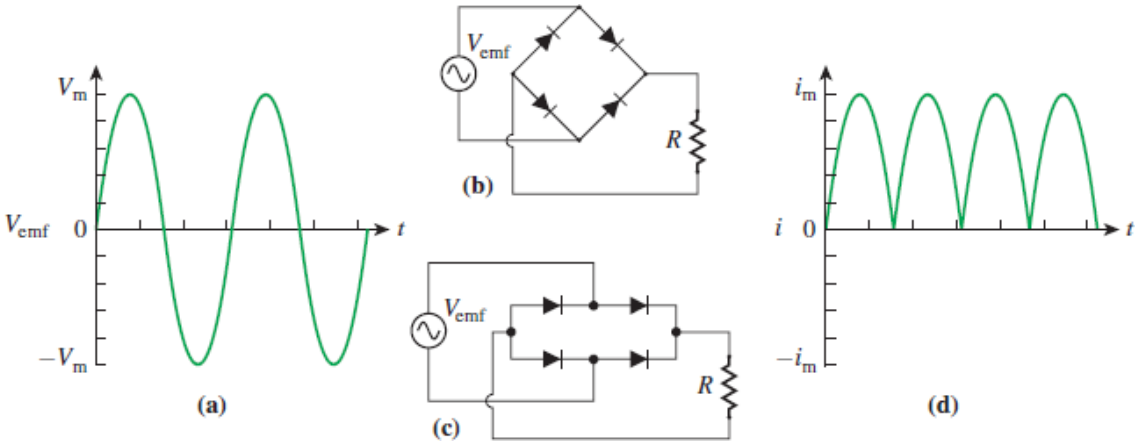


FIGURE 30.36 Circuit containing a source of time-varying emf, a resistor, and four diodes, forming a fullwave rectifier: (a) the emf as a function of time; (b) the circuit diagram; (c) alternative way of drawing the circuit diagram; (d) the current flowing through the circuit as a function of time.

To illustrate how the fullwave rectifier works, Figure 30.37 shows instantaneous views of the circuit with positive and negative voltage. In Figure 30.37a, the voltage from the source of emf is positive. The black diodes are conducting current, while the gray diodes are not. The voltage is reversed in Figure 30.37b, and the current flows through the other pair of diodes; the current in the resistor is still in the same direction.

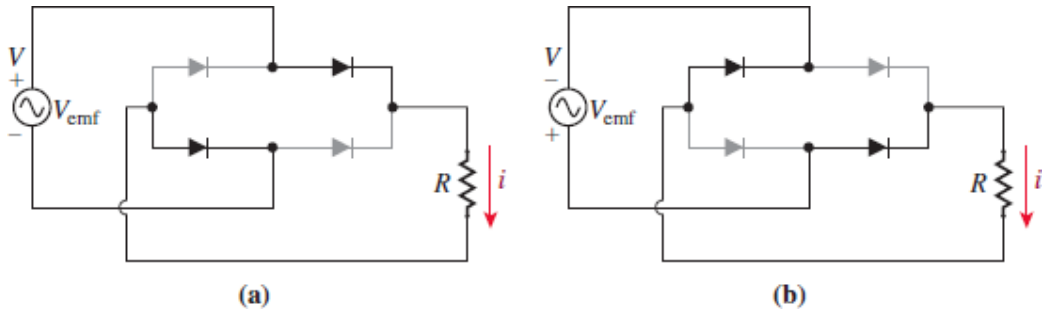

FIGURE 30.37 A fullwave rectifier with the diodes that are not conducting current at the given instant in gray. The current in the resistor always flows in the same direction. (a) Positive voltage. (b) Negative voltage.

Although the fullwave rectifier does indeed convert alternating current to direct current, the resulting direct current varies with time. This variance, often called *ripple,* can be smoothed out by adding a capacitor to the output of the rectifier, creating an RC circuit with a time constant governed by the choice of R and C, as shown in Figure 30.38. In Figure 30.38a, the time-varying emf is shown, and the circuit diagram is presented in Figure 30.38b. The direct current is filtered by the added capacitor. The resulting current as a function of time is shown in Figure 30.38c. The current still varies with time but much less so than the current flowing out of the fullwave rectifier without a capacitor.

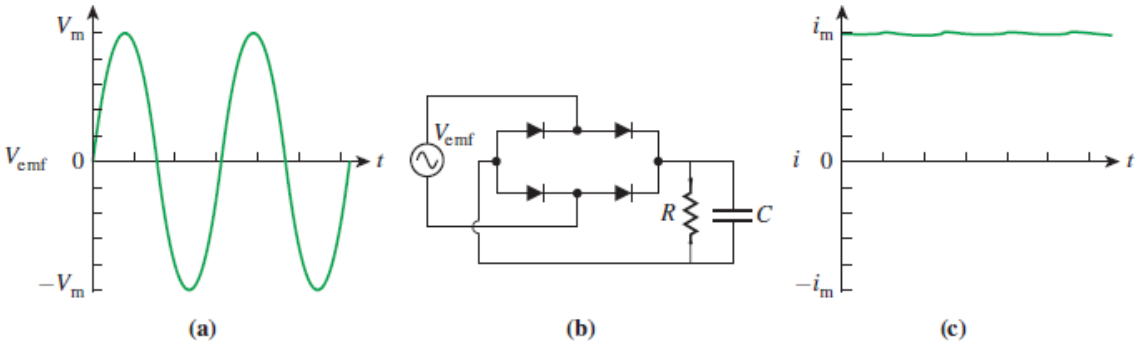

FIGURE 30.38 Circuit containing a source of time-varying emf, a resistor, a capacitor, and four diodes, forming a filtered fullwave rectifier: (a) the emf as a function of time; (b) the circuit diagram; (c) the current flowing through the circuit as a function of time.

Self-Test Opportunity 30.6

A typical alternator found in automobiles produces three-phase alternating current. Each phase is shifted by 120° from the next phase. Draw the circuit diagram for the fullwave rectifier for this alternator, based on the circuit diagram in Figure 30.36c but incorporating six diodes instead of four.

WHAT WE HAVE LEARNED EXAM STUDY GUIDE

- The energy stored in the electric field of a capacitor with capacitance C and charge q is given by $U_E = \frac{1}{2}\left(q^2/C\right)$; the energy stored in the magnetic field of an inductor with inductance L that is carrying current i is given by $U_B = \frac{1}{2}Li^2$.
- The current in a single-loop circuit containing an inductor and a capacitor (an LC circuit) oscillates with a frequency given by $\omega_0 = 1/\sqrt{LC}$.
- The current in a single-loop circuit containing a resistor, an inductor, and a capacitor (an RLC circuit) oscillates with a frequency given by $\omega = \sqrt{\omega_0^2 - (R/2L)^2}$, where $\omega_0 = 1/\sqrt{LC}$.
- The charge, q, on a capacitor in a single-loop RLC circuit oscillates and decreases exponentially with time according to $q = q_{\max}e^{-Rt/2L}\cos(\omega t)$, where $q_{\max}$ is the original charge on the capacitor.
- For a single-loop circuit containing a source of time-varying emf and a resistor, R, $V_R = I_R R$, where V_R and I_R are the voltage and the current, respectively.
- For a single-loop circuit containing a source of time-varying emf that has frequency ω and a capacitor, $V_C = I_C X_C$, where V_C and I_C are the voltage and the current, respectively, and $X_C = 1/\omega C$ is the capacitive reactance.
- For a single-loop circuit containing a source of time-varying emf that has frequency ω and an inductor, $V_L = I_L X_L$, where V_L and I_L are the voltage and the current, respectively, and $X_L = \omega L$ is the inductive reactance.
- For a single-loop RLC circuit containing a source of time-varying emf that has frequency ω, $V = IZ$, where V and I are

the voltage and the current, respectively, and $Z = \sqrt{R^2 + (X_L - X_C)^2}$ is the impedance.

- The phase constant, ϕ, between the current and the voltage in a single-loop RLC circuit containing a source of time-varying emf that has frequency ω is given by $\phi = \tan^{-1}\left(\frac{X_L - X_C}{R}\right)$.
- The average power in a single-loop RLC circuit containing a source of time-varying emf that has frequency ω is given by $\langle P \rangle = I_{\text{rms}} V_{\text{rms}} \cos\phi$, where $I_{\text{rms}} = I_{\text{m}}/\sqrt{2}$ and $V_{\text{rms}} = V_{\text{m}}/\sqrt{2}$.
- All currents, voltages, and powers quoted for alternating-current (AC) circuits are typically root-mean-square values.
- A transformer with N_{P} windings in the primary coil and N_{S} windings in the secondary coil can convert a primary alternating voltage, V_{P}, to a secondary alternating voltage, V_{S}, given by $V_{\text{S}} = V_{\text{P}} \frac{N_{\text{S}}}{N_{\text{P}}}$, and a primary alternating current, I_{P}, to a secondary alternating current, I_{S}, given by $I_{\text{S}} = I_{\text{p}} \frac{N_{\text{P}}}{N_{\text{S}}}$.

ANSWERS TO SELF-TEST OPPORTUNITIES

30.1 For this circuit, $\omega_0 = 2\pi f = 2\pi(200\text{ kHz})\text{ rad/s} = 4\pi \cdot 10^5\text{ rad/s}; \phi = 0$ since $q(0) = q_{\max}$

a) true $(\cos \omega_0 t = -1)$

b) false $(\sin \omega_0 t = 0)$

c) false $(\cos \omega_0 t = -1 \text{ and } \sin \omega_0 t = 0)$

d) false $(\cos \omega_0 t = 0 \text{ and } \sin \omega_0 t = 1)$

30.2 It can be seen that k/m corresponds to $1/LC$, and $b/2m$ corresponds to $R/2L$. Thus, the inductance, L, plays the role of the mass, m, the capacitance, C, corresponds to the inverse spring constant, $1/k$, and the resistance, R, has the function of the damping constant, b.

30.3

a) true

b) true

c) false

30.4

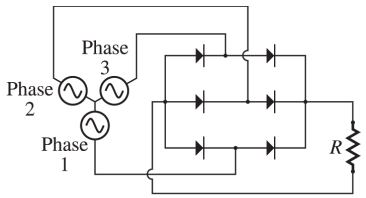
a) true

b) true

c) false

30.5 The resistance is inversely proportional to the inverse of the area of the wire and thus inversely proportional to the square of the radius. Therefore, a wire that was 10 times thicker would have a resistance that was 100 times lower.

30.6



Three-phase bridge rectifier

PROBLEM-SOLVING GUIDELINES

1. Most problems concerning AC circuits require you to calculate resistance, capacitive reactance, inductive reactance, or impedance. Be sure that you understand what each of these quantities is and how to use them in calculating currents and voltages.

2. You will often have to distinguish between the instantaneous current or voltage in a circuit and the root-mean-square or maximum value of current or voltage. The common convention is to use lowercase i and v for instantaneous values and uppercase I and V for constant values (with subscripts as necessary). Be sure you use notation that is clear so that you won't become confused during the calculations.

3. Remember the phase relations for AC circuits: For a resistor, current and voltage are in phase; for a capacitor, current leads voltage; for an inductor, current lags voltage.

4. Phasors add by vector operations, not by simple scalar arithmetic. Whenever you use phasors to determine current or voltage, check the results by checking the phase relationships given in the preceding guideline.

5. It is usually easier to work with angular frequency (ω) than with frequency (f) in analyzing AC circuits. Most often, you will be given an angular frequency in the problem statement, but if you are given a frequency, convert it to an angular frequency by multiplying it by 2π.

MULTIPLE-CHOICE QUESTIONS

30.1 A 200-Ω resistor, a 40.0-mH inductor and a 3.0-μF capacitor are connected in series with a source of time-varying emf that provides 10.0 V at a frequency of 1000 Hz. What is the impedance of the circuit?

a) 200 Ω

b) 228 Ω

c) 342 Ω

d) 282 Ω

30.2 For which values of f is $X_L > X_C$?

a) $f > 2\pi(LC)^{1/2}$

b) $f > (2\pi LC)^{-1}$

c) $f > \left(2\pi(LC)^{1/2}\right)^{-1}$

d) $f > 2\pi LC$

30.3 Which statement about the phase relation between the electric and magnetic fields in an LC circuit is correct?

a) When one field is at its maximum, the other is also, and the same for the minimum values.

b) When one field is at maximum strength, the other is at minimum (zero) strength.

c) The phase relation, in general, depends on the values of L and C.

30.4 For the band-pass filter shown in Figure 30.25, how can the width of the frequency response be increased?

a) increase R_1

b) decrease C_1

c) increase R_2

d) increase C_2

e) do any of the above

30.5 The phase constant, ϕ, between the voltage and the current in an AC circuit depends on the _____ .

a) inductive reactance

b) capacitive reactance

c) resistance

d) all of the above

30.6 The AM radio band covers the frequency range from 520 kHz to 1610 kHz. Assuming a fixed inductance in a simple LC circuit, what ratio of capacitance is necessary to cover this frequency range? That is, what is the value of $C_{\mathrm{h}}/C_{\mathrm{l}}$, where C_{h} is the capacitance for the highest frequency and C_{l} is the capacitance for the lowest frequency?

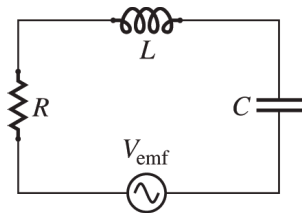
a) 9.59

b) 0.104

c) 0.568

d) 1.76

30.7 In the RLC circuit in the figure, $R = 60\ \Omega$, $L = 3$ mH, $C = 4$ mF, and the source of time-varying emf has a peak voltage of 120 V. What should the angular frequency, ω, be to produce the largest current in the resistor?



a) 4.2 rad/s

b) 8.3 rad/s

c) 204 rad/s

d) 289 rad/s

e) 5000 rad/s

f) 20,000 rad/s

30.8 A standard North American wall socket plug is labeled 110 V. This label indicates the _____ value of the voltage.

a) average

b) maximum

c) root-mean-square (rms)

d) instantaneous

30.9 A circuit contains a source of time-varying emf, which is given by $V_{\text{emf}} = 120.0 \text{ sin } [(377 \text{ rad/s})t]$ V, and a capacitor with capacitance $C = 5.00$ μF. What is the current in the circuit at $t = 1.00$ s?

a) 0.226 A

b) 0.451 A

c) 0.555 A

d) 0.750 A

e) 1.25 A

30.10 A source of time-varying emf supplies $V_{\text{max}} = 115.0$ V at $f = 60.0$ Hz in a series RLC circuit in which $R = 374\ \Omega$, $L = 0.310$ H, and $C = 5.50$ μF. What is the impedance of this circuit?

a) 321 Ω

b) 523 Ω

c) 622 Ω

d) 831 Ω

e) 975 Ω

CONCEPTUAL QUESTIONS

30.11 What is the impedance of a series RLC circuit when the frequency of time-varying emf is set to the resonant frequency of the circuit?

30.12 Estimate the total energy stored in the 5.00 km of space above Earth's surface if the average magnitude of the magnetic field at Earth's surface is about $0.500 \cdot 10^{-4}$ T.

30.13 In a DC circuit containing a capacitor, a current will flow through the circuit for only a very short time, while the capacitor is being charged or discharged. On the other hand, a steady alternating current will flow in a circuit containing the same capacitor but powered by a source of time-varying emf. Does it mean that charges are crossing the gap (dielectric) of the capacitor?

30.14 In an RL circuit with alternating current, the current lags behind the voltage. What does this mean, and how can it be explained qualitatively, based on the phenomenon of electromagnetic induction?

30.15 In Solved Problem 30.3, the voltage supplied by the source of time-varying emf is 33.0 V, the voltage across the resistor is $V_R = IR = 13.1$ V, and the voltage across the inductor is $V_L = IX_L = 30.0$ V. Does this circuit obey Kirchhoff's rules?

30.16 Why is rms power specified for an AC circuit, not average power?

30.17 Why can't we use a universal charger that plugs into a household outlet to charge all our electrical devices—cell phone, toy dog, can opener, and so on—rather than using a separate charger with its own transformer for each device?

30.18 If you use a parallel plate capacitor with air in the gap between the plates as part of a series RLC circuit in a generator, you can measure current flowing through the generator. Why is it that the air gap in the capacitor does not act like an open switch, blocking all current flow in the circuit?

30.19 A common configuration of wires has twisted pairs as opposed to straight, parallel wires. What is the technical advantage of using twisted pairs of wires versus straight, parallel pairs?

30.20 In a classroom demonstration, an iron core is inserted into a large solenoid connected to an AC power source. The effect of the core is to magnify the magnetic field in the solenoid by the relative magnetic permeability, κ_{m}, of the core (where κ_{m} is a dimensionless constant, substantially greater than unity for a ferromagnetic material, introduced in Chapter 28) or, equivalently, to replace the magnetic permeability of free space, μ_0, with the magnetic permeability of the core, $\mu = \kappa_{\mathrm{m}}\mu_0$.

a) The measured root-mean-square current drops from approximately 10 A to less than 1 A and remains at the lower value. Explain why.

b) What would happen if the power source were DC?

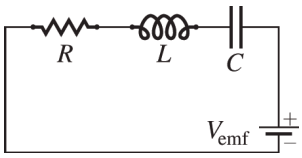
30.21 Along Capitol Drive in Milwaukee, Wisconsin, there are a large number of radio broadcasting towers. Contrary to expectation, radio reception there is terrible; unwanted stations often interfere with the one tuned in. Given that a car radio tuner is a resonant oscillator—its resonant frequency is adjusted to that of the desired station—explain this crosstalk phenomenon.

30.22 A series RLC circuit is in resonance when driven by a sinusoidal voltage at its resonant frequency, $\omega_0 = (LC)^{-1/2}$. But if the same circuit is driven by a *square-wave voltage* (which is alternately on and off for equal time intervals), it will exhibit resonance at its resonant frequency and at $\frac{1}{3}, \frac{1}{5}, \frac{1}{7}, \ldots$, of this frequency. Explain why.

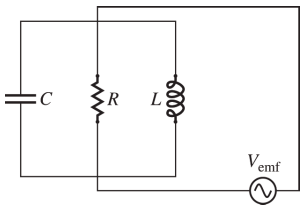
30.23 Is it possible for the voltage amplitude across the inductor in a series RLC circuit to exceed the voltage amplitude of the voltage supply? Why or why not?

30.24 Why can't a transformer be used to step up or step down the voltage in a DC circuit?

30.25 The figure shows a circuit with a source of constant emf connected in series to a resistor, an inductor, and a capacitor. What is the steady-state current flow through the circuit?



•**30.26** An RLC circuit has a capacitor, a resistor, and an inductor connected in parallel, as shown in the figure, and a source of time-varying emf providing V_{rms} at a frequency f. Find an expression for I_{rms} in terms of V_{rms}, f, L, C, and R.

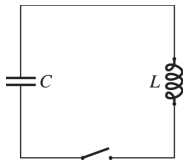


EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One •**and two** •• indicate increasing level of problem difficulty.

Sections 30.1 and 30.2

30.27 For the LC circuit in the figure, $L = 32.0$ mH and $C = 45.0$ μF. The capacitor is charged to $q_0 = 10.0$ μC, and at $t = 0$, the switch is closed. At what time is the energy stored in the capacitor first equal to the energy stored in the inductor?



30.28 A 2.00-μF capacitor is fully charged by being connected to a 12.0-V battery. The fully charged capacitor is then connected to a 0.250-H inductor. Calculate

(a) the maximum current in the inductor and (b) the frequency of oscillation of the LC circuit.

30.29 An LC circuit consists of a 1.00-mH inductor and a fully charged capacitor. After 2.10 ms, the energy stored in the capacitor is half of its original value. What is the capacitance?

30.30 The time-varying current in an LC circuit where $C = 10.0$ μF is given by $i(t) = (1.00\text{A})\sin(1200.t)$, where t is in seconds.

a) At what time after $t = 0$ does the current reach its maximum value?

b) What is the total energy of the circuit?

c) What is the inductance, L?

•**30.31** A 10.0-μF capacitor is fully charged by a 12.0-V battery and is then disconnected from the battery and allowed to discharge through a 0.200-H inductor. Find the first three times when the charge on the capacitor is 80.0-μC, taking $t = 0$ as the instant when the capacitor is connected to the inductor.

•**30.32** A 4.00-mF capacitor is connected in series with a 7.00-mH inductor. The peak current in the wires between the capacitor and the inductor is 3.00 A.

a) What is the total electric energy in this circuit?

b) Write an expression for the charge on the capacitor as a function of time, assuming the capacitor is fully charged at $t = 0$ s.

Section 30.3

30.33 A circuit contains a 4.50-nF capacitor and a 4.00-mH inductor. If some charge is placed initially on the capacitor, an oscillating current with angular frequency ω_0 is produced. By what factor does this angular frequency change if a 1.00-kΩ resistor is connected in series with the capacitor and the inductor?

•**30.34** An RLC oscillator circuit contains a 50.0-Ω resistor and a 1.00-mH inductor. What capacitance is necessary for the time constant of the circuit (the $1/e$ value) to be equal to the oscillation period? Plot the voltage across the resistor as a function of time.

•**30.35** A 2.00-μF capacitor was fully charged by being connected to a 12.0-V battery. The fully charged capacitor is then connected in series with a resistor and an inductor: $R = 50.0\ \Omega$ and $L = 0.200$ H. Calculate the damped frequency of the resulting circuit.

•**30.36** An LC circuit consists of a capacitor, $C = 2.50\ \mu\text{F}$, and an inductor, $L = 4.00$ mH. The capacitor is fully charged using a battery and then connected to the inductor. An oscilloscope is used to measure the frequency of the oscillations in the circuit. Next, the circuit is opened, and a resistor, *R,* is inserted in series with the inductor and the capacitor. The capacitor is again fully charged using the same battery and then connected to the circuit. The angular frequency of the damped oscillations in the RLC circuit is found to be 20.0% less than the angular frequency of the oscillations in the LC circuit.

a) Determine the resistance of the resistor.

b) How long after the capacitor is reconnected in the circuit will the amplitude of the damped current through the circuit be 50.0% of the initial amplitude?

c) How many complete damped oscillations will have occurred in that time?

Section 30.4

30.37 At what frequency will a 10.0-μF capacitor have the reactance $X_C = 200.\ \Omega$?

30.38 A capacitor with capacitance $C = 5.00 \cdot 10^{-6}$ F is connected to an AC power source having a peak value of 10.0 V and $f = 100.$ Hz. Find the reactance of the capacitor and the maximum current in the circuit.

Section 30.5

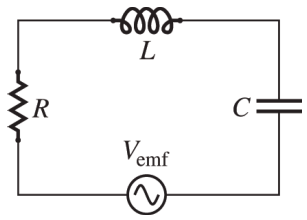
30.39 A series circuit contains a 100.0-Ω resistor, a 0.500-H inductor, a 0.400-μF capacitor, and a source of time-varying emf providing 40.0 V.

a) What is the resonant angular frequency of the circuit?

b) What current will flow through the circuit at the resonant frequency?

30.40 A variable capacitor used in an RLC circuit produces a resonant frequency of 5.0 MHz when its capacitance is set to 15 pF. What will the resonant frequency be when the capacitance is increased to 380 pF?

30.41 Determine the phase constant and the impedance of the RLC circuit shown in the figure when the frequency of the time-varying emf is 1.00 kHz, $C = 100.\ \mu\text{F}$, $L = 10.0\ \text{mH}$, and $R = 100.\ \Omega$.



30.42 What is the resonant frequency of the series RLC circuit of Problem 30.41 if $C = 4.00\ \mu\text{F}$, $L = 5.00\ \text{mH}$, and $R = 1.00\ \text{k}\Omega$? What is the maximum current in the circuit if $V_{\text{m}} = 10.0\ \text{V}$. at the resonant frequency?

•**30.43** In a series RLC circuit, $V = (12.0\ \text{V})(\sin \omega t)$, $R = 10.0\ \Omega$, $L = 2.00\ \text{H}$, and $C = 10.0\ \mu\text{F}$. At resonance, determine the amplitude of the voltage across the inductor. Is the result reasonable, considering that the voltage supplied to the entire circuit has an amplitude of 12.0 V?

•**30.44** An AC power source with $V_{\text{m}} = 220.\ \text{V}$ and $f = 60.0\ \text{Hz}$ is connected in a series RLC circuit. The resistance, *R,* inductance, *L,* and capacitance, *C,* of this circuit are, respectively, 50.0 Ω, 0.200 H, and 0.0400 mF. Find each of the following quantities:

a) the inductive reactance

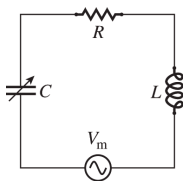
b) the capacitive reactance

c) the impedance of the circuit

d) the maximum current through the circuit at this frequency

e) the maximum potential difference across each circuit element

•30.45 The series RLC circuit shown in the figure has $R = 2.20\ \Omega$, $L = 9.630\ \text{mH}$, $C = 2.27\ \text{mF}$, $V_\text{m} = 110.\ \text{V}$, and $\omega = 377\ \text{rad/s}$.



a) What is the maximum current, I_m, in this circuit?

b) What is the phase constant, ϕ, between the voltage and the current?

c) The capacitance, C, can be varied. What value of C will allow the largest current amplitude oscillations to occur, and what are the magnitudes of this current, I'_m, and the phase angle, ϕ', between the current and the voltage?

•30.46 Design an RC high-pass filter that passes a signal with frequency 5.00 kHz, has a ratio $V_\text{out}/V_\text{in} = 0.500$, and has an impedance of 1.00 kΩ at very high frequencies.

a) What components will you use?

b) What is the phase of V_out relative to V_in at the frequency of 5.00 kHz?

•• 30.47 Design an RC high-pass filter that rejects 60.0-Hz line noise from a circuit used in a detector. Your criteria are reduction of the amplitude of the line noise by a factor of 1000. and total impedance at high frequencies of 2.00 kΩ.

a) What components will you use?

b) What is the frequency range of the signals that will be passed with at least 90.0% of their amplitude?

Section 30.6

30.48 What is the maximum value of the AC voltage whose root-mean-square value is (a) 110 V or (b) 220 V?

30.49 The quality factor, *Q,* of a circuit can be defined by $Q = \omega_0(U_E + U_B)/P$. Express the quality factor of a series RLC circuit in terms of its resistance *R,* inductance *L,* and capacitance *C.*

30.50 A label on a hair dryer reads "110V 1250W." What is the peak current in the hair dryer, assuming that it behaves like a resistor?

30.51 A radio tuner has a resistance of 1.00 μΩ a capacitance of 25.0 nF, and an inductance of 3.00 mH.

a) Find the resonant frequency of this tuner.

b) Calculate the power in the circuit if a signal at the resonant frequency produces an emf across the antenna of $V_{\text{rms}} = 1.50$ mV.

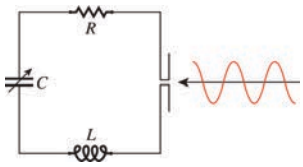
•**30.52** A circuit contains a 100.-Ω resistor, a 0.0500-H inductor, a 0.400-μF capacitor, and a source of time-varying emf connected in series. The time-varying emf corresponds to $V_{\text{rms}} = 50.0$ V. at a frequency of 2000. Hz.

a) Determine the current in the circuit.

b) Determine the voltage drop across each component of the circuit.

c) How much power is drawn from the source of emf?

•**30.53** The figure shows a simple FM antenna circuit in which $L = 8.22$ μH and *C* is variable (the capacitor can be tuned to receive a specific station). The radio signal from your favorite FM station produces a sinusoidal time-varying emf with an amplitude of 12.9 μV and a frequency of 88.7 MHz in the antenna.



a) To what value, C_0, should you tune the capacitor in order to best receive this station?

b) Another radio station's signal produces a sinusoidal time-varying emf with the same amplitude, 12.9 μV, but with a frequency of 88.5 MHz in the antenna. With the circuit tuned to optimize reception

at 88.7 MHz, what should the value, R_0, of the resistance be in order to reduce by a factor of 2 (compared to the current if the circuit were optimized for 88.5 MHz) the current produced by the signal from this station?

Section 30.7

30.54 The transmission of electric power occurs at the highest possible voltage to reduce losses. By how much could the power loss be reduced by raising the voltage by a factor of 10.0?

30.55 Treat the solenoid and coil of Solved Problem 29.2 as a transformer.

a) Find the root-mean-square voltage in the coil if the solenoid has a root-mean-square voltage of 120 V and a frequency of 60. Hz. The length of the solenoid is 12.0 cm.

b) What is the voltage in the coil if the frequency is 0 Hz (DC current)?

30.56 A transformer has 800 turns in the primary coil and 40 turns in the secondary coil.

a) What happens if an AC voltage of 100. V is across the primary coil?

b) If the initial AC current is 5.00 A, what is the output current?

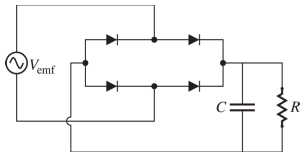
c) What happens if a DC current at 100. V flows into the primary coil?

d) If the initial DC current is 5.00 A, what is the output current?

30.57 A transformer contains a primary coil with 200 turns and a secondary coil with 120 turns. The secondary coil drives a current I through a 1.00-kΩ resistor. If an input voltage of $V_{\text{rms}} = 75.0$ V is applied across the primary coil, what is the power dissipated in the resistor?

Section 30.8

30.58 Consider the filtered fullwave rectifier shown in the figure. If the frequency of the source of time-varying emf is 60. Hz, what is the frequency of the resulting current?



•**30.59** A voltage $V_{rms} = 110$ V at a frequency of 60. Hz is applied to the primary coil of a transformer. The transformer has a ratio $N_P/N_S = 11$. The secondary coil is used as the source of V_{emf} for the filtered fullwave rectifier of Problem 30.58.

a) What is the maximum voltage in the secondary coil of the transformer?

b) What is the DC voltage provided to the resistor?

Additional Exercises

30.60 A vacuum cleaner motor can be viewed as an inductor with an inductance of 100. mH. For a 60.0-Hz AC voltage of $V_{\text{rms}} = 115.\ \text{V}$, what capacitance must be in series with the motor to maximize the power output of the vacuum cleaner?

30.61 When you turn the dial on a radio to tune it, you are adjusting a variable capacitor in an LC circuit. Suppose you tune to an AM station broadcasting at a frequency of 1000. kHz, and there is a 10.0-mH inductor in the tuning circuit. When you have tuned in the station, what is the capacitance of the capacitor?

30.62 A series RLC circuit has a source of time-varying emf providing 12.0 V at a frequency f_0, with $L = 7.00\ \text{mH}$, $R = 100.\Omega$, and $C = 0.0500\ \text{mF}$.

a) What is the resonant frequency of this circuit?

b) What is the average power dissipated in the resistor at this resonant frequency?

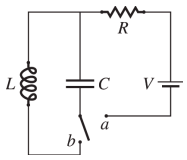
30.63 What are the maximum values of (a) current and (b) voltage when an incandescent 60-W light bulb (at 110 V) is connected to a wall plug labeled 110 V?

30.64 A 360-Hz source of emf is connected in a circuit consisting of a capacitor, a 25-mH inductor, and an 0.80-Ω resistor. For the current and the voltage to be in phase, what should the value of C be?

30.65 What is the resistance in an RLC circuit with $L = 65.0\ \text{mH}$ and $C = 1.00\ \mu\text{F}$ if the circuit loses 3.50% of its total energy as thermal energy in each cycle?

30.66 A transformer with 400. turns in its primary coil and 20. turns in its secondary coil is designed to deliver an average power of 1200. W with a maximum voltage of 60.0 V. What is the maximum current in the primary coil?

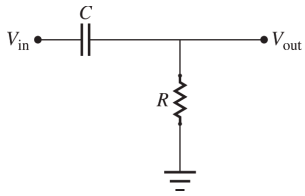
30.67 A 5.00-μF capacitor in series with a 4.00-Ω resistor is charged with a 9.00-V battery for a long time by closing the switch (position a in the figure). The capacitor is then discharged through an inductor ($L = 40.0\ \text{mH}$) by closing the switch (position b) at $t = 0$.



a) Determine the maximum current through the inductor.

b) What is the first time at which the current is at its maximum?

•**30.68** In the RC high-pass filter shown in the figure, $R = 10.0\ \text{k}\Omega$ and $C = 0.0470\ \mu\text{F}$. What is the 3.00-dB frequency of this circuit (where dB means basically the same for electric current as it did for sound in Chapter 16)? That is, at what frequency does the ratio of output voltage to input voltage satisfy $20 \log(V_{\text{out}}/V_{\text{in}}) = -3.00$?



•**30.69** The discussion of RL, RC, and RLC circuits in this chapter has assumed a purely resistive resistor, one whose inductance and capacitance are exactly zero. While the capacitance of a resistor can generally be neglected, inductance is an intrinsic part of the resistor. Indeed, one of the most widely used resistors, the wire-wound resistor, is nothing but a solenoid made of highly resistive wire. Suppose a wire-wound resistor of unknown resistance is connected to a DC power supply. At a voltage of $V = 10.0\ \text{V}$ across the resistor, the current through the resistor is 1.00 A. Next, the same resistor is connected to an AC power source providing $V_{\text{rms}} = 10.0\ \text{V}$ at a variable frequency. When the frequency is 20.0 kHz, a current, $I_{\text{rms}} = 0.800\ \text{A}$, is measured through the resistor.

a) Calculate the resistance of the resistor.

b) Calculate the inductive reactance of the resistor.

c) Calculate the inductance of the resistor.

d) Calculate the frequency of the AC power source at which the inductive reactance of the resistor exceeds its resistance.

•**30.70** In a certain RLC circuit, a 20.0-Ω resistor, a 10.0-mH inductor, and a 5.00-μF capacitor are connected in series with an AC power source for which $V_{\text{rms}} = 10.0\ \text{V}$. and $f = 100.\ \text{Hz}$. Calculate

a) the amplitude of the current,

b) the phase between the current and the voltage, and

c) the maximum voltage across each component.

•**30.71** a) A loop of wire 5.00 cm in diameter is carrying a current of 2.00 A. What is the energy density of the magnetic field at its center?

b) What current has to flow in a straight wire to produce the same energy density at a point 4.00 cm from the wire?

•**30.72** A 75,000-W light bulb (yes, there are such things!) operates at $I_{\text{rms}} = 200.$ A and $V_{\text{rms}} = 440.$ V in a 60.0-Hz AC circuit. Find the resistance, *R,* and self-inductance, *L,* of this bulb. Its capacitive reactance is negligible.

•**30.73** Show that the power dissipated in a resistor connected to an AC power source with a frequency ω oscillates with a frequency 2ω.

•**30.74** A 300.-Ω resistor is connected in series with a 4.00-μF capacitor and a source of time-varying emf providing $V_{\text{rms}} = 40.0$ V.

a) At what frequency will the potential drop across the capacitor equal that across the resistor?

b) What is the rms current through the circuit when this occurs?

•**30.75** An electromagnet consists of 200 loops and has a length of 10.0 cm and a cross-sectional area of 5.00 cm^2. Find the resonant frequency of this electromagnet when it is attached to the Earth (treat the Earth as a spherical capacitor).

•**30.76** Laboratory experiments with series RLC circuits require some care, as these circuits can produce large voltages at resonance. Suppose you have a 1.00-H inductor (not difficult to obtain) and a variety of resistors and capacitors. Design a series RLC circuit that will resonate at a frequency (not an angular frequency) of 60.0 Hz and will produce at resonance a magnification of the voltage across the capacitor or the inductor by a factor of 20.0 times the input voltage or the voltage across the resistor.

•**30.77** A particular RC low-pass filter has a breakpoint frequency of 200. Hz. At what frequency will the output voltage divided by the input voltage be 0.100?

MULTI-VERSION EXERCISES

30.78 An inductor with inductance $L = 42.1$ mH is connected to an AC power source that supplies $V_{\text{emf}} = 19.1$ V at $f = 605$ Hz. Find the reactance of the inductor.

30.79 An inductor with inductance $L = 52.5$ mH is connected to an AC power source that supplies $V_{\text{emf}} = 19.9$ V at $f = 669$ Hz. Find the maximum current in the circuit.

30.80 An inductor with inductance L is connected to an AC power source that supplies $V_{\text{emf}} = 20.7$ V at $f = 733$ Hz. If the reactance of the inductor is to be 81.52 Ω, what should the value of L be?

30.81 An inductor with inductance L is connected to an AC power source that supplies $V_{\text{emf}} = 21.5$ V at $f = 797$ Hz. If the maximum current in the circuit is to be 0.1528 A, what should the value of L be?

In the last few chapters we have studied electric and magnetic fields and seen how they can change over time. The present chapter concludes our study of electromagnetism and focuses on how the interaction between electric and magnetic fields gives rise to electromagnetic waves.

Literally every place on Earth is bathed in electromagnetic waves, of which the most obvious type is probably visible light. Other types of electromagnetic waves that are familiar to you range from TV and radio waves to microwaves and X-rays. Our cell phones, wireless Internet connections, and the GPS system all utilize electromagnetic waves, as do tanning booths and laser pointers. In this chapter, we'll examine the nature of electromagnetic waves, including their similarities and differences and their transmission of energy and pressure to other objects. Solar power plants, like the one shown in Figure 31.1, are impressive demonstrations of how the energy contained in electromagnetic waves emitted by the Sun can be harnessed.

FIGURE 31.1 The solar power plant Solúcar PS10, located near Seville, Spain, concentrates the power from the Sun's electromagnetic radiation to produce electricity.

Kevin Foy/Alamy Stock Photo

Most of the results in this chapter apply only to electromagnetic waves propagating through vacuum. For practical purposes, however, electromagnetic waves propagating through Earth's atmosphere can be treated in the same way. There are some significant differences for electromagnetic waves propagating through other media, but these are not addressed in this chapter.

The next chapter is the first to focus on *optics*—the properties and behavior of light—and many of those properties apply to other electromagnetic waves as well.

WHAT WE WILL LEARN

- Changing electric fields induce magnetic fields, and changing magnetic fields induce electric fields.
- Maxwell's equations describe electromagnetic phenomena.
- Electromagnetic waves have both electric and magnetic fields.
- Solutions of Maxwell's equations can be expressed in terms of sinusoidally varying traveling waves.
- For an electromagnetic wave, the electric field is perpendicular to the magnetic field and both fields are perpendicular to the direction in which the wave is traveling.
- The speed of light can be expressed in terms of constants related to electric and magnetic fields.
- Light is an electromagnetic wave.
- Electromagnetic waves can transport energy and momentum.
- The intensity of an electromagnetic wave is proportional to the square of the root-mean-square magnitude of the electric field of the wave.
- The direction of the electric field of a traveling electromagnetic wave is called the *polarization direction*.

31.1 Maxwell's Law of Induction for Induced Magnetic Fields

In Chapter 29, we saw that a changing magnetic field induces an electric field. According to Faraday's Law of Induction,

$$\oint \vec{E} \bullet d\vec{s} = -\frac{d\Phi_B}{dt}, \qquad \textbf{(31.1)}$$

where $\vec{E}$ is the electric field induced around a closed loop by the changing magnetic flux, Φ_B, through that loop. In a similar way, a changing electric field induces a magnetic field. **Maxwell's Law of Induction** (named for British physicist James Clerk Maxwell, 1831–1879) describes this phenomenon as follows:

$$\oint \vec{B} \bullet d\vec{s} = \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}, \qquad \textbf{(31.2)}$$

where $\vec{B}$ is the magnetic field induced around a closed loop by a changing electric flux, Φ_E, through that loop. This equation is similar to equation 31.1 except for the constant $\mu_0 \epsilon_0$ and the lack of a negative sign. The constant is a consequence of the SI units used for magnetic fields. The fact that the right-hand side of equation 31.2 does not have a negative sign implies that the induced magnetic field has the opposite sign from that of an induced electric field when both are induced under similar conditions, as we'll see shortly.

First, note that it is *not at all obvious* that equation 31.2 can be written in analogy to equation 31.1. When Maxwell first wrote this

equation, it represented a major step forward in the unification of electricity and magnetism. Faraday discovered his law in 1831, but it took a quarter of a century for Maxwell to come up with the counterpart. What is stated here as simple fact is in reality the first great conceptual leap toward the unification of all physical forces of nature. This unification began with Maxwell's work one and a half centuries ago and continues in modern physics research today.

A circular capacitor can be used to illustrate an induced magnetic field (Figure 31.2). For the capacitor shown in Figure 31.2a, the charge is constant, and a constant electric field appears between the plates. There is no magnetic field. For the capacitor shown in Figure 31.2b, the charge is increasing with time. Thus, the electric flux between the plates is increasing with time. A magnetic field, $\vec{B}$, is induced, represented by the purple loops, which also indicate the direction of $\vec{B}$. Along each loop, the magnetic field vector has the same magnitude and is directed tangentially to the loop. When the charge stops increasing, the electric flux remains constant and the magnetic field disappears.

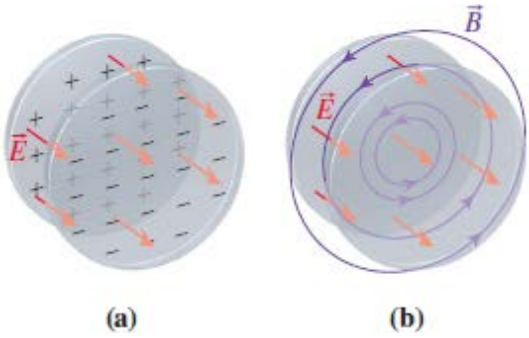

FIGURE 31.2 (a) A charged circular capacitor. The red arrows represent the electric field between the plates. (b) A capacitor with charge increasing with time. The red arrows represent the electric field, and the purple loops represent the induced magnetic field.

Next, consider a uniform magnetic field that is also constant in time, as in Figure 31.3a. In Figure 31.3b, the magnetic field is still uniform in space but is increasing with time, which induces an electric field, shown by the red loops. The electric field vector has constant magnitude along each loop and is directed tangentially to the loops as shown. Note that this induced electric field points in the opposite direction from the induced magnetic field caused by an increasing electric field (Figure 31.2b).

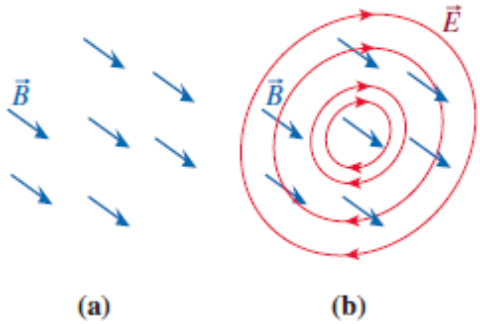

FIGURE 31.3 (a) A constant uniform magnetic field. (b) A uniform magnetic field increasing with time, which induces an electric field represented by the red loops.

Now recall Ampere's Law:

$$\oint \vec{B} \bullet d\vec{s} = \mu_0 i_{\text{enc}}, \qquad \textbf{(31.3)}$$

which relates the integral around a loop of the dot product of the magnetic field and the differential displacement along the loop, $\vec{B} \cdot d\vec{s}$, to the current flowing through the loop. However, Maxwell realized that this equation is incomplete because it does not account for contributions to the magnetic field caused by changing electric fields. Equations 31.2 and 31.3 can be combined to produce a description of magnetic fields created by moving charges and by changing electric fields:

$$\oint \vec{B} \bullet \vec{ds} = \mu_0 \epsilon_0 \frac{d\Phi_E}{dt} + \mu_0 i_{\text{enc}}. \qquad \textbf{(31.4)}$$

Equation 31.4 is called the **Maxwell-Ampere Law.** You can see that for the case of constant current, such as current flowing in a conductor, this equation reduces to Ampere's Law. For the case of a changing electric field without current flowing, such as the electric field between the plates of a capacitor, this equation reduces to Maxwell's Law of Induction. It is important to realize that the Maxwell-Ampere Law describes two different sources of magnetic field: the conventional current (as discussed in Chapter 28) and the time-varying electric flux (examined in more detail in the following subsection).

Displacement Current

Looking at the Maxwell-Ampere Law (equation 31.4), you can see that the expression $\epsilon_0 d\Phi_E/dt$ on the right-hand side of the equation must have the units of current. Although no actual "current" is "displaced," this term is called the **displacement current,** i_{d}:

$$i_{\mathrm{d}} = \epsilon_0 \frac{d\Phi_E}{dt}. \qquad \textbf{(31.5)}$$

With this definition, we can rewrite equation 31.4 as

$$\oint \vec{B} \bullet d\vec{s} = \mu_0 (i_{\mathrm{d}} + i_{\mathrm{enc}}).$$

Again, let's consider a parallel plate capacitor with circular plates, now placed in a circuit in which a current, *i*, is flowing while the capacitor is charging (Figure 31.4). For a parallel plate capacitor, the charge, *q*, is related to the electric field between the plates, *E*, as follows (see Chapter 24)

$$q = \epsilon_0 AE,$$

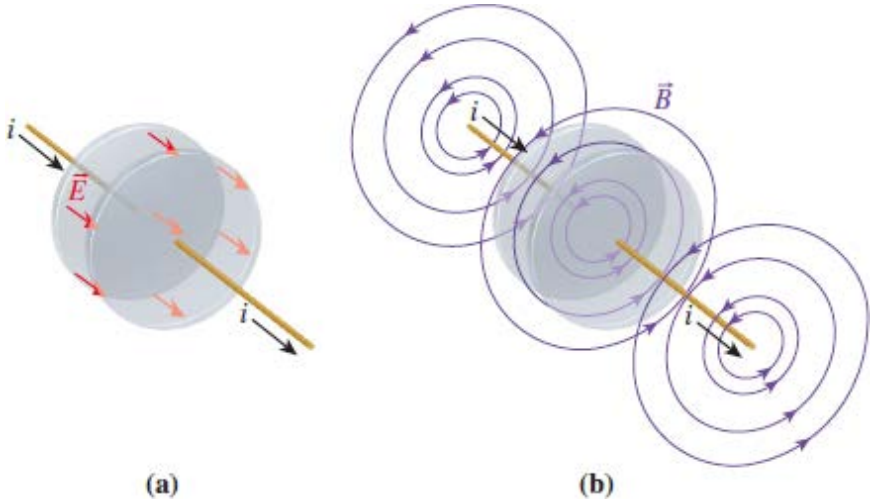

FIGURE 31.4 A parallel plate capacitor in a circuit being charged by a current, *i*: (a) the electric field between the plates at a given instant; (b) the magnetic field around the wires and between the plates of the capacitor.

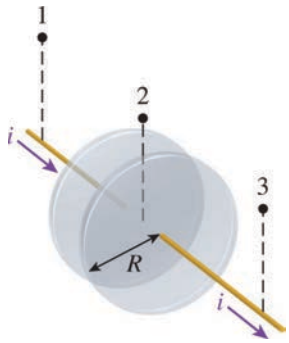
where A is the area of the plates. The current, i, in the circuit can be obtained by taking the time derivative of this equation:

$$i = \frac{dq}{dt} = \epsilon_0 A \frac{dE}{dt}. \qquad (31.6)$$

Concept Check 31.1

The displacement current, i_d, for the charging circular capacitor with radius *R* shown in the figure is equal to the conduction current, *i,* in the wires. Points 1 and 3 are located a perpendicular distance *r* from the wires, and point 2 is located the same perpendicular distance *r* from the center of the capacitor, such that $r > R$. Rank the magnetic fields at points 1, 2, and 3, from largest magnitude to smallest.



a) $B_1 > B_2 > B_3$

b) $B_3 > B_2 > B_1$

c) $B_1 = B_3 > B_2$

d) $B_2 > B_1 = B_3$

e) $B_1 = B_2 = B_3$

Assuming that the electric field between the plates of the capacitor is uniform, we can obtain an expression for the displacement current:

$$i_d = \epsilon_0 \frac{d\Phi_E}{dt} = \epsilon_0 \frac{d(AE)}{dt} = \epsilon_0 A \frac{dE}{dt}. \qquad \textbf{(31.7)}$$

Thus, the current in the circuit, i, given by equation 31.6, is equal to the displacement current, i_{d}, given by equation 31.7. Although no actual current is flowing between the plates of the capacitor, in the sense that no actual charges move across the capacitor gap from one plate to the other, the displacement current can be used to calculate the induced magnetic field.

To calculate the magnetic field between the two circular plates of the capacitor, we assume that the volume between the two plates can be replaced with a conductor of radius R carrying current i_{d}. In Chapter 28, we saw that the magnetic field at a perpendicular distance r from the center of the capacitor is given by

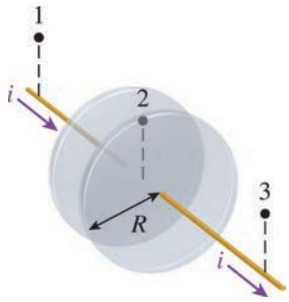
$$B = \left(\frac{\mu_0 i_{\mathrm{d}}}{2\pi R^2} \right) r \quad (\text{for } r < R).$$

The system outside the capacitor can be treated as a current-carrying wire, so the magnetic field at a perpendicular distance r from the wire is

$$B = \frac{\mu_0 i_{\mathrm{d}}}{2\pi r} \quad (\text{for } r > R).$$

Concept Check 31.2

The displacement current, i_{d}, for the charging circular capacitor with radius *R* shown in the figure is equal to the conduction current, *i,* in the wires. Points 1 and 3 are located a perpendicular distance *r* from the wires, and point 2 is located the same perpendicular distance *r* from the center of the capacitor, such that $r < R$. Rank the magnetic fields at points 1, 2, and 3, from largest magnitude to smallest.



a) $B_1 > B_2 > B_3$

b) $B_3 > B_2 > B_1$

c) $B_1 = B_3 > B_2$

d) $B_2 > B_1 = B_3$

e) $B_1 = B_2 = B_3$

Maxwell's Equations

The Maxwell-Ampere Law (equation 31.4) completes the set of four equations known as **Maxwell's equations,** which describe the interactions between electrical charges, currents, electric fields, and magnetic fields. These equations treat electricity and magnetism as two aspects of a unified force called **electromagnetism.** All of the results described previously for electricity and magnetism are still valid, but these equations show how electric and magnetic fields interact with each other, giving rise to a broad range of electromagnetic phenomena. This chapter focuses on electromagnetic waves and Chapter 34 on wave optics. A summary of Maxwell's equations is given in Table 31.1. (Again, as a reminder, $\oiint d\vec{A}$ in the first two equations represents integration over a closed surface, and $\oint d\vec{s}$ in the last two equations indicates integration over a closed curve.)

Table 31.1 Maxwell's Equations Describing Electromagnetic Phenomena

Name	Equation	Description
Gauss's Law for Electric Fields	$\oiint \vec{E} \bullet d\vec{A} = \frac{q_{\text{enc}}}{\in_0}$	The net electric flux through a closed surface is proportional to the net enclosed electric charge.
Gauss's Law for Magnetic Fields	$\oiint \vec{B} \bullet d\vec{A} = 0$	The net magnetic flux through a closed surface is zero (no magnetic monopoles exist).
Faraday's Law of Induction	$\oint \vec{E} \bullet d\vec{s} = -\frac{d\Phi_B}{dt}$	An electric field is induced by a changing magnetic flux.
Maxwell-Ampere Law	$\oint \vec{B} \bullet d\vec{s} = \mu_0 \in_0 \frac{d\Phi_E}{dt} + \mu_0 i_{\text{enc}}$	A magnetic field is induced by a changing electric flux or by a current.

If you scrutinize Maxwell's equations, you might notice a lack of symmetry between $\vec{E}$ and $\vec{B}$. This difference arises from the fact that electric charges exist in isolation and a corresponding current appears when charges move, but apparently no isolated, stationary magnetic charges occur in nature. Particles that hypothetically have a single magnetic charge (a north pole or a south pole, but not both) are called *magnetic monopoles,* but empirically it has been found that magnetic poles always come in pairs, a north pole together with a south pole. There is no fundamental reason for the absence of magnetic monopoles, and many experiments have searched unsuccessfully for them. The most sensitive of these experiments was MACRO, which used a massive detector that operated for many years in a laboratory located deep under the Gran Sasso mountain in Italy. MACRO searched for magnetic monopoles in cosmic rays, without success.

We'll now begin our study of **electromagnetic waves.** Electromagnetic waves consist of electric and magnetic fields, can travel through vacuum without any supporting medium, and do not involve moving charges or currents. The existence of electromagnetic waves was first demonstrated in 1888 by the German physicist Heinrich Hertz (1857–1894). Hertz used an RLC circuit that induced a current in an inductor that drove a spark gap. A spark gap consists of two electrodes that, when a potential difference is applied across them, produce a spark by exciting the gas between the electrodes. Hertz placed a loop and a small spark gap several meters apart. He observed that sparks were induced in the remote loop in a pattern that correlated with the electromagnetic oscillations in the primary RLC circuit. Thus, electromagnetic waves were able to travel through space without any medium to support them. For this contribution and others, the basic unit of oscillation, cycles per second, was named the hertz (Hz) in his honor.

31.2 Wave Solutions to Maxwell's Equations

As Section 31.7 will show, it is possible to use advanced calculus to derive a general wave equation from Maxwell's equations starting with those equations in differential form. However, we'll first assume that electromagnetic waves propagating in vacuum (no moving charges or currents) have the form of a traveling wave and show that this form satisfies Maxwell's equations.

Proposed Solution

We assume the following equations express the electric and magnetic fields in a particular electromagnetic wave that happens to be traveling in the positive *x*-direction:

$$\vec{E}\left(\vec{r}, t\right) = E_{\max} \sin(\kappa x - \omega t)\hat{y}$$

and

$$\vec{B}\left(\vec{r}, t\right) = B_{\max} \sin(\kappa x - \omega t)\hat{z}, \qquad \textbf{(31.8)}$$

where $\kappa = 2\pi/\lambda$ is the wave number and $\omega = 2\pi f$ is the angular frequency of a wave with wavelength λ and frequency *f*. Note that the magnitudes of both fields have no dependence on the *y*- or *z*-coordinates, only on the *x*-coordinate and time. This type of wave, in which the electric and magnetic field vectors lie in a plane, is called a **plane wave.** Equation 31.8 indicates that this particular electromagnetic wave is traveling in the positive *x*-direction because, as the time *t* increases, the coordinate *x* has to increase to maintain the same value for the fields. The wave described by equation 31.8 is shown in Figure 31.5.

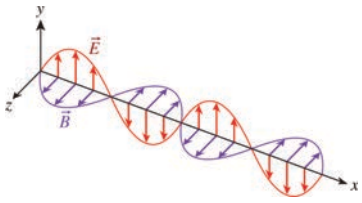


FIGURE 31.5
Representation of an electromagnetic wave traveling in the positive *x*-direction at a given instant.

In the particular case illustrated in Figure 31.5, the electric field is completely in the *y*-direction and the magnetic field is completely in the *z*-direction; that is, both fields are perpendicular to the direction of wave propagation. It turns out that the electric field is always perpendicular to the direction the wave is traveling and is always perpendicular to the magnetic field. However, in general, for an electromagnetic wave that is propagating along the *x*-axis, the electric field can point anywhere in the *yz*-plane.

The representation of the wave in Figure 31.5 is an instantaneous abstraction. The vectors shown represent the magnitude and the direction for the electric and magnetic fields; however, you should realize that these fields are not solid objects. Nothing made of matter actually moves left and right or up and down as the wave travels. The vectors pointing left and right and up and down represent the electric and magnetic fields.

Concept Check 31.3

An electromagnetic plane wave is traveling through vacuum. The electric field of the wave is given by $\vec{E} = E_{max}\cos(\kappa x - \omega t)\hat{y}$. Which of the following equations describes the magnetic field of the wave?

a) $\vec{B} = B_{max}\cos(\kappa x - \omega t)\hat{x}$

b) $\vec{B} = B_{max}\cos(\kappa y - \omega t)\hat{y}$

c) $\vec{B} = B_{max}\cos(\kappa z - \omega t)\hat{z}$

d) $\vec{B} = B_{max}\cos(\kappa y - \omega t)\hat{z}$

e) $\vec{B} = B_{max}\cos(\kappa x - \omega t)\hat{z}$

Showing that the traveling wave described by equation 31.8 satisfies all of Maxwell's equations involves quite a bit of vector calculus but also uses many of the concepts that have been developed in the preceding chapters. The following subsections work through this process in detail, one equation at a time.

Gauss's Law for Electric Fields

Let's start with Gauss's Law for Electric Fields. For an electromagnetic wave in vacuum, there is no enclosed charge anywhere ($q_{\text{enc}} = 0$); thus, we must show that the proposed solution of equation 31.8 satisfies

$$\oiint \vec{E} \bullet d\vec{A} = 0. \tag{31.9}$$

We choose a rectangular box as a Gaussian surface enclosing a portion of the vector representation of the wave (Figure 31.6). For the faces of the box in the *yz*-plane, $\vec{E} \bullet d\vec{A}$ is zero because the vectors $\vec{E}$ and $d\vec{A}$ are perpendicular to each other. The same is true for the faces in the *xy*-plane. The faces in the *xz*-plane contribute $+EA_1$ and $-EA_1$, where A_1 is the area of the top face and the bottom face. Thus, the integral is zero, and Gauss's Law for Electric Fields is satisfied.

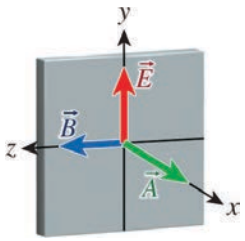

FIGURE 31.6 Gaussian surface (gray box) around a portion of the vector representation of an electromagnetic wave traveling in the positive *x*-direction. The area vector is shown for the front face of the Gaussian surface.

If we analyzed the vector representation at different times, we would get a different electric field. However, because the electric field is always in the *y*-direction, the integral will always be zero.

Gauss's Law for Magnetic Fields

For Gauss's Law for Magnetic Fields, we must show that

$$\oiint \vec{B} \bullet d\vec{A} = 0. \tag{31.10}$$

We again use the closed surface in Figure 31.6 for the integration. For the faces in the *yz*-plane and for those in the *xz*-plane, $\vec{B} \bullet d\vec{A}$ is zero because the vectors $\vec{B}$ and $d\vec{A}$ are perpendicular to each other. The faces in the *xy*-plane contribute $+BA_2$ and $-BA_2$, where A_2 is the area of each of the two faces in the *xy*-plane. Thus, the integral is zero, and Gauss's Law for Magnetic Fields is satisfied.

Faraday's Law of Induction

Now let's address Faraday's Law of Induction:

$$\oint \vec{E} \bullet d\vec{s} = -\frac{d\Phi_B}{dt}. \qquad \textbf{(31.11)}$$

To evaluate the integral on the left-hand side of this equation, we assume a closed loop in the xy-plane that has width dx and height h and goes from a to b to c to d and back to a, as depicted by the gray rectangle in Figure 31.7. The differential area $d\vec{A} = \hat{n}dA = \hat{n}hdx$ of this rectangle has its unit surface normal vector, $\hat{n}$, pointing in the positive z-direction. Note that the electric and magnetic fields change with distance along the x-axis. Thus, going from point x to point $x + dx$, the electric field changes from $\vec{E}(x)$ to $\vec{E}(x + dx) = \vec{E}(x) + d\vec{E}$.

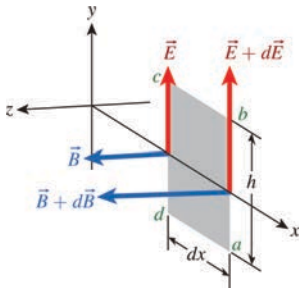

FIGURE 31.7 Two snapshots of the electric and magnetic fields in an electromagnetic wave. The gray area represents an integration loop for Faraday's Law.

To evaluate the integral of equation 31.11 over the closed loop, we split the loop into four pieces, integrating counterclockwise from *a* to *b*, *b* to *c*, *c* to *d*, and *d* to *a*. The contributions to the integral that are parallel to the *x*-axis, from integrating from *b* to *c* and from *d* to *a*, are zero because the electric field is always perpendicular to the direction of integration. For the integrations in the *y*-direction, *a* to *b* and *c* to *d*, the electric field is parallel or antiparallel to the direction of integration; therefore, the scalar product reduces to a conventional product. Because the electric field is independent of the *y*-coordinate, it can be taken out of the integral. Thus, the integral along each of the segments in the *y*-direction is a simple product of the integrand (the magnitude of the electric field at the corresponding *x*-coordinate) and the length of the integration interval (*h*), times −1 for the integration in the negative *y*-direction because $\vec{E}$ is antiparallel to the direction of integration. Thus, the integral of equation 31.11 evaluates to

$$\oint \vec{E} \bullet d\vec{s} = E \int_a^b ds - E \int_c^d ds = (E + dE)(h) - Eh = (dE$$

The right-hand side of equation 31.11 is given by

$$-\frac{d\Phi_B}{dt} = -A\frac{dB}{dt} = -(h)(dx)\frac{dB}{dt},$$

where *dt* is the time during which the wave travels a distance *dx*. Thus, we have

$$(h)(dE) = -(h)(dx)\frac{dB}{dt},$$

or

$$\frac{dE}{dx} = -\frac{dB}{dt}. \qquad \textbf{(31.12)}$$

The derivatives dE/dx and dB/dt are each taken with respect to a single variable, although both E and B depend on both x and t. Thus, we can more appropriately write equation 31.12 using partial derivatives:

$$\frac{\partial E}{\partial x} = -\frac{\partial B}{\partial t}. \tag{31.13}$$

Using the assumed forms for the electric and magnetic fields (equation 31.8), we can expand the partial derivatives:

$$\frac{\partial E}{\partial x} = \frac{\partial}{\partial x}(E_{\max}\sin(\kappa x - \omega t)) = \kappa E_{\max}\cos(\kappa x - \omega t),$$

and

$$\frac{\partial B}{\partial t} = \frac{\partial}{\partial t}(B_{\max}\sin(\kappa x - \omega t)) = -\omega B_{\max}\cos(\kappa x - \omega t).$$

Substituting these expressions into equation 31.13 gives

$$\kappa E_{\max}\cos(\kappa x - \omega t) = -\left[-\omega B_{\max}\cos(\kappa x - \omega t)\right].$$

The angular frequency and wave number are related via

$$\frac{\omega}{\kappa} = \frac{2\pi f}{(2\pi/\lambda)} = f\lambda = c, \tag{31.14}$$

where c is the speed of the wave. (In general, we could use v for the speed of this wave. However, we choose to use c, because, as we'll see, all electromagnetic waves propagate in vacuum with a characteristic speed, the speed of light, which is conventionally represented by c.) Thus, we have

$$\frac{E_{\max}}{B_{\max}} = \frac{\omega}{\kappa} = c.$$

We can use equation 31.8 to rewrite this equation in terms of the ratio of the magnitudes of the fields at a fixed place and time as

$$\frac{E}{B} = \frac{\left|\vec{E}\left(\vec{r}, t\right)\right|}{\left|\vec{B}\left(\vec{r}, t\right)\right|} = \frac{E_{\max}\left|\sin\left(\kappa x - \omega t\right)\right|}{B_{\max}\left|\sin\left(\kappa x - \omega t\right)\right|} = c. \quad \textbf{(31.15)}$$

Thus, equation 31.8 satisfies Faraday's Law of Induction if the ratio of the electric and magnetic field magnitudes is *c*.

Maxwell-Ampere Law

Finally, we address the Maxwell-Ampere Law. For electromagnetic waves, in which no current flows, we can write

$$\oint \vec{B} \bullet \vec{ds} = \mu_0 \varepsilon_0 \frac{d\Phi_E}{dt}. \qquad \textbf{(31.16)}$$

To evaluate the integral on the left-hand side of this equation, we assume a closed loop in the *xz*-plane that has width *dx* and height *h*, represented by the gray rectangle in Figure 31.8. The differential area of this rectangle is oriented in the positive *y*-direction.

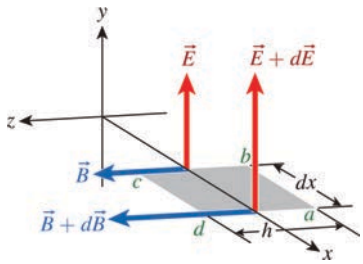

FIGURE 31.8 Representations of the electric and magnetic fields in an electromagnetic wave at a given instant. The gray area represents an integration loop for the Maxwell-Ampere Law.

The integral around the loop in the counterclockwise direction (*a* to *b* to *c* to *d* to *a*) is given by

$$\oint \vec{B} \bullet \vec{ds} = Bh - (B + dB)(h) = -(dB)(h). \quad \textbf{(31.17)}$$

As before, the parts of the loop parallel to the *x*-axis do not contribute to the integral. The right-hand side of equation 31.16 can be written as

$$\mu_0 \epsilon_0 \frac{d\Phi_E}{dt} = \mu_0 \epsilon_0 A \frac{dE}{dt} = \mu_0 \epsilon_0 (h)(dx) \frac{dE}{dt}, \quad \textbf{(31.18)}$$

where *dt* is the time during which the wave travels a distance *dx*. Substituting from equations 31.17 and 31.18 into equation 31.16, we get

$$-(dB)(h) = \mu_0 \epsilon_0 (h)(dx) \frac{dE}{dt}.$$

Expressing this equation in terms of partial derivatives, as we did for equation 31.12, we get

$$-\frac{\partial B}{\partial x} = \mu_0 \epsilon_0 \frac{\partial E}{\partial t}.$$

Now, using equation 31.8, we have

$$-\left[\kappa B_{\max} \cos(\kappa x - \omega t)\right] = -\mu_0 \epsilon_0 \omega E_{\max} \cos(\kappa x - \omega t),$$

or

$$\frac{E_{\max}}{B_{\max}} = \frac{\kappa}{\mu_0 \epsilon_0 \omega} = \frac{1}{\mu_0 \epsilon_0 c}.$$

We can express this equation in terms of the electric and magnetic field magnitudes as before:

$$\frac{E}{B} = \frac{1}{\mu_0 \epsilon_0 c}. \tag{31.19}$$

Equation 31.8 satisfies the Maxwell-Ampere Law if the ratio of the electric and magnetic field magnitudes is given by $1/\mu_0 \epsilon_0 c$.

The Speed of Light

From equations 31.15 and 31.19, we can conclude that

$$\frac{E}{B} = \frac{1}{\mu_0 \epsilon_0 c} = c,$$

which leads to

$$c = \frac{1}{\sqrt{\mu_0 \epsilon_0}}. \qquad \textbf{(31.20)}$$

Thus, the speed of an electromagnetic wave can be expressed in terms of the two fundamental constants related to electric and magnetic fields: the magnetic permeability and the electric permittivity of free space (vacuum). Putting the accepted values of these constants into equation 31.20 gives

$$c = \frac{1}{\sqrt{\left(4\pi \cdot 10^{-7}\,\mathrm{H/m}\right)\left(8.85 \cdot 10^{-12}\,\mathrm{F/m}\right)}} = 3.00 \cdot 10^{8}\,\mathrm{m/s}$$

This calculated speed is equal to the measured speed of light. This equality means that all electromagnetic waves travel (in vacuum) at the speed of light and suggests that light is an electromagnetic wave.

Concept Check 31.4

What is the time required for laser light to travel from the Earth to the Moon and back again? The distance between the Earth and the Moon is $3.84 \cdot 10^8$m.

a) 0.640 s

b) 1.28 s

c) 2.56 s

d) 15.2 s

e) 85.0 s

Equation 31.15 states $E/B = c$. Even though c is a very large number, equation 31.15 does not mean that the electric field magnitude is much larger than the magnetic field magnitude. In fact, electric and magnetic fields are measured in different units, so a direct comparison is not possible.

The speed of light plays an important role in the theory of special relativity, which we'll examine in Chapter 35. The speed of light is always the same in any reference frame. Thus, if you send an electromagnetic wave out in a specific direction, any observer, regardless of whether that observer is moving toward you or away from you or in another direction, will see that wave moving at the speed of light. This amazing result, along with the plausible postulate that the laws of physics are the same for all inertial observers, leads to the theory of special relativity.

The speed of light can be measured extremely precisely, much more precisely than the meter could be determined from the original reference standard. Therefore, the speed of light is now defined to be precisely

$$c = 299,792,458\ \mathrm{m/s}. \qquad \textbf{(31.21)}$$

Self-Test Opportunity 31.1

The brightest star in the night sky is Sirius, which is at a distance of $8.30 \cdot 10^{16}$ m from Earth. When we see the light from this star, how far back in time (in years) are we looking?

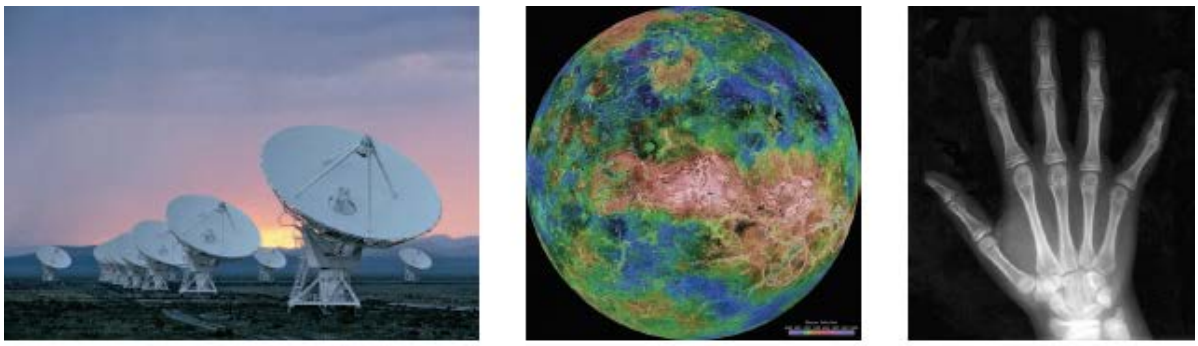
The definition of the meter is now simply the distance that light can traverse in vacuum in a time interval of $1/299{,}792{,}458$ s.

31.3 The Electromagnetic Spectrum

All electromagnetic waves travel at the speed of light. However, the wavelength and the frequency of electromagnetic waves vary dramatically. The speed of light, c, the wavelength, λ, and the frequency, f, are related by

$$c = \lambda f. \qquad \textbf{(31.22)}$$

Examples of electromagnetic waves are light, radio waves, microwaves, X-rays, and gamma rays. Three applications of electromagnetic waves are shown in Figure 31.9.



(a) (b) (c)

FIGURE 31.9 (a) Very Large Array radio telescope. (b) False color radar image of the surface of Venus. (c) X-ray image of a hand.

a: Kim Steele/Getty Images; **b:** JPL/NASA; **c:** W. Bauer and G. D. Westfall

The **electromagnetic spectrum** is illustrated in Figure 31.10, which includes electromagnetic waves with wavelengths ranging from 1000 m and longer to less than 10^{-12}m, with corresponding frequencies ranging from 10^5 to 10^{20} Hz. Electromagnetic waves

with wavelengths (and frequencies) in certain ranges are identified by characteristic names:

- **Visible light** refers to electromagnetic waves that we can see with our eyes, with wavelengths from 400 nm (blue) to 700 nm (red). The response of the human eye peaks at around 550 nm (green) and drops off quickly away from that wavelength. Other wavelengths of electromagnetic waves are invisible to the human eye. However, we can detect them by other means.

- **Infrared waves**, with wavelengths just longer than visible light up to around 10^{-4}m, are felt as warmth. Detectors of infrared waves can be used to measure heat leaks in homes and offices, as well as locate brewing volcanoes. Many animals have developed the ability to see infrared waves, so they can see in the dark. Infrared beams are also used in automatic faucets in public restrooms and in remote control units for TV and DVD players.
- **Ultraviolet rays**, with wavelengths just shorter than visible light down to a few nanometers $\left(10^{-9}\ \mathrm{m}\right)$, can damage skin and cause sunburn. Fortunately, Earth's atmosphere, particularly its ozone layer, prevents most of the Sun's ultraviolet rays from reaching Earth's surface. Ultraviolet rays are used in hospitals to sterilize equipment and also produce optical properties such as fluorescence.
- **Radio waves** have frequencies ranging from several hundred kHz (AM radio) to 100 MHz (FM radio). They are also widely used in astronomy because they can pass through clouds of dust and gas that block visible light; the Very Large Array shown in Figure 31.9a is a collection of telescopes that utilize radio waves.
- **Microwaves,** used to pop popcorn in microwave ovens and transmit phone messages through relay towers or satellites, have frequencies around 10 GHz. Radar uses waves with wavelengths between those of radio waves and microwaves, which enable them to travel easily through the atmosphere and reflect off objects from the size of a baseball to the size of

a storm cloud. Figure 31.9b shows a radar image of the surface of Venus, which is always obscured by clouds that block visible light.

- **X-rays** used to produce medical images, such the one shown in Figure 31.9c, have wavelengths on the order of 10^{-10}m. This length is about the same as the distance between atoms in a solid crystal, so X-rays are used to determine the detailed molecular structure of any material that can be crystallized.
- **Gamma rays** emitted in the decay of radioactive nuclei have very short wavelengths, on the order of 10^{-12}m, and can cause damage to human cells. They are often used in medicine to destroy cancer cells or other malignant tissues that are hard to reach.

Self-Test Opportunity 31.2

An FM radio station broadcasts at 90.5 MHz, and an AM radio station broadcasts at 870 kHz. What are the wavelengths of these electromagnetic waves?

Communication Frequency Bands

The frequency ranges assigned to radio and television broadcasts are shown in Figure 31.11. The range of frequencies assigned to AM (amplitude modulation) radio stations is from 535 kHz to 1705 kHz. FM (frequency modulation) radio stations use the frequencies between 88.0 MHz and 108.0 MHz. VHF (very high frequency) television operates in two ranges: 54.0 MHz to 88.0 MHz for channels 2 through 6, and 174.0 MHz to 216.0 MHz for channels 7 through 13. UHF (ultra-high frequency) television channels 14 through 51 broadcast in the range from 470.0 MHz to 698.0 MHz. Most high-definition television (HDTV) broadcasts use the UHF band and channels 14 through 51. Satellite radio uses the frequencies 2.33 and 2.34 GHz. 5G cell phones operate in three major frequency groups: the lower frequency band overlaps the previous 4G bands; the middle frequency band handles high-speed communications with wide coverage; and the upper band handles ultra-high-speed connections at the expense of a lack of range.

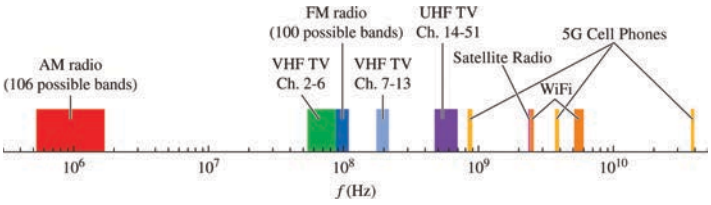

FIGURE 31.11 The frequency bands assigned to radio broadcasts, television broadcasts, cell phones, satellite radio, and WiFi computer connections in the United States.

A radio or television station transmits a carrier signal on a given frequency. The carrier signal is a sine wave with a frequency equal to the frequency of the broadcasting station. In the case of AM broadcasts, the amplitude of the carrier wave is modified by the information being transmitted, as illustrated in Figure 31.12a. The modulation of the amplitude of the carrier signal carries the transmitted message. Figure 31.12a shows a simple sine wave, indicating that a simple tone is being transmitted. The signal is received by a tuned RLC circuit whose resonant frequency is equal to the frequency of the carrier signal. The current induced in the

circuit is proportional to the message being transmitted. AM transmission is vulnerable to noise and signal loss because the message is proportional to the amplitude of the signal, which can change if conditions vary.

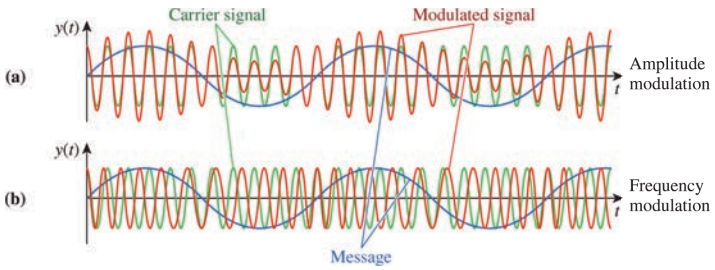

FIGURE 31.12 (a) Amplitude modulation. (b) Frequency modulation. For both cases, the green curve represents the carrier signal, the red curve represents the modulated signal, and the blue curve signifies the information being transmitted.

For FM transmission, the frequency of the carrier signal is modified by the message to produce a modulated signal, as shown in Figure 31.12b. This type of transmission is much less affected by noise and signal loss because the message is extracted from frequency shifts of the carrier signal, rather than from changes in the amplitude of the carrier signal. FM radio receivers commonly use a *Foster-Seeley discriminator* to demodulate the FM signal. A Foster-Seeley discriminator uses an RLC circuit tuned to the frequency of the carrier signal and connected to two diodes, resembling the fullwave rectifier discussed in Chapter 30. If the input equals the carrier frequency, the two halves of the tuned circuit produce the same rectified voltage and the output is zero. As the frequency of the carrier signal changes, the balance between the two halves of the rectified circuit changes, resulting in a voltage proportional to the frequency deviation of the carrier signal. A Foster-Seeley discriminator is sensitive to amplitude variations and is usually coupled with a limiter amplifier stage to desensitize it to variations in the strength of the carrier wave by allowing lower power signals to pass through it unaffected while removing the peaks of the signals that exceed a certain power level.

HDTV transmitters broadcast information digitally in the form of zeros and ones. One byte of information contains eight bits, where a bit is a zero or a one. The screen is subdivided into picture elements (pixels) with digital representations of the red, green, and blue color of each pixel. Currently, the highest resolution for HDTV is 1080i, which has 1920 pixels in the horizontal direction and 1080 pixels in the vertical direction. Half the picture (every other horizontal line) is updated 60 times every second, and the two halves of the image are interlaced to form the complete image. (See the subsection "Applications of Polarization" in Section 31.6 for more information on video formats.) HDTV is broadcast using a compression-decompression (codec) technique, typically the standard known as MPEG-2, to reduce the amount of data that must be transmitted. A typical HDTV station broadcasts about 17 megabytes of information per second. Note TV is no longer broadcast in analog mode: All TV broadcasts are now digital.

Cell phone transmissions occur in the frequency bands from 824 to 894 MHz and 1.85 to 1.99 GHz. WiFi data connections for computers operate in the ranges from 2.401 to 2.484 GHz (for the international standard; the U.S. standard band has an upper limit of 2.473 GHz) and from 5.15 to 5.85 GHz. These frequencies are in the microwave range, and some people worry about prolonged exposure to electromagnetic waves emitted by cell phones and WiFi. However, the relatively low power of these devices combined with the fact that the energy of these waves is much lower than that of other waves that are commonly encountered, such as visible light, argue that such exposure presents little danger. Chapter 37 on quantum mechanics will discuss the energy of the photons associated with electromagnetic waves.

Traveling Electromagnetic Waves

Subatomic processes can produce electromagnetic waves such as gamma rays, X-rays, and light. Electromagnetic waves can also be produced by an RLC circuit connected to an antenna (Figure 31.13). The connection between the RLC circuit and the antenna occurs through a transformer. A dipole antenna is used to approximate an electric dipole. The voltage and current in the antenna vary sinusoidally with time and cause the flow of charge in the antenna to oscillate with the frequency, ω_0, of the RLC circuit. The accelerating charges create **traveling electromagnetic waves.** These waves travel from the antenna at speed c and with frequency $f = \omega_0/(2\pi)$.

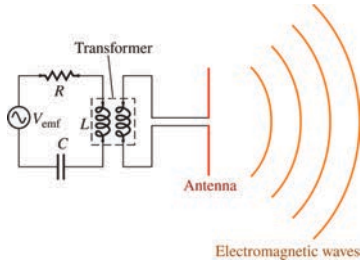

FIGURE 31.13 An RLC circuit coupled to an antenna that emits traveling electromagnetic waves.

The traveling electromagnetic waves propagate as wave fronts spreading out spherically from the antenna. However, at a large distance from the antenna, the wave fronts appear to be almost flat, or planar. Thus, such a traveling wave is described by equation 31.8. If a second RLC circuit tuned to the same frequency, ω_0, as the emitting circuit is placed in the path of these electromagnetic waves, voltage and current will be induced in this second circuit. These induced oscillations are the basis for radio transmission and reception. If the second circuit has $\omega = 1/\sqrt{LC}$, different from ω_0, much smaller voltages and currents will be induced. Only if the resonant frequency of the receiving circuit is the same as or very close to the transmitted frequency will any

signal be induced in the receiving circuit. Thus, the receiver can select a transmission with a given frequency and reject all others.

The principle of transmission of electromagnetic waves was discovered by Heinrich Hertz in 1888, as described in Section 31.1, and was used by the Italian physicist Guglielmo Marconi (1874–1937) to transmit wireless signals.

31.4 Poynting Vector and Energy Transport

When you walk out into the sunlight, you feel warmth. If you stay out too long in the bright sunshine, you become sunburned. These phenomena are caused by electromagnetic waves emitted from the Sun. These electromagnetic waves carry energy that was generated in the nuclear reactions in the core of the Sun.

The rate at which energy is transported by an electromagnetic wave is usually defined in terms of a vector, $\vec{S}$ given by

$$\vec{S} = \frac{1}{\mu_0}\vec{E} \times \vec{B}. \qquad \textbf{(31.23)}$$

This quantity is called the **Poynting vector,** after British physicist John Poynting (1852–1914), who first discussed its properties. The magnitude of $\vec{S}$ is related to the instantaneous rate at which energy is transported by an electromagnetic wave over a given area, or more simply, the instantaneous power per unit area:

$$S = \left|\vec{S}\right| = \left(\frac{\text{power}}{\text{area}}\right)_{\text{instantaneous}}. \qquad \textbf{(31.24)}$$

The units of the Poynting vector are thus watts per square meter $\left(\text{W}/\text{m}^2\right)$.

For an electromagnetic wave, where $\vec{E}$ is perpendicular to $\vec{B}$, equation 31.23 yields

$$S = \frac{1}{\mu_0}EB.$$

According to equation 31.15, the magnitudes of the electric field and the magnetic field are directly related via $E/B = c$. Thus, we can express the instantaneous power per unit area of an electromagnetic wave in terms of the magnitude of the electric field or that of the magnetic field. Since it is usually easier to measure an electric field than a magnetic field, the instantaneous power per unit area is given by

$$S = \frac{1}{c\mu_0} E^2. \qquad \textbf{(31.25)}$$

We can now substitute a sinusoidal form for the electric field, $E = E_{\max} \sin(\kappa x - \omega t)$, and obtain an expression for the transmitted power per unit area. However, the usual means of describing the power per unit area in an electromagnetic wave is the intensity, I, of the wave, given by

$$I = S_{\text{ave}} = \left(\frac{\text{power}}{\text{area}} \right)_{\text{ave}} = \frac{1}{c\mu_0} \left[E_{\max}^2 \sin^2(\kappa x - \omega t) \right]_{\text{ave}}.$$

The units of intensity are the same as the units of the Poynting vector, W/m^2. The time-averaged value of $\sin^2(\kappa x - \omega t)$ is $\frac{1}{2}$, so we can express the intensity as

$$I = \frac{1}{c\mu_0} E_{\text{rms}}^2, \qquad \textbf{(31.26)}$$

where $E_{\text{rms}} = E_{\max}/\sqrt{2}$.

Because the magnitudes of the electric and magnetic fields of an electromagnetic wave are related by $E = cB$ and c is such a large number, you might conclude that the energy transported by the electric field is much larger than the energy transported by the magnetic field. Actually these energies are *the same*. To see this, recall from Chapters 24 and 29 that the energy density of an electric field is given by

$$u_E = \tfrac{1}{2}\epsilon_0 E^2,$$

and the energy density of a magnetic field is given by

$$u_B = \frac{1}{2\mu_0} B^2.$$

Page 960

If we substitute $E = cB$ and $c = 1/\sqrt{\mu_0 \epsilon_0}$ into the expression for the energy density of the electric field, we get

$$u_E = \tfrac{1}{2}\epsilon_0 (cB)^2 = \tfrac{1}{2}\epsilon_0 \left(\frac{B}{\sqrt{\mu_0 \epsilon_0}} \right)^2 = \frac{1}{2\mu_0} B^2 = u_B. \textbf{(31.2}$$

Thus, the energy density of the electric field is the same as the energy density of the magnetic field everywhere in the electromagnetic wave.

EXAMPLE 31.1 Using Solar Panels to Charge an Electric Car

Suppose that a photovoltaic (solar power to electric power) solar array (Figure 31.14a) is used to charge an electric car (Figure 31.14b). A typical driver in the United States drives 14,300 miles per year or 39.2 miles per day. The electric car shown in Figure 31.14b can travel 330. miles using 75.0 kWh of energy. The typical cost of a household solar array is $2.75 per watt. Suppose that sunlight is incident on the solar array for an average of 4.00 hours per day with an average intensity of $0.600\ \mathrm{kW/m^2}$. Solar array power ratings correspond to a sunlight intensity of $1.00\ \mathrm{kW/m^2}$.

(a)

(b)

FIGURE 31.14 (a) Photovoltaic solar panels mounted on the roof of a house. (b) A plug-in electric car capable of driving 37 miles on a single charge.

a: imaginima/E+/Getty Images; **b:** Anton Violin/Alamy Stock Photo

PROBLEM

What would be the cost of the solar array that could provide the average daily energy needs of the electric car?

SOLUTION

The solar array needs to supply enough energy daily to allow the electric car to travel 39.2 miles:

$$\frac{75.0\ \text{kWh}}{330.\ \text{miles}} 39.2\ \text{miles} = 8.91\ \text{kWh}.$$

The required power of the solar array is

$$P = \frac{8.91\ \text{kWh}}{4.00\ \text{h}} \frac{1.00\ \text{kW/m}^2}{0.600\ \text{kW/m}^2} = 3.71\ \text{kW}.$$

The cost of the solar array would be

$$C_{\text{solar}} = (3.71 \cdot 10^3\ \text{W})(2.75\ \$/\text{W}) = \$10{,}200.$$

DISCUSSION

Over a span of 10 years, the energy cost of driving the electric car would be \$10,200 or 7.29 cents per mile. If gasoline costs \$4.00 per gallon and a gasoline-powered car averages 20.0 miles per gallon, the energy cost of driving a gasoline-powered car the same distance over 10.0 years would be

$$C_{\text{gas}} = \frac{(10.0\ \text{years})\left(14{,}300\dfrac{\text{miles}}{\text{year}}\right)\left(4.00\dfrac{\$}{\text{gallon}}\right)}{20.0\dfrac{\text{miles}}{\text{gallon}}} = \$$

which corresponds to 20.0 cents per mile.

The energy cost over the 10-year period is \$10,200 for solar power compared to \$28,600 for gasoline power. Your solar-powered electric car would be a carbon-neutral, zero-emission mode of transportation (the same as riding your bicycle, without the exercise benefits). Material scientists are working to increase the efficiency of commercially available solar cells. Mass production has dramatically lowered the cost of solar panels in recent years, and this decrease is expected to continue in the future. Many major carmakers are currently moving toward phasing out gasoline-powered vehicles and making only electric vehicles.

EXAMPLE 31.2 The Root-Mean-Square Electric and Magnetic Fields from Sunlight

The average intensity of sunlight at the Earth's surface is approximately $1400\ \mathrm{W/m^2}$, if the Sun is directly overhead.

PROBLEM

What are the root-mean-square electric and magnetic fields of these electromagnetic waves?

SOLUTION

The intensity of sunlight can be related to the root-mean-square electric field using equation 31.26:

$$I = \frac{1}{c\mu_0} E_{\mathrm{rms}}^2.$$

Solving for the root-mean-square electric field gives us

$$\begin{aligned} E_{\mathrm{rms}} &= \sqrt{Ic\mu_0} = \sqrt{(1400\ \mathrm{W/m^2})(3.00 \cdot 10^8 \mathrm{m/s})(4\pi \cdot 10} \\ &= 730\ \mathrm{V/m}. \end{aligned}$$

In comparison, the root-mean-square electric field in a typical home is $5 - 10\ \mathrm{V/m}$. Standing directly under an electric power transmission line, one would experience a root-mean-square electric field of $200 - 10{,}000\ \mathrm{V/m}$ depending on the conditions.

The root-mean-square magnetic field of sunlight is

$$B_{\mathrm{rms}} = \frac{E_{\mathrm{rms}}}{c} = \frac{730\ \mathrm{V/m}}{3.00 \cdot 10^8 \mathrm{m/s}} = 2.4\ \mu\mathrm{T}.$$

In comparison, the root-mean-square value of the Earth's magnetic field is 50 μT, the root-mean-square magnetic field found in a typical home is 0.5 μT, and the root-mean-square magnetic field under a power transmission line is 2 μT.

31.5 Radiation Pressure

When you walk out into the sunlight, you feel warmth, but you do not feel any force from the sunlight. Sunlight is exerting a pressure on you, but that pressure is so small that you cannot notice it. Because the electromagnetic waves making up sunlight are radiated from the Sun and travel to the Earth, they are referred to as **radiation.** Chapter 18 discussed radiation as one way to transfer heat. As we'll see in Chapter 40 on nuclear physics, this type of radiation is not necessarily the same as radioactive radiation resulting from the decay of unstable nuclei. However, radio waves, infrared waves, visible light, and X-rays are all fundamentally the same electromagnetic radiation. (Which is not to say, however, that all kinds of electromagnetic radiation have the same effect on the human body. For example, UV light can give you sunburn and even trigger skin cancer, whereas there is no credible evidence that radiation emitted from cell phones can cause cancer.)

Let's calculate the magnitude of the pressure exerted by these radiated electromagnetic waves. Electromagnetic waves carry energy, U, as shown in Section 31.4. Electromagnetic waves also have linear momentum, $\vec{p}$. This concept is subtle because electromagnetic waves have no mass, and we saw in Chapter 7 that momentum is equal to mass multiplied by velocity. Maxwell showed that if a plane wave of radiation is totally absorbed by a surface (perpendicular to the direction of the plane wave) for a time interval, Δt, and an amount of energy, ΔU, is absorbed by the surface in that process, then the magnitude of the momentum transferred to that surface by the wave in that time interval is

$$\Delta p = \frac{\Delta U}{c}.$$

Chapter 35 on relativity will show that this relationship between energy and momentum holds for massless objects; for now, it is stated as a fact, without proof.

The magnitude of the force on the surface is then $F = \Delta p/\Delta t$ (Newton's Second Law). The total energy, ΔU, absorbed by an area A of the surface during the time interval Δt is equal to the product of the area, the time interval, and the radiation intensity, I (introduced in Section 31.4): $\Delta U = IA\Delta t$. Therefore, the magnitude of the force exerted by the electromagnetic wave on this area is

$$F = \frac{\Delta p}{\Delta t} = \frac{\Delta U}{c\Delta t} = \frac{IA\Delta t}{c\Delta t} = \frac{IA}{c}.$$

Since pressure is defined as force (magnitude) per unit area, the radiation pressure, p_{r}, is

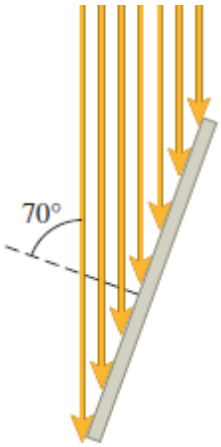
$$p_{\mathrm{r}} = \frac{F}{A},$$

and, consequently,

$$p_{\mathrm{r}} = \frac{I}{c} \text{ (for total absorption).} \qquad \textbf{(31.28)}$$

Concept Check 31.5

What is the radiation pressure due to sunlight incident on a perfectly absorbing surface, whose surface normal vector is at an angle of 70° relative to the incident light?



a) $(4.67\ \mu\text{Pa})(\cos 70^\circ)$

b) $(4.67\ \mu\text{Pa})(\sin 70^\circ)$

c) $(4.67\ \mu\text{Pa})(\tan 70^\circ)$

d) $(4.67\ \mu\text{Pa})(\cot 70^\circ)$

Equation 31.28 states that the radiation pressure due to electromagnetic waves is simply the intensity divided by the speed of light, but only for the case of total absorption of the radiation by the surface.

The other limiting case is total reflection of the electromagnetic waves. In that case, the momentum transfer is *twice* as big as for total absorption, just like the momentum transfer from a ball to a wall is twice as big in a perfectly elastic collision as in a perfectly inelastic collision. In the perfectly elastic collision, the ball's initial momentum is reversed and $\Delta p = p_\text{i} - (-p_\text{i}) = 2p_\text{i,}$ whereas for the totally inelastic collision, $\Delta p = p_\text{i} - 0 = p_\text{i}$, as explained in Chapter 7. So, the radiation pressure for the case of perfect reflection of the electromagnetic waves off a surface is

$$p_{\mathrm{r}} = \frac{2I}{c} \text{ (for perfect reflection).} \qquad \textbf{(31.29)}$$

The radiation pressure from sunlight is comparatively small. The intensity of sunlight at the Earth's surface is at most $1400\ \mathrm{W/m^2}$, when the Sun is directly overhead and there are no clouds in the sky. (This can happen only between the Tropics of Cancer and Capricorn, located at $\pm 23^\circ$ latitude relative to the Equator.) Thus, the maximum radiation pressure for sunlight that is totally absorbed is

$$p_{\mathrm{r}} = \frac{I}{c} = \frac{1400\ \mathrm{W/m^2}}{3 \cdot 10^8\ \mathrm{m/s}} = 4.67 \cdot 10^{-6}\ \mathrm{N/m^2} = 4.67\ \mu\mathrm{Pa}.$$

Concept Check 31.6

What is the maximum radiation pressure due to sunlight incident on a perfectly reflecting surface?

a) 0

b) 2.34 μPa

c) 4.67 μPa

d) 9.34 μPa

For comparison, atmospheric pressure is 101 kPa (see Chapter 13), which is greater than the sunlight's radiation pressure on the surface of Earth by more than a factor of 20 billion. Another useful comparison is the lowest pressure difference that human hearing can detect, which is generally quoted as approximately 20 μPa for sounds in the 1-kHz frequency range, where the human ear is most sensitive (see Chapter 16).

EXAMPLE 31.3 Radiation Pressure from a Laser Pointer

A green laser pointer has a power of 1.00 mW. You shine the laser pointer perpendicularly on a mirror, which reflects the light. The spot of light on the mirror is 2.00 mm in diameter.

PROBLEM

What force does the light from the laser pointer exert on the mirror?

SOLUTION

The intensity of the light is given by

$$I = \frac{\text{power}}{\text{area}} = \frac{1.00 \cdot 10^{-3}\ \text{W}}{\pi\left(1.00 \cdot 10^{-3}\ \text{m}\right)^2} = 318\ \text{W/m}^2.$$

Page 963

The radiation pressure for a perfectly reflecting surface is given by equation 31.29 and also is equal to the force exerted by the light divided by the area over which it acts:

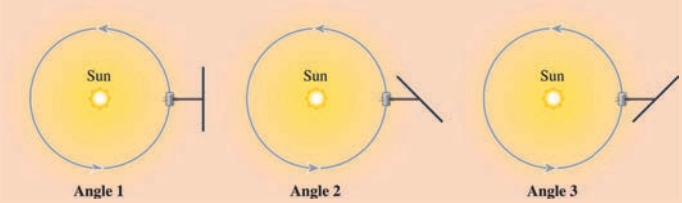
$$p_\text{r} = \frac{\text{force}}{\text{area}} = \frac{2I}{c}.$$

Thus, the force exerted on the mirror is

$$\text{Force} = (\text{area})\left(\frac{2I}{c}\right) = \pi\left(1.0 \cdot 10^{-3}\,\text{m}\right)^2 \frac{2\left(318\ \text{W/m}^2\right)}{3.00 \cdot 10^8 \text{m/s}}$$

Self-Test Opportunity 31.3

Suppose you have a satellite in orbit around the Sun, as shown in the figure. The orbit is in the counterclockwise direction looking down on the north pole of the Sun. You want to deploy a solar sail consisting of a large, totally reflecting mirror, which can be oriented so that it is perpendicular to the light coming from the Sun or at an angle with respect to the light coming from the Sun. Describe the effect on the orbit of your satellite for the three deployment angles shown in the figure.



SOLVED PROBLEM 31.1 Solar Stationary Satellite

Suppose researchers want to place a satellite that will remain stationary above the north pole of the Sun in order to study the Sun's long-term rotational characteristics. The satellite will have a totally reflecting solar sail and be located at a distance of $1.50 \cdot 10^{11}$m from the center of the Sun. The intensity of sunlight at that distance is $1400\ \mathrm{W/m^2}$. The plane of the solar sail is perpendicular to a line connecting the satellite and the center of the Sun. The mass of the satellite and sail is 100.0 kg.

PROBLEM

What is the required area of the solar sail?

SOLUTION

THINK

In an equilibrium position for the satellite, the area of the solar sail times the radiation pressure from the Sun produces a force that is balanced by the gravitational force between the satellite and the Sun. We can equate these two forces and solve for the area of the solar sail.

SKETCH

Figure 31.15 is a diagram of the satellite with a solar sail near the Sun.

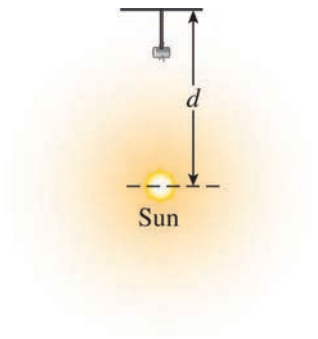


FIGURE 31.15 A satellite with a solar sail near the Sun.

RESEARCH

The satellite will be stationary if the force of gravity, F_g, is balanced by the force from the radiation pressure of sunlight, F_{rp}:

$$F_{\text{g}} = F_{\text{rp}}.$$

The force corresponding to the radiation pressure from sunlight is equal to the radiation pressure, p_r, times the area of the solar sail, A:

$$F_{\text{rp}} = p_{\text{r}} A.$$

The radiation pressure can be expressed in terms of the intensity of the sunlight, I, incident on the totally reflecting solar sail:

$$p_{\text{r}} = \frac{2I}{c}.$$

The force of gravity between the satellite and the Sun is given by

$$F_{\text{g}} = G\frac{m m_{\text{Sun}}}{d^2},$$

where G is the universal gravitational constant, m is the mass of the satellite and sail, m_{sun} is the mass of the Sun, and d is the distance between the satellite and the Sun.

SIMPLIFY

We can combine all these equations to obtain

$$\left(\frac{2I}{c}\right)A = G\frac{mm_{\text{Sun}}}{d^2}.$$

Solving for the area of the solar sail gives us

$$A = G\frac{cmm_{\text{Sun}}}{2Id^2}.$$

CALCULATE

Putting in the numerical values, we get

$$A = (6.67 \cdot 10^{-11}\text{m}^3\,\text{kg}^{-1}\text{s}^{-2})\frac{(3.00 \cdot 10^8\,\text{m/s})(100.0\,\text{kg})(}{2(1400\,\text{W/m}^2)(1.50 \cdot}$$

ROUND

We report our result to three significant figures:

$$A = 6.32 \cdot 10^4\,\text{m}^2.$$

DOUBLE-CHECK

If the solar sail were circular, the radius of the sail would be

$$R = \sqrt{\frac{A}{\pi}} = \sqrt{\frac{6.32 \cdot 10^4\text{m}^2}{\pi}} = 142\,\text{m}.$$

We can relate the thickness of the sail, t, times the density, ρ, of the material from which the sail is constructed to the mass per unit area of the sail:

$$t\rho = \frac{m}{A}.$$

If the sail were composed of a sturdy material such as kapton $\left(\rho = 1420\,\mathrm{kg/m^3}\right)$ and had a mass of 75 kg, the thickness of the sail would be

$$t = \frac{75\,\mathrm{kg}}{\left(1420\,\mathrm{kg/m^3}\right)\left(6.32 \cdot 10^4\,\mathrm{m^2}\right)} = 8.36 \cdot 10^{-7}\mathrm{m} = 0.83$$

Kapton is a polyimide film developed to remain stable in the wide range of temperatures found in space; from near absolute zero to over 600 K. Current production techniques cannot produce kapton this thin. However, the required areal mass density may be realizable using other materials in the future.

SOLVED PROBLEM 31.2 Laser-Powered Sailing

One idea for propelling long-range spacecraft involves using a high-powered laser beam, rather than sunlight, focused on a large totally reflecting sail. The spacecraft could then be propelled from Earth. Suppose a 10.0-GW laser could be focused at long distances. The spacecraft has a mass of 200.0 kg, and its reflecting sail is large enough to intercept all of the light emitted by the laser.

PROBLEM

Neglecting gravity, how long would it take the spacecraft to reach a speed of 30.0% of the speed of light, starting from rest?

SOLUTION

THINK

The radiation pressure from the laser produces a constant force on the spacecraft's sail, resulting in a constant acceleration. Using the constant acceleration, we can calculate the time to reach the final speed starting from rest.

SKETCH

Figure 31.16 is a diagram of a laser focusing light on the spacecraft with a totally reflecting sail.

FIGURE 31.16 A laser focusing its light on a spacecraft with a totally reflecting sail.

RESEARCH

The radiation pressure, p_r, from the light with intensity I produced by the laser is

$$p_r = \frac{2I}{c}.$$

Pressure is defined as force, F, per unit area, A, of the spot the beam produces on the sail, so we can write

$$\frac{2I}{c} = \frac{F}{A}.$$

The intensity of the laser is given by the power, P, of the laser divided by the spot's area, A. Assuming that the sail of the spacecraft can intercept the entire laser beam, we can write

$$\frac{F}{A} = \frac{2(P/A)}{c}.$$

Solving for the force exerted by the laser beam on the sail and using Newton's Second Law, we can write

$$F = \frac{2P}{c} = ma. \qquad \text{(i)}$$

SIMPLIFY

We can solve equation (i) for the acceleration:

$$a = \frac{2P}{mc}.$$

Assuming that all the power of the laser remains focused on the sail of the spacecraft, the spacecraft will experience a constant acceleration. Then, the final speed, v, of the spacecraft can be related to the time it takes to reach that speed through

$$v = at = 0.300c.$$

Solving for the time gives us

$$t = \frac{0.300c}{2P/mc} = \frac{0.300mc^2}{2P}.$$

CALCULATE

Putting in the numerical values gives us

$$t = \frac{0.300mc^2}{2P} = \frac{0.300(200.0\,\text{kg})(3.00 \cdot 10^8\text{m/s})^2}{2(10.0 \cdot 10^9\,\text{W})} = 27($$

ROUND

We report our result to three significant figures:

$$t = 270{,}000{,}000\,\text{s} = 8.56\,\text{yr}.$$

DOUBLE-CHECK

To double-check our result, we calculate the acceleration of the spacecraft:

$$a = \frac{2P}{mc} = \frac{2(10.0 \cdot 10^9\,\text{W})}{(200\,\text{kg})(3.00 \cdot 10^8\text{m/s})} = 0.333\,\text{m/s}^2.$$

This acceleration is 3% of the acceleration due to gravity at the surface of the Earth. This acceleration is produced by a laser with 10 times the power of a typical power station, which must run continuously for 8.56 yr. The distance the spacecraft will travel during that time is

$$x = \tfrac{1}{2}\text{at}^2 = \tfrac{1}{2}\left(0.333\,\text{m/s}^2\right)\left(2.70 \cdot 10^8\text{s}\right)^2 = 1.21 \cdot 10^{16}\,\text{m}$$

which is slightly more than $1\frac{1}{4}$ times the distance light travels in a year. The laser must remain focused on the spacecraft at

this distance. Thus, although our calculations seem reasonable, the requirements for a laser-driven spacecraft with a reflecting sail seem difficult to achieve. In Chapter 35, we'll see that we must modify this calculation because the speed involved is a significant fraction of the speed of light.

31.6 Polarization

For the electromagnetic wave represented in Figure 31.5, the electric field always points along the y-axis. The direction in which the wave is traveling is the positive x-direction, so the electric field of the electromagnetic wave lies within a plane of oscillation (Figure 31.17).

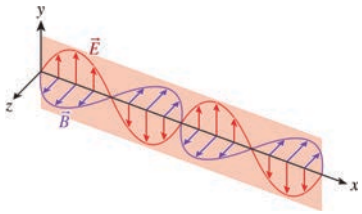

FIGURE 31.17 An electromagnetic wave with the plane of oscillation of the electric field shown in pink.

We can visualize the polarization of an electromagnetic wave by looking at the electric field vector of the wave in the yz-plane, which is perpendicular to the direction in which the wave is traveling (Figure 31.18a). The electric field vector changes from the positive y-direction to the negative y-direction and back again as the wave travels. The electric field of the wave oscillates in the y-direction only, never changing its orientation. This type of wave is called a **plane-polarized wave** in the y-direction.

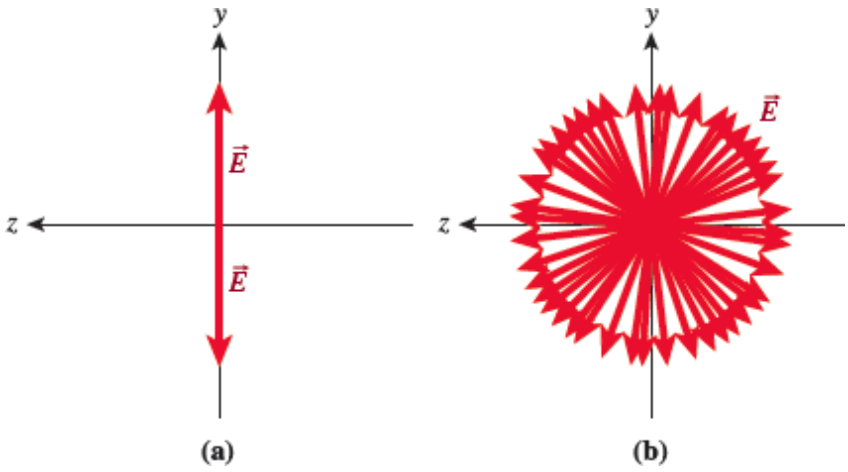

FIGURE 31.18 (a) Electric field vectors in the *yz*-plane, defining the plane of polarization to be the *xy*-plane. (b) Electric field vectors oriented at random angles.

The electromagnetic waves making up the light emitted by most common light sources, such as the Sun or an incandescent light bulb, have random polarizations. Each wave has its electric field vector oscillating in a different plane. Such light is called **unpolarized light.** Light from an unpolarized source can be represented by many vectors like the ones shown in Figure 31.18a, but with random orientations (Figure 31.18b). Unpolarized light can also be represented by summing the *y*-components and the *z*-components separately to produce the net *y*- and *z*-components. Unpolarized light has equal components in the *y*- and *z*-directions (Figure 31.19a). If there is less net polarization in the *y*-direction than in the *z*-direction, then the light is said to be partially polarized in the *z*-direction (Figure 31.19b).

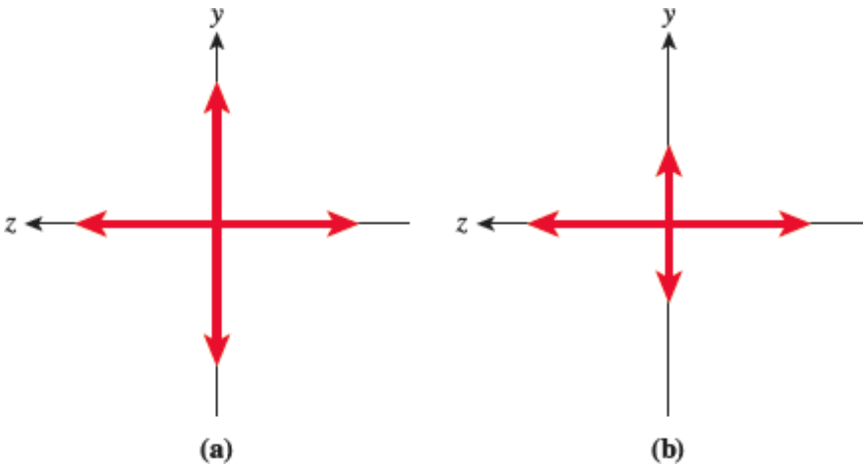

FIGURE 31.19 (a) Net components of the electric field for unpolarized light. (b) Net components of the electric field for partially polarized light.

Unpolarized light can be transformed to polarized light by passing the unpolarized light through a polarizer. A **polarizer** allows only one component of the electric field vectors of the light waves to pass through. One way to make a polarizer is to produce a material that consists of long parallel chains of molecules. This discussion will not go into the details of the molecular structure but will simply characterize each polarizer by a polarizing direction. Unpolarized light passing through a polarizer emerges polarized in the polarizing direction (Figure 31.20). The components of the light that have the same direction as the polarizer are transmitted, but the components of the light that are perpendicular to the polarizer are absorbed.

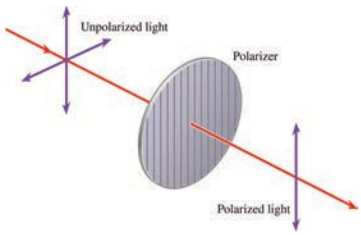

FIGURE 31.20
Unpolarized light passing through a vertical polarizer. After the light passes through the polarizer, it is vertically polarized.

Now let's consider the intensity of the light that passes through a polarizer. Unpolarized light with intensity I_0 has equal components in the y- and z-directions. After passing through a vertical polarizer, only the y-component (or vertical component) remains. The intensity, I, of the light that passes through the polarizer is given by

$$I = \tfrac{1}{2} I_0, \qquad \textbf{(31.30)}$$

because the unpolarized light had equal contributions from the y- and z-components and only the y-components are transmitted by the polarizer. The factor $\frac{1}{2}$ applies only to the case of unpolarized light passing through a polarizer.

Let's consider polarized light passing through a polarizer (Figure 31.21). If the polarizer axis is parallel to the polarization direction of the incident polarized light, all of the light will be transmitted with the original polarization (Figure 31.21a). If the polarizing angle of the polarizer is perpendicular to the

polarization of polarized light, no light will be transmitted (Figure 31.21b).

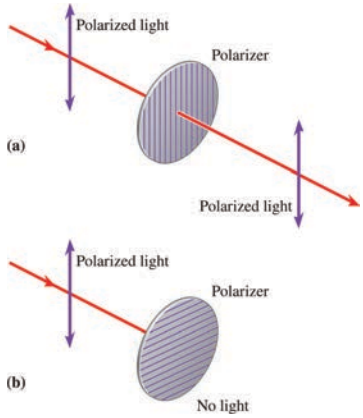

FIGURE 31.21 (a) Vertically polarized light incident on a vertical polarizer. (b) Vertically polarized light incident on a horizontal polarizer.

What happens when polarized light is incident on a polarizer and the polarization of the light is neither parallel nor perpendicular to the polarizing angle of the polarizer (Figure 31.22)? Let's assume that the angle between the incident polarized light and the polarizing angle is θ. The magnitude of the transmitted electric field, E, is given by

$$E = E_0 \cos\theta,$$

where E_0 is the magnitude of the electric field of the incident polarized light. From equation 31.26, we can see that the intensity of the light before passing through the polarizer, I_0, is given by

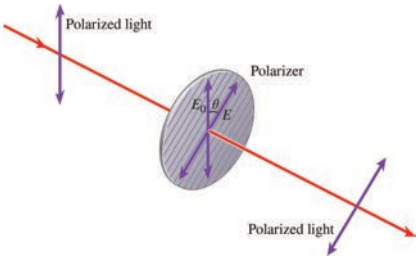

FIGURE 31.22
Polarized light passing through a polarizer whose polarizing angle is neither parallel nor perpendicular to the polarization of the incident light.

$$I_0 = \frac{I}{c\mu_0} E_{\text{rms}}^2 = \frac{1}{2c\mu_0} E_0^2.$$

After the light passes through the polarizer, the intensity, I, is given by

$$I = \frac{1}{2c\mu_0} E^2.$$

We can express the transmitted intensity in terms of the initial intensity as follows:

$$I = \frac{2}{2c\mu_0} E^2 = \frac{1}{2c\mu_0} (E_0 \cos\theta)^2 = I_0 \cos^2\theta. \quad \textbf{(31.31)}$$

This equation is called the **Law of Malus.** It applies only to polarized light incident on a polarizer.

EXAMPLE 31.4 Three Polarizers

Suppose that unpolarized light with intensity I_0 is initially incident on the first of three polarizers in a line. The first polarizer has a polarizing direction that is vertical. The second polarizer has a polarizing angle of 45.0° with respect to the vertical. The third polarizer has a polarizing angle of 90.0° with respect to the vertical.

PROBLEM

What is the intensity of the light after passing through all three polarizers, in terms of the initial intensity?

SOLUTION

Figure 31.23 illustrates the light passing through the three polarizers. The intensity of the unpolarized light is I_0. The intensity of the light after passing through the first polarizer is

$$I_1 = \tfrac{1}{2} I_0.$$

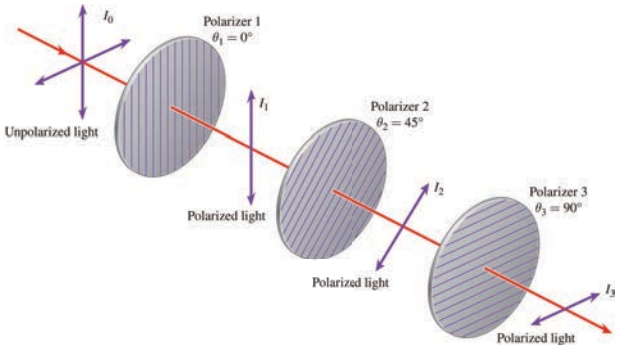

FIGURE 31.23 Unpolarized light passing through three polarizers.

The intensity of the light after passing through the second polarizer is

$$I_2 = I_1 \cos^2(45^\circ - 0^\circ) = I_1 \cos^2 45^\circ = \tfrac{1}{2} I_0 \cos^2 45^\circ.$$

The intensity of the light after passing through the third polarizer is

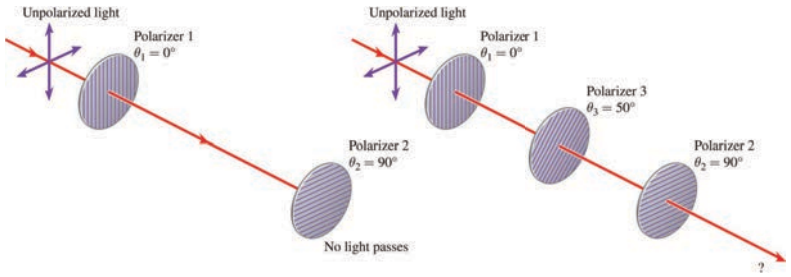
$$I_3 = I_2 \cos^2(90^\circ - 45^\circ) = I_2 \cos^2 45^\circ = \tfrac{1}{2} I_0 \cos^4 45^\circ,$$

or $I_3 = I_0/8$.

The fact that $\frac{1}{8}$ of the light's initial intensity is transmitted is somewhat surprising because polarizers 1 and 3 have polarizing angles that are perpendicular to each other. Acting by themselves, polarizers 1 and 3 would block all of the light. Yet by adding an additional obstacle (polarizer 2) between these two polarizers, $\frac{1}{8}$ of the original intensity gets through. A series of polarizers with small differences in their polarizing angles can thus be used to rotate the polarization direction of light with only modest losses in intensity.

Concept Check 31.7

The figure shows unpolarized light incident on polarizer 1 with polarizing angle $\theta_1 = 0^\circ$ and then on polarizer 2 with polarizing angle $\theta_2 = 90^\circ$, which results in no light passing through. If polarizer 3 with polarizing angle $\theta_3 = 50^\circ$ is placed between polarizers 1 and 2, which of the following statements is true?



a) No light passes through the three polarizers.

b) Less than half, but more than zero, of the light passes through the three polarizers.

c) Exactly half of the light passes through the three polarizers.

d) More than half, but not all, of the light passes through the three polarizers.

e) All of the light passes through the three polarizers.

SOLVED PROBLEM 31.3 Multiple Polarizers

Suppose you have light polarized in the vertical direction and want to rotate the polarization to the horizontal direction ($\theta = 90.0^\circ$). If you pass the vertically polarized light through a polarizer whose polarizing angle is horizontal, all the light will be blocked. If, instead, you use a series of 10 polarizers, each of which has a polarizing angle θ that is 9.00° more than that of the preceding one, with the first polarizer having $\theta = 9.00^\circ$, you can rotate the polarization by 90.0° and still have light passing through.

PROBLEM

What fraction of the intensity of the incident light is transmitted through the 10 polarizers?

SOLUTION

THINK

Each polarizer is rotated 9.00° from the preceding polarizer. Thus, each polarizer transmits a fraction of the intensity equal to $f = \cos^2 9^\circ$. The fraction transmitted is then f^{10}.

SKETCH

Figure 31.24 shows the direction of the initial polarization and the orientations of the 10 polarizers.

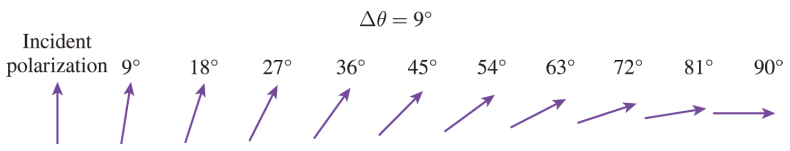


FIGURE 31.24 The direction of the polarization of the incident light and the direction of the polarizing angles of 10 polarizers.

RESEARCH

The intensity, I, of polarized light passing through a polarizer whose polarizing direction makes an angle θ with the polarization of the incident light is given by

$$I = I_0 \cos^2\theta,$$

where I_0 is the intensity of the incident polarized light. In this case, the polarizing direction of each successive polarizer is rotated $\Delta\theta = 9^\circ$ relative to the polarizing direction of the preceding polarizer. Thus, each polarizer reduces the intensity by the factor

$$\frac{I}{I_0} = \cos^2\Delta\theta.$$

SIMPLIFY

The reduction in intensity after the light has passed through 10 polarizers, each with its polarization direction differing from that of the preceding polarizer by $\Delta\theta$ is

$$\frac{I_{10}}{I_0} = \left(\cos^2\Delta\theta\right)^{10}.$$

CALCULATE

Putting in the numerical values, we get

$$\frac{I_{10}}{I_0} = \left(\cos^2 9^\circ\right)^{10} = 0.780546.$$

ROUND

We report our result to three significant figures:

$$\frac{I_{10}}{I_0} = 0.781 = 78.1\,\%.$$

DOUBLE-CHECK

Using 10 polarizers, each rotated by 9° more than the preceding one, the polarization of the incident polarized light was rotated by 90° and 78.1% of the light was transmitted, whereas using one polarizer rotated by 90° would have blocked all of the incident light. To see if our answer is reasonable, let's assume that instead of 10 polarizers, we use n polarizers, each rotated by an angle $\Delta\theta = \theta_{\max}/n$, where $\theta_{\max} = 90^\circ$. For each polarizer, the angle between its polarization direction and that of the preceding polarizer is small, so we can use the small-angle approximation for $\cos\Delta\theta$ to write

$$\frac{I_1}{I_0} \approx \left(1 - \frac{(\Delta\theta)^2}{2}\right)^2.$$

Page 970

The intensity of the light that passes through the n polarizers is then

$$\frac{I_n}{I_0} \approx \left(1 - \frac{(\theta_{\max}/n)^2}{2}\right)^{2n} = \left(1 - \frac{\theta_{\max}^2}{2n^2}\right)^{2n}.$$

For large n,

$$\frac{I_n}{I_0} \approx 1 = 100\,\%.$$

Using 10 polarizers to rotate the polarization of the incident polarized light allowed 78.1% of the light to pass. Using more polarizers with smaller changes in the polarization direction would allow the transmission to approach 100%. Thus, our result seems reasonable.

Applications of Polarization

Polarization has many practical applications. Sunglasses often have a polarized coating that blocks reflected light, which is usually polarized. A computer's or television's liquid crystal display (LCD) has an array of liquid crystals sandwiched between two polarizers whose polarizing angles are rotated 90° with respect to each other. Normally, the liquid crystal rotates the polarization of the light between the two polarizers so that light passes through. An array of addressable electrodes applies a varying voltage across each of the liquid crystals, causing the liquid crystals to rotate the polarization less, darkening the area covered by the electrode. The television or computer monitor screen can then display a large number of picture elements, or *pixels*, that produce a high-resolution image.

Figure 31.25a shows a top view of the layers of an LCD screen. Unpolarized light is emitted by a backlight. This light passes through a vertical polarizer. The polarized light then passes through a transparent layer of conducting pixel pads. These pads are designed to put varying amounts of voltage across the next layer, which is composed of liquid crystals, with respect to the transparent common electrode. If no voltage is applied across the liquid crystals, they rotate the polarization of the incident light by 90˚. This light with rotated polarization can then pass through the transparent common electrode, the color filter, the horizontal polarizer, and the screen cover. When voltage of varying magnitude is applied to the pixel pad, the liquid crystals rotate the polarization of the incident light by a varying amount. When the full voltage is applied to the pixel pad, the polarization of the incident light is not rotated, and the horizontal polarizer blocks any light transmitted through the transparent common electrode and the color filter.

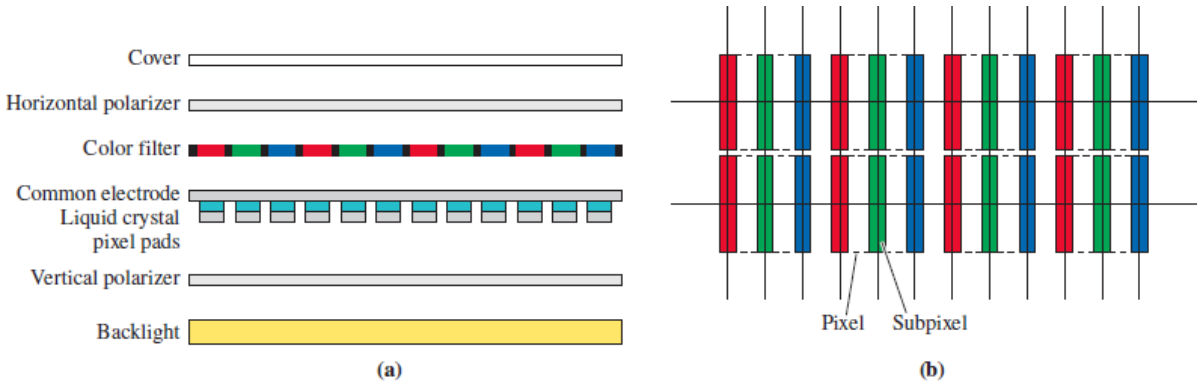

FIGURE 31.25 (a) Top view of the layers making up an LCD screen. (b) Front view of a subset of pixels and subpixels on an LCD screen.

Figure 31.25b shows a front view of a small segment of the LCD screen, illustrating how the screen produces an image. The image is created by an array of pixels. Each pixel is subdivided into three subpixels: one red, one green, and one blue. By varying the voltage across each subpixel, a superposition of red, green, and blue light is created, producing a color on that pixel. It is difficult to connect a single wire to each subpixel, however. A high-definition 1080p LCD screen has 1080 times 1920 times 3 subpixels, or 6,220,800 subpixels. These subpixels are connected in columns and rows, as shown in Figure 31.25b. To turn on a subpixel, a voltage from both a column and a row must be applied. Thus, the subpixels are turned on one row at a time. With the voltage for one row on, the voltages for the subpixels in the desired columns are turned on. A small capacitor holds the voltage until the row is turned on again.

A high-definition 1080p LCD screen is scanned 60 times a second, producing a complete image in each scan. On a high-definition 1080i screen, every other row of the image is scanned 60 times a second and then the two images are interlaced. Another high-definition standard is 720p, which scans 720 rows 60 times a second with a horizontal resolution of 1280 pixels. The 720p and 1080i standards are in common use in television broadcasting. The standard resolution for a television image is 480i, with every other

row being updated 60 times a second and producing 640 columns of pixels.

Viewing a 3D movie also involves the use of polarization filters. Moviegoers are equipped with glasses that have different polarization filters built into each lens. The projection equipment generates two different images with different polarizations on the screen. These images are also slightly offset from each other, and the viewer's brain constructs the 3D illusion by combining the two offset images. Older projection systems use linear polarization filters with polarization directions perpendicular to each other. However, this type of system yields diminished 3D effects when viewers tilt their heads sideways.

Modern 3D movie projection equipment uses circular polarization filters. Circular polarized light comes in two orthogonal varieties, left-circular and right-circular. Circular polarization filters work just like linear polarization filters, subject to a corresponding version of the Law of Malus. The 3D viewing glasses used with this modern equipment have one lens that passes left-circular and one lens that passes right-circular polarized light. This type of glasses produces 3D effects that are not affected when viewers tilt their heads.

There is one important difference between linearly polarized and circular polarized light: Linear polarized light remains in the same state of polarization after being reflected by a mirror, whereas circular polarized light changes its state from left-circular polarized to right-circular polarized, or vice versa. Figure 31.26 shows an interesting experiment you can do yourself: Hold a pair of 3D viewing glasses with circular polarization in front of a mirror and take a picture through one of the lenses. You can see that the light passing through the left lens, reflecting off the mirror, and then passing through the same lens again gets totally attenuated. In contrast, the light passing through the left lens, reflecting off the mirror, and then passing through the right lens is transmitted without being attenuated. If 3D glasses with linear polarization filters were used for this experiment instead, the light would pass through the lenses at half of its original intensity (equation 31.30), and the entire image of the camera phone could be seen in the mirror.

FIGURE 31.26 A camera phone takes a picture of its reflection in a mirror through 3D viewing glasses with circular polarization filters. One lens of the glasses polarizes light in a left-circular fashion, and the other polarizes it in a right-circular fashion.

W. Bauer and G. D. Westfall

31.7 Derivation of the Wave Equation

Table 31.1 lists the four equations known as Maxwell's equations in integral form. There are also equivalent differential versions of these equations, which is the way they are usually printed on T-shirts and posters:

$$\vec{\nabla} \cdot \vec{E} = \frac{\rho}{\epsilon_0},$$
$$\vec{\nabla} \times \vec{E} = -\frac{\partial}{\partial t}\vec{B},$$
$$\vec{\nabla} \cdot \vec{B} = 0,$$

and

$$\vec{\nabla} \times \vec{B} = \epsilon_0 \mu_0 \frac{\partial}{\partial t}\vec{E} + \mu_0 \vec{j},$$

where ρ is the charge density (charge q per unit volume) and $\vec{j}$ is the current density. In vacuum and in the absence of charges, both are zero; $\rho = 0$ and $\vec{j} = 0$. The symbol $\vec{\nabla}$ is the gradient operator, which represents the vector with the partial derivatives in each spatial direction. In Cartesian coordinates, it is $\vec{\nabla} = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$.

In Section 31.2, we saw that electromagnetic waves as described by equation 31.8 are valid solutions to all the Maxwell equations in vacuum. However, strictly speaking, we have not yet written the wave equation that the electric field and the magnetic field obey. Now, with the aid of the differential form of Maxwell's equations, we can derive the wave equation for the electric field, which is

$$\frac{\partial^2}{\partial t^2}\overrightarrow{E} - c^2\nabla^2\overrightarrow{E} = 0. \tag{31.32}$$

The wave equation for the magnetic field is

$$\frac{\partial^2}{\partial t^2}\overrightarrow{B} - c^2\nabla^2\overrightarrow{B} = 0. \tag{31.33}$$

DERIVATION 31.1 Wave Equation for the Electric Field in Vacuum

To derive the wave equation for the electric field in vacuum, we take the vector product of the second Maxwell equation and the gradient operator, $\vec{\nabla}$:

$$\vec{\nabla} \times \vec{\nabla} \times \vec{E} = -\vec{\nabla} \times \frac{\partial}{\partial t} \vec{B}. \qquad \textbf{(i)}$$

On the right-hand side of equation (i), we can interchange the order of the time derivative and the spatial derivative:

$$-\vec{\nabla} \times \frac{\partial}{\partial t} \vec{B} = -\frac{\partial}{\partial t} \left(\vec{\nabla} \times \vec{B} \right) = -\frac{\partial}{\partial t} \left(\in_0 \mu_0 \frac{\partial \vec{E}}{\partial t} \right)$$

The second step of this transformation makes use of the third Maxwell equation with $\vec{j} = 0$, which is appropriate in vacuum. The left-hand side of equation (i) is a double vector product. Chapter 1 introduced the BAC-CAB rule for double vector products: $\vec{A} \times \left(\vec{B} \times \vec{C} \right) = \vec{B} \left(\vec{A} \cdot \vec{C} \right) - \vec{C} \left(\vec{A} \cdot \vec{B} \right)$. Applying this rule, we find

$$\vec{\nabla} \times \vec{\nabla} \times \vec{E} = \vec{\nabla} \left(\vec{\nabla} \cdot \vec{E} \right) - \nabla^2 \vec{E} = -\nabla^2 \vec{E}, \qquad \textbf{(iii)}$$

where the first Maxwell equation $\left(\text{in vacuum: } \vec{\nabla} \cdot \vec{E} = 0\right)$ is used in the second step. The symbol ∇^2 is the scalar product of the gradient operator with itself: $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$. If we substitute from equations (ii) and (iii) into equation (i) and use the fact that the speed of light is $c = 1/\sqrt{\mu_0 \epsilon_0}$ (equation 31.20) we obtain the desired wave equation:

$$\frac{\partial^2}{\partial t^2}\vec{E} - \frac{1}{\epsilon_0 \mu_0}\nabla^2 \vec{E} = \frac{\partial^2}{\partial t^2}\vec{E} - c^2 \nabla^2 \vec{E} = 0.$$

This implies that electromagnetic waves moving at the speed of light are indeed a solution of Maxwell's equations, as discussed (but not exactly proven) in Section 31.2.

Self-Test Opportunity 31.4

Derive the wave equation for the magnetic field (equation 31.33) in the same way as Derivation 31.1 handles the wave equation for the electric field.

Self-Test Opportunity 31.5

Show that $\vec{E}\left(\vec{r}, t\right) = E_{\text{max}} \sin(kx - \omega t)\hat{y}$ and $\vec{B}\left(\vec{r}, t\right) = B_{\text{max}} \sin(kx - \omega t)\hat{z}$ are indeed solutions of the wave equation for the electric and magnetic fields.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- When a capacitor is being charged, a displacement current can be visualized between the plates, given by $i_{\mathrm{d}} = \epsilon_0 d\Phi_E/dt$, where Φ_E is the electric flux.
- Maxwell's equations describe how electrical charges, currents, electric fields, and magnetic fields affect each other, forming a unified theory of electromagnetism.
  - Gauss's Law for Electric Fields, $\oiint \vec{E} \bullet d\vec{A} = q_{\mathrm{enc}}/\epsilon_0$, relates the net electric flux through a closed surface to the net enclosed electric charge.
  - Gauss's Law for Magnetic Fields, $\oiint \vec{B} \bullet d\vec{A} = 0$, states that the net magnetic flux through any closed surface is zero.
  - Faraday's Law of Induction, $\oint \vec{E} \bullet d\vec{s} = -d\Phi_B/dt$, relates the induced electric field to the changing magnetic flux.
  - The Maxwell-Ampere Law, $\oint \vec{B} \bullet d\vec{s} = \mu_0 \epsilon_0 d\Phi_E/dt + \mu_0 i_{\mathrm{enc}}$, relates the induced magnetic field to the changing electric flux and to the current.
- For an electromagnetic wave traveling in the positive x-direction, the electric and magnetic fields can be described by $\vec{E}\left(\vec{r}, t\right) = E_{\max} \sin(\kappa x - \omega t)\hat{y}$ and $\vec{B}\left(\vec{r}, t\right) = B_{\max} \sin(\kappa x - \omega t)\hat{z}$, where $\kappa = 2\pi/\lambda$ is the wave number and $\omega = 2\pi f$ is the angular frequency.
- The magnitudes of the electric and magnetic fields of an electromagnetic wave at any fixed time and place are

related by the speed of light, $E = cB$.

- The speed of light can be related to the two basic electromagnetic constants: $c = 1/\sqrt{\mu_0 \epsilon_0}$.
- The instantaneous power per unit area carried by an electromagnetic wave is the magnitude of the Poynting vector, $S = [1/(c\mu_0)]E^2$, where E is the magnitude of the electric field.
- The intensity of an electromagnetic wave is defined as the average power per unit area carried by the wave, $I = S_{\text{ave}} = [1/(c\mu_0)]E_{\text{rms}}^2$, where E_{rms} is the root-mean-square magnitude of the electric field.
- For an electromagnetic wave, the energy density carried by the electric field is $u_E = \frac{1}{2}\epsilon_0 E^2$, and the energy density carried by the magnetic field is $u_B = [1/(2\mu_0)]B^2$. For any such wave, $u_E = u_B$.
- The radiation pressure exerted by electromagnetic waves of intensity I is given by $p_{\text{r}} = I/c$ if the electromagnetic waves are totally absorbed or by $p_{\text{r}} = 2I/c$ if the waves are perfectly reflected.
- The polarization of an electromagnetic wave is given by the direction of the electric field vector.
- The intensity of unpolarized light that has passed through a polarizer is $I = I_0/2$, where I_0 is the intensity of the unpolarized light incident on the polarizer.
- The intensity of polarized light that has passed through a polarizer is $I = I_0 \cos^2\theta$, where I_0 is the intensity of the polarized light incident on the polarizer and θ is the angle between the polarization of the incident polarized light and the polarizing angle of the polarizer.

ANSWERS TO SELF-TEST OPPORTUNITIES

31.1 $t = \dfrac{d}{c} = \dfrac{8.30 \cdot 10^{16}\ \text{m}}{3.00 \cdot 10^{8}\ \text{m/s}} = 2.77 \cdot 10^{8}\text{s} = 8.77\ \text{yr}.$

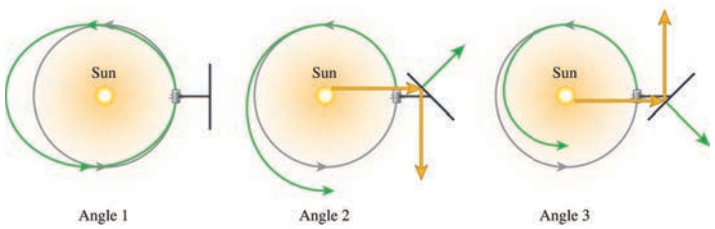
31.2 $c = \lambda f \Rightarrow \lambda = \dfrac{c}{f}$

$$\lambda_{\text{FM}} = \frac{3.00 \cdot 10^{8}\ \text{m}}{90.5 \cdot 10^{6}\ \text{Hz}} = 3.31\ \text{m}$$

$$\lambda_{\text{AM}} = \frac{3.00 \cdot 10^{8}\ \text{m}}{870 \cdot 10^{3}\ \text{Hz}} = 345\ \text{m}.$$

31.3 Deployment angle 1 will produce an elliptical orbit with the Sun at one focus. The force from radiation pressure depends on the inverse square of the distance, just as the force of gravity does. Thus, the orbit will become an ellipse, just as if the mass of the Sun or the mass of the object were suddenly reduced slightly. Because the force is perpendicular to the velocity of the satellite, the energy of the satellite is not affected.

Deployment angle 2 will result in a growing orbit. The resulting force from the reflected light produces a component of force that is in the same direction as the velocity of the spacecraft. Thus, the spacecraft gains energy, and the radius of the orbit increases. Note that the speed of the spacecraft decreases but its total energy increases.



Deployment angle 3 will result in a shrinking orbit. The resulting force from the reflected light produces a component of force that is

in the opposite direction from the velocity of the spacecraft. Thus, the spacecraft loses energy, and the radius of the orbit decreases. Note that the speed of the spacecraft increases but its total energy decreases.

31.4 Take the vector product of the gradient operator $\vec{\nabla}$ and the fourth Maxwell equation: $\vec{\nabla} \times \vec{\nabla} \times \vec{B} = \epsilon_0 \mu_0 \vec{\nabla} \times \frac{\partial}{\partial t} \vec{E}$.

The right-hand side of this equation is

$$\varepsilon_0 \mu_0 \vec{\nabla} \times \frac{\partial}{\partial t} \vec{E} = \varepsilon_0 \mu_0 \frac{\partial}{\partial t} \left(\vec{\nabla} \times \vec{E} \right) = \varepsilon_0 \mu_0 \frac{\partial}{\partial t} \left(-\frac{\partial \vec{B}}{\partial t} \right) =$$

The left-hand side is $\vec{\nabla} \times \vec{\nabla} \times \vec{B} = \vec{\nabla} \left(\vec{\nabla} \cdot \vec{B} \right) - \nabla^2 \vec{B} = -\nabla^2 \vec{B}$.

31.5 $\frac{\partial^2}{\partial t^2} \sin(\kappa x - \omega t) = -\omega^2 \sin(\kappa x - \omega t)$

and

$$\frac{\partial^2}{\partial x^2} \sin(\kappa x - \omega t) = -\kappa^2 \sin(\kappa x - \omega t).$$

Thus, this function is a solution for $c = \omega / \kappa$.

PROBLEM-SOLVING GUIDELINES

1. The same basic relationships that characterize any waves apply to electromagnetic waves. Remember that $c = \lambda f$ and $\omega = c\kappa$, where c is the speed of an electromagnetic wave. Review Chapter 15 if necessary.

2. It is often helpful to draw a diagram showing the direction of the wave motion and the orientation of both the electric and magnetic fields. Remember the relationships between $\vec{E}$ and $\vec{B}$ for both magnitude and direction, including $E/B = (\mu_0 \varepsilon_0)^{-1/2} = c$ for electromagnetic waves.

MULTIPLE-CHOICE QUESTIONS

31.1 Which of the following phenomena can be observed for electromagnetic waves but not for sound waves?

a) interference

b) diffraction

c) polarization

d) absorption

e) scattering

31.2 Which of the following statements concerning electromagnetic waves are incorrect? (Select all that apply.)

a) Electromagnetic waves in vacuum travel at the speed of light.

b) The magnitudes of the electric field and the magnetic field are equal.

c) Only the electric field vector is perpendicular to the direction of the wave's propagation.

d) Both the electric field vector and the magnetic field vector are perpendicular to the direction of propagation.

e) An electromagnetic wave carries energy only when $E = B$.

31.3 The international radio station Voice of Slobbovia announces that it is "transmitting to North America on the 49-meter band." Which frequency is the station transmitting on?

a) 820 kHz

b) 6.12 MHz

c) 91.7 MHz

d) The information given tells nothing about the frequency.

31.4 Which of the following exerts the largest amount of radiation pressure?

a) a 1-mW laser pointer on a 2-mm-diameter spot 1 m away

b) a 200-W light bulb on a 4-mm-diameter spot 10 m away

c) a 100-W light bulb on a 2-mm-diameter spot 4 m away

d) a 200-W light bulb on a 2-mm-diameter spot 5 m away

e) All of the above exert the same pressure.

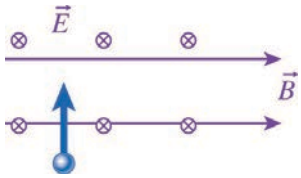
31.5 What is the direction of the net force on the moving positive charge in the figure?

a) into the page

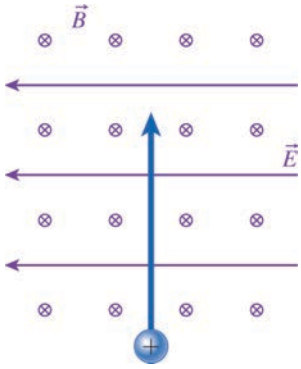
b) toward the right

c) out of the page

d) toward the left



31.6 A proton moves perpendicularly to crossed electric and magnetic fields as shown in the figure. What is the direction of the net force on the proton?



a) toward the left

b) toward the right

c) into the page

d) out of the page

31.7 It is speculated that isolated magnetic "charges" (magnetic monopoles) may exist somewhere in the universe. Which of Maxwell's equations, (1) Gauss's Law for Electric Fields, (2) Gauss's Law for Magnetic Fields, (3) Faraday's Law of Induction, and/or (4) the Maxwell-Ampere Law, would be altered by the existence of magnetic monopoles?

a) only (2)

b) (1) and (2)

c) (2) and (3)

d) only (3)

31.8 According to Gauss's Law for Magnetic Fields, all magnetic field lines form a complete loop. Therefore, the direction of the magnetic field $\vec{B}$ points from _____ pole to _____ pole outside of an ordinary bar magnet and from _____ pole to _____ pole inside the magnet.

a) north, south, north, south

b) north, south, south, north

c) south, north, south, north

d) south, north, north, south

31.9 Unpolarized light with intensity $I_{\text{in}} = 1.87\ \text{W/m}^2$ passes through two polarizers. The emerging polarized light has intensity $I_{\text{out}} = 0.383\ \text{W/m}^2$. What is the angle between the two polarizers?

a) 23.9°

b) 34.6°

c) 50.2°

d) 72.7°

e) 88.9°

31.10 The average intensity of sunlight at the Earth's surface is approximately $1400\ \text{W/m}^2$, if the Sun is directly overhead. The average distance between the Earth and the Sun is $1.50 \cdot 10^{11}\text{m}$. What is the average power emitted by the Sun?

a) $99.9 \cdot 10^{25}$ W

b) $4.0 \cdot 10^{26}$ W

c) $6.3 \cdot 10^{27}$ W

d) $4.3 \cdot 10^{28}$ W

e) $5.9 \cdot 10^{29}$ W

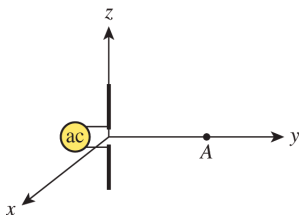
CONCEPTUAL QUESTIONS

31.11 In a polarized light experiment, a setup similar to the one in Figure 31.23 is used. Unpolarized light with intensity I_0 is incident on polarizer 1. Polarizers 1 and 3 are crossed (at a 90° angle), and their orientations are fixed during the experiment. Initially, polarizer 2 has its polarizing angle at 45°. Then, at time $t = 0$, polarizer 2 starts to rotate with angular velocity ω about the direction of propagation of light in a clockwise direction as viewed by an observer looking toward the light source. A photodiode is used to monitor the intensity of the light emerging from polarizer 3.

a) Determine an expression for this intensity as a function of time.

b) How would the expression from part (a) change if polarizer 2 were rotated about an axis parallel to the direction of propagation of the light but displaced by a distance $d < R$, where R is the radius of the polarizer?

31.12 A dipole antenna is located at the origin with its axis along the z-axis. As electric current oscillates up and down the antenna, polarized electromagnetic radiation travels away from the antenna along the positive y-axis. What are the possible directions of electric and magnetic fields at point A on the y-axis? Explain.



31.13 Does the information in Section 31.6 affect the answer to Example 31.2 regarding the root-mean-square magnitude of electric field at the Earth's surface from the Sun?

31.14 Maxwell's equations predict that there are no magnetic monopoles. If these monopoles existed, how would the motion of

charged particles change as they approached such a monopole?

31.15 If two communication signals were sent at the same time to the Moon, one via radio waves and one via visible light, which one would arrive at the Moon first?

31.16 Show that Ampere's Law is not necessarily consistent if the surface through which the flux is to be calculated is a closed surface, but that the Maxwell-Ampere Law always is. (Hence, Maxwell's introduction of his law of induction and the displacement current are not optional; they are logically necessary.) Show also that Faraday's Law of Induction does not suffer from this consistency problem.

31.17 Maxwell's equations and Newton's laws of motion are mutually inconsistent; the great edifice of classical physics is fatally flawed. Explain why.

31.18 Practically everyone who has studied the electromagnetic spectrum has wondered how the world would appear if we could see over a range of frequencies comparable to the ten octaves over which we can hear rather than the less than one octave over which we can see. (An octave refers to a factor of 2 in frequency.) But this is practically impossible. Why?

31.19 Isotropic electromagnetic waves expand uniformly outward in all directions in three dimensions. Electromagnetic waves from a small, isotropic source are not plane waves, which have constant maximum amplitudes.

a) How does the maximum amplitude of the electric field of radiation from a small, isotropic source vary with distance from the source?

b) Compare this with the electrostatic field of a point charge.

31.20 A pair of sunglasses is held in front of a flat-panel computer monitor (which is on) so that the lenses are always parallel to the display. As the lenses are rotated, it is noticed that the intensity of light coming from the display and passing through the lenses is varying. Why?

31.21 Two polarizing filters are crossed at 90°, so when light is shined from behind the pair of filters, no light passes through. A

third filter is inserted between the two, initially aligned with one of them. Describe what happens as the intermediate filter is rotated through an angle of 360°.

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One •• indicate increasing level of problem difficulty.

Section 31.1

31.22 An electric field of magnitude 200.0 V/m is directed perpendicular to a circular planar surface with radius 6.00 cm. If the electric field increases at a rate of 10.0 V/(m s), determine the magnitude and the direction of the magnetic field at a radial distance 10.0 cm away from the center of the circular area.

•**31.23** A wire of radius 1.00 mm carries a current of 20.0 A. The wire is connected to a parallel plate capacitor with circular plates of radius $R = 4.00$ cm and a separation between the plates of $s = 2.00$ mm. What is the magnitude of the magnetic field due to the changing electric field at a point that is a radial distance of $r = 1.00$ cm from the center of the parallel plates? Neglect edge effects.

•**31.24** The current flowing in a solenoid that is 20.0 cm long and has a radius of 2.00 cm and 500. turns decreases from 3.00 A to 1.00 A in 0.100 s. Determine the magnitude of the induced electric field inside the solenoid 1.00 cm from its center.

31.25 A parallel plate capacitor has air between disk-shaped plates of radius 4.00 mm that are coaxial and 1.00 mm apart. Charge is being accumulated on the plates of the capacitor. What is the displacement current between the plates at an instant when the rate of charge accumulation on the plates is 10.0 μC/s?

•**31.26** A parallel plate capacitor has circular plates of radius 10.0 cm that are separated by a distance of 5.00 mm. The potential across the capacitor is increased at a constant rate of 1.20 kV/s. Determine the magnitude of the magnetic field between the plates at a distance $r = 4.00$ cm from the center.

•**31.27** The voltage across a cylindrical conductor of radius r, length L, and resistance R varies with time. The time-varying voltage causes a time-varying current, i, to flow in the cylinder. Show that the displacement current equals $\varepsilon_0 \rho di/dt$, where ρ is the resistivity of the conductor.

Section 31.2

31.28 The amplitude of the electric field of an electromagnetic wave is 250. V/m. What is the amplitude of the magnetic field of the electromagnetic wave?

31.29 Determine the distance in feet that light can travel in vacuum during 1.00 ns.

31.30 How long does it take light to travel from the Moon to the Earth? From the Sun to the Earth? From Jupiter to the Earth?

31.31 Alice made a telephone call from her home telephone in New York to her fiancé stationed in Baghdad, about 10,000 km away, and the signal was carried on a telephone cable. The following day, Alice called her fiancé again from work using her cell phone, and the signal was transmitted via a satellite 36,000 km above the Earth's surface, halfway between New York and Baghdad. Estimate the time taken for the signals sent by (a) the telephone cable and (b) via the satellite to reach Baghdad, assuming that the signal speed in both cases is the same as the speed of light, *c*. Would there be a noticeable delay in either case?

•**31.32** Electric and magnetic fields in many materials can be analyzed using the relationships for these fields in vacuum, but substituting relative values of the permittivity and the permeability, $\in = \kappa \in_0$ and $\mu = \kappa_m \mu_0$, for their vacuum values, where κ is the dielectric constant and κ_m the relative permeability of the material. Calculate the ratio of the speed of electromagnetic waves in vacuum to their speed in such a material.

Section 31.3

31.33 The wavelength range for visible light is 400 nm to 700 nm (see Figure 31.10) in air. What is the frequency range of visible light?

31.34 The antenna of a cell phone is a straight rod 8.0 cm long. Calculate the operating frequency of the signal from this phone, assuming that the antenna length is $\frac{1}{4}$ of the wavelength of the signal.

•**31.35** Suppose an RLC circuit in resonance is used to produce a radio wave of wavelength 150 m. If the circuit has a 2.0-pF capacitor, what size inductor is used?

•**31.36** Three FM radio stations covering the same geographical area broadcast at frequencies 91.1, 91.3, and 91.5 MHz, respectively. What is the maximum allowable wavelength width of the band-pass filter in a radio receiver such that the FM station 91.3 can be played free of interference from FM 91.1 or FM 91.5? Use $c = 3.00 \cdot 10^8 \text{m/s}$, and calculate the wavelength to an uncertainty of 1 mm.

Section 31.4

31.37 A monochromatic point source of light emits 1.5 W of electromagnetic power uniformly in all directions. Find the Poynting vector at a point situated at each of the following locations:

a) 0.30 m from the source

b) 0.32 m from the source

c) 1.00 m from the source

31.38 Consider an electron in a hydrogen atom, which is 0.050 nm from the proton in the nucleus.

a) What electric field does the electron experience?

b) In order to produce an electric field whose root-mean-square magnitude is the same as that of the field in part (a), what intensity must a laser light have?

31.39 A 3.00-kW carbon dioxide laser is used in laser welding. If the beam is 1.00 mm in diameter, what is the amplitude of the electric field in the beam?

31.40 Suppose that charges on a dipole antenna oscillate slowly at a rate of 1.00 cycle/s, and the antenna radiates electromagnetic waves in a region of space. If someone measured the time-varying magnetic field in the region and found its maximum to be 1.00 mT, what would be the maximum electric field, E, in the region, in units of volts per meter? What is the period of the charge oscillation? What is the magnitude of the Poynting vector?

31.41 Calculate the average value of the Poynting vector, S_{ave}, for an electromagnetic wave having an electric field of amplitude 100. V/m.

a) What is the average energy density of this wave in J/m^3?

b) How large is the amplitude of the magnetic field?

•**31.42** The most intense beam of light that can propagate through dry air must have an electric field whose maximum amplitude is no greater than the breakdown value for air: $E_{\text{max}}^{\text{air}} = 3.0 \cdot 10^6\ \text{V/m}$, assuming that this value is unaffected by the frequency of the wave.

a) Calculate the maximum amplitude the magnetic field of this wave can have.

b) Calculate the intensity of this wave.

c) What happens to a wave more intense than this?

•• **31.43** A continuous-wave (cw) argon-ion laser beam has an average power of 10.0 W and a beam diameter of 1.00 mm. Assume that the intensity of the beam is the same throughout the cross section of the beam (which is not true, as the actual distribution of intensity is a Gaussian function).

a) Calculate the intensity of the laser beam. Compare this with the average intensity of sunlight at Earth's surface $\left(1400.\ \mathrm{W/m^2}\right)$.

b) Find the root-mean-square electric field in the laser beam.

c) Find the average value of the Poynting vector over time.

d) If the wavelength of the laser beam is 514.5 nm in vacuum, write an expression for the instantaneous Poynting vector, where the instantaneous Poynting vector is zero at $t = 0$ and $x = 0$.

e) Calculate the root-mean-square value of the magnetic field in the laser beam.

•• **31.44** A voltage, V, is applied across a cylindrical conductor of radius r, length L, and resistance R. As a result, a current, i, is flowing through the conductor, which gives rise to a magnetic field, B. The conductor is placed along the y-axis, and the current is flowing in the positive y-direction. Assume that the electric field is uniform throughout the conductor.

a) Find the magnitude and the direction of the Poynting vector at the surface of the conductor of the static electric and magnetic fields.

b) Show that $\int \vec{S} \cdot d\vec{A} = i^2 R$.

Section 31.5

31.45 Radiation from the Sun reaches the Earth at a rate of $1.40\,\mathrm{kW/m^2}$ above the atmosphere and at a rate of $1.00\,\mathrm{kW/m^2}$ on an ocean beach.

a) Calculate the maximum values of E and B above the atmosphere.

b) Find the pressure and the force exerted by the radiation on a person lying flat on the beach who has an area of $0.750\,\mathrm{m^2}$ exposed to the Sun.

31.46 Scientists have proposed using the radiation pressure of sunlight for travel to other planets in the Solar System. If the intensity of the electromagnetic radiation produced by the Sun is about $1.40\,\mathrm{kW/m^2}$ near the Earth, what size would a sail have to be to accelerate a spaceship with a mass of 10.0 metric tons at $1.00\,\mathrm{m/s^2}$?

a) Assume that the sail absorbs all the incident radiation.

b) Assume that the sail perfectly reflects all the incident radiation.

31.47 A solar sail is a giant circle (with a radius $R = 10.0\,\mathrm{km}$) made of a material that is perfectly reflecting on one side and totally absorbing on the other side. In deep space, away from other sources of light, the cosmic microwave background will provide the primary source of radiation incident on the sail. Assuming that this radiation is that of an ideal black body at $T = 2.725\,\mathrm{K}$, calculate the net force on the sail due to its reflection and absorption. Also assume that any heat transferred to the sail will be conducted away, and that the photons are incident perpendicular to the surface of the sail.

•**31.48** Two astronauts are at rest in outer space, one 20.0 m from the Space Shuttle and the other 40.0 m from the shuttle. Using a 100.0-W laser, the astronaut located 40.0 m away from the shuttle decides to propel the other astronaut toward the Space Shuttle. He focuses the laser on a piece of totally reflecting fabric on her space suit. If her total mass with equipment is 100.0 kg, how long will it take her to reach the Space Shuttle?

•**31.49** A laser that produces a spot of light that is 1.00 mm in diameter is shone perpendicularly on the center of a thin, perfectly reflecting circular (2.00 mm in diameter) aluminum plate mounted vertically on a flat piece of cork that floats on the surface of the water in a large beaker. The mass of this "sailboat" is 0.100 g, and it travels 2.00 mm in 63.0 s. Assuming that the laser power is constant in the region where the sailboat is located during its motion, what is the power of the laser? (Neglect air resistance and the viscosity of water.)

•**31.50** A tiny particle of density 2000. kg/m^3 is at the same distance from the Sun as the Earth is $\left(1.50 \cdot 10^{11}\ \text{m}\right)$. Assume that the particle is spherical and perfectly reflecting. What would its radius have to be for the outward radiation pressure on it to be 1.00% of the inward gravitational attraction of the Sun? (Take the Sun's mass to be $2.00 \cdot 10^{30}$ kg.)

•**31.51** Silica aerogel, an extremely porous, thermally insulating material made of silica, has a density of 1.00 mg/cm^3. A thin circular slice of aerogel has a diameter of 2.00 mm and a thickness of 0.10 mm.

a) What is the weight of the aerogel slice (in newtons)?

b) What are the intensity and the radiation pressure of a 5.00-mW laser beam of diameter 2.00 mm on the sample?

c) How many 5.00-mW lasers with a beam diameter of 2.00 mm would be needed to make the slice float in the Earth's gravitational field? Use $g = 9.81\ \text{m/s}^2$.

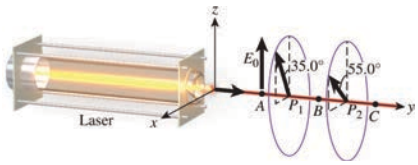
Section 31.6

31.52 Two polarizers are out of alignment by 30.0°. If light of intensity $1.00\ \mathrm{W/m^2}$ and initially polarized halfway between the polarizing angles of the two filters passes through both filters, what is the intensity of the transmitted light?

31.53 A 10.0-mW vertically polarized laser beam passes through a polarizer whose polarizing angle is 30.0°. from the horizontal. What is the power of the laser beam when it emerges from the polarizer?

•**31.54** Unpolarized light of intensity I_0 is incident on a series of five polarizers, with the polarization direction of each rotated 10.0° from that of the preceding one. What fraction of the incident light will pass through the series?

•**31.55** A laser produces light that is polarized in the vertical direction. The light travels in the positive y-direction and passes through two polarizers, which have polarizing angles of 35.0° and 55.0° from the vertical, as shown in the figure. The laser beam is collimated (neither converging nor expanding), has a circular cross section with a diameter of 1.00 mm, and has an average power of 15.0 mW at point A. At point C, what are the amplitudes of the electric and magnetic fields, and what is the intensity of the laser light?



Additional Exercises

31.56 A laser beam takes 50.0 ms to be reflected back from a totally reflecting sail on a spacecraft. How far away is the sail?

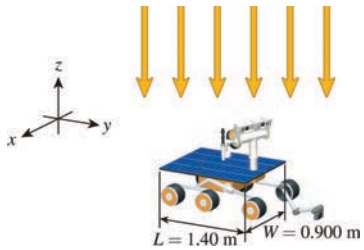
31.57 A house with a south-facing roof has photovoltaic panels on the roof. The photovoltaic panels have an efficiency of 10.0% and occupy an area with dimensions 3.00 m by 8.00 m. The average solar radiation incident on the panels is 300. $\mathrm{W/m^2}$, averaged over all conditions for a year. How many kilowatt-hours of electricity will the solar panels generate in a 30-day month?

31.58 What is the radiation pressure due to Betelgeuse (which has a luminosity, or power output, 10,000 times that of the Sun) at a distance from it equal to that of Uranus's orbit from the Sun?

31.59 A 200.-W laser produces a beam with a cross-sectional area of 1.00 $\mathrm{mm^2}$ and a wavelength of 628 m. What is the amplitude of the electric field in the beam?

31.60 What is the wavelength of the electromagnetic waves used for cell phone communications at 848.97 MHz?

31.61 As shown in the figure, sunlight is coming straight down (negative z-direction) on a solar panel (of length $L = 1.40$ m and width $W = 0.900$ m) on the Mars rover *Spirit*. The amplitude of the electric field in the solar radiation is 673 V/m and is uniform (the radiation has the same amplitude everywhere). If the solar panel converts solar radiation to electrical power with an efficiency of 18.0%, how much average power can the panel generate?



31.62 A 14.9-μF capacitor, a 24.3-kΩ resistor, a switch, and a 25.0-V battery are connected in series. What is the rate of change of the electric field between the plates of the capacitor at $t = 0.3621$ s after the switch is closed? The area of the plates is 1.00 $\mathrm{cm^2}$.

31.63 A focused 300-W spotlight delivers 40% of its light within a circular area with a diameter of 2 m. What is the root-mean-square electric field in this illuminated area?

31.64 What is the electric field amplitude of an electromagnetic wave whose magnetic field amplitude is $5.00 \cdot 10^{-3}$ T?

31.65 What is the distance between successive heating antinodes in a microwave oven's cavity? A microwave oven typically operates at a frequency of 2.4 GHz.

31.66 The solar constant measured by Earth satellites is roughly $1400\ \mathrm{W/m^2}$.

a) Find the maximum electric field of the electromagnetic radiation from the Sun.

b) Find the maximum magnetic field of these electromagnetic waves.

•**31.67** The peak electric field at a distance of 2.25 m from a light bulb is 21.2 V/m.

a) What is the peak magnetic field there?

b) What is the power output of the bulb?

•**31.68** If the peak electric field due to a star whose radius is twice that of the Sun is 44.0 V/m at a distance of 15 AU, what is its temperature? Treat the star as a blackbody.

•**31.69** A 5.00-mW laser pointer has a beam diameter of 2.00 mm.

a) What is the root-mean-square value of the electric field in this laser beam?

b) Calculate the total electromagnetic energy in 1.00 m of this laser beam.

•**31.70** At the surface of the Earth, the Sun delivers an estimated $1.00\ \mathrm{kW/m^2}$ of energy. Suppose sunlight hits a 10.0 m by 30.0 m roof at an angle of 90.0°.

a) Estimate the total power incident on the roof.

b) Find the radiation pressure on the roof.

•**31.71** The National Ignition Facility has the most powerful laser in the world; it uses 192 beams to aim 500. TW of power at a spherical pellet of diameter 2.00 mm. How fast would a pellet of density 2.00 $\mathrm{g/cm^3}$ accelerate if only one of the laser beams hits it for 1.00 ns and 2.00% of the light is absorbed?

•**31.72** A resistor consists of a solid cylinder of radius r and length L. The resistor has resistance R and is carrying current i. Use the Poynting vector to calculate the power radiated out of the surface of the resistor.

•**31.73** A radio tower is transmitting 30.0 kW of power equally in all directions. Assume that the radio waves that hit the Earth are reflected.

a) What is the magnitude of the Poynting vector at a distance of 12.0 km from the tower?

b) What is the root-mean-square value of the electric force on an electron at this location?

•**31.74** Quantum theory says that electromagnetic waves actually consist of discrete packets—photons—each with energy $E = \hbar\omega$, where $\hbar = 1.054572 \cdot 10^{-34}$ J s is Planck's reduced constant and ω is the angular frequency of the wave.

a) Find the momentum of a photon.

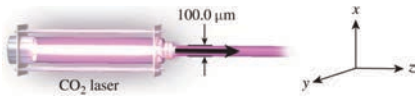
b) Find the magnitude of angular momentum of a photon. Photons are *circularly polarized;* that is, they are described by a superposition of two plane-polarized waves with equal field amplitudes, equal frequencies, and perpendicular polarizations, one-quarter of a cycle (90° or $\pi/2$ rad) out of phase, so the electric and magnetic field vectors at any fixed point rotate in a circle with the angular frequency of the waves. It can be shown that a circularly polarized wave of energy U and angular frequency ω has an angular momentum of magnitude $L = U/\omega$. (The direction of the angular momentum is given by the thumb of the right hand, when the fingers are curled in the direction in which the field vectors circulate.)

c) The ratio of the angular momentum of a particle to $\hbar$ is its spin quantum number. Determine the spin quantum number of the

photon.

•31.75 A microwave operates at 250. W. Assuming that the waves emerge from a point source emitter on one side of the oven, how long does it take to melt an ice cube 2.00 cm on a side that is 10.0 cm away from the emitter if 10.0% of the photons that strike the cube are absorbed by it? How many photons of wavelength 10.0 cm hit the ice cube per second? Assume a cube density of $0.960\ \mathrm{g/cm^3}$

•31.76 An industrial carbon dioxide laser produces a beam of radiation with average power of 6.00 kW at a wavelength of 10.6 μm. Such a laser can be used to cut steel up to 25 mm thick. The laser light is polarized in the *x*-direction, travels in the positive *z*-direction, and is collimated (neither diverging or converging) at a *constant* diameter of 100.0 μm. Write the equations for the laser light's electric and magnetic fields as a function of time and of position *z* along the beam. Recall that $\vec{E}$ and $\vec{B}$ are vectors. Leave the overall phase unspecified, but be sure to check the relative phase between $\vec{E}$ and $\vec{B}$.



MULTI-VERSION EXERCISES

31.77 During the testing of a new light bulb, a sensor is placed 31.9 cm from the bulb. It records an intensity of 182.9 $\mathrm{W/m^2}$ for the radiation emitted by the bulb. What is the root-mean-square value of the electric field at the sensor's location?

31.78 During the testing of a new light bulb, a sensor is placed 42.1 cm from the bulb. It records an intensity of 191.4 $\mathrm{W/m^2}$ for the radiation emitted by the bulb. What is the root-mean-square value of the magnetic field at the sensor's location?

31.79 During the testing of a new light bulb, a sensor is placed 52.5 cm from the bulb. It records a root-mean-square value of $9.142 \cdot 10^{-7}$ T for the magnetic field of the radiation emitted by the bulb. What is the intensity of that radiation at the sensor's location?

31.80 During the testing of a new light bulb, a sensor is placed 17.7 cm from the bulb. It records a root-mean-square value of 279.9 V/m for the electric field of the radiation emitted from the bulb. What is the intensity of that radiation at the sensor's location?

31.81 To visually examine sunspots through a telescope, astronomers have to reduce the intensity of the sunlight to avoid harming their retinas. They accomplish this intensity reduction by mounting two polarizers on the telescope. The first polarizer has a polarizing angle of 28.1° relative to the horizontal, and the second has a polarizing angle of 88.6°. By what fraction is the intensity of the incident sunlight reduced by the polarizers?

31.82 To visually examine sunspots through a telescope, astronomers have to reduce the intensity of the sunlight to avoid harming their retinas. They accomplish this intensity reduction by mounting two polarizers on the telescope. The first polarizer has a

polarizing angle of 38.3° relative to the horizontal. If the astronomers want to reduce the intensity of the sunlight by a factor of 0.7584, what polarizing angle should the second polarizer have with the horizontal? Assume that this angle is greater than that of the first polarizer.

31.83 To visually examine sunspots through a telescope, astronomers have to reduce the intensity of the sunlight to avoid harming their retinas. They accomplish this intensity reduction by mounting two linear polarizers on the telescope. The second polarizer has a polarizing angle of 110.6° relative to the horizontal. If the astronomers want to reduce the intensity of the sunlight by a factor of 0.7645, what polarizing angle should the first polarizer have with the horizontal? Assume that this angle is smaller than that of the second polarizer.

The study of light is divided into three fields: geometric optics, wave optics, and quantum optics. In Chapter 31, we learned that light is an electromagnetic wave, and in Chapter 34 we will deal with the wave properties of light. This chapter discusses **geometric optics,** in which light is characterized as rays. Quantum optics makes use of the fact that light is quantized, its energy localized in point particles called *photons* (Chapters 36 and 37).

Rainbows (Figure 32.1) can be seen only when there are water droplets in the air and the Sun is behind the observer. Why is that? The reason has to do with how raindrops reflect and refract light—the two optical processes that are the main subjects of this chapter.

FIGURE 32.1 Primary and secondary rainbows formed by refraction and reflection of light in raindrops over Ka'anapali Beach on Maui, Hawaii.

W. Bauer and G. D. Westfall

We have seen that light is a wave, but in this chapter we will examine systems in which its wavelength is small compared to other physical dimensions of the system. Then we can ignore the wave character of light and consider only how light travels through

air—or glass, or water, or any other transparent medium. It turns out that thinking about light in this way is enough to explain the optics of mirrors, lenses, and other optical devices, including prisms and even rainbows. Later, in Chapter 34, we will examine systems in which the wavelength is not negligibly small and see how that characteristic gives rise to other optical effects.

This chapter primarily considers visible light, but keep in mind that the laws of reflection, refraction, and image formation also apply to other kinds of electromagnetic waves. For instance, many useful properties of radio waves are based on reflection and refraction.

WHAT WE WILL LEARN

- In cases where the wavelength is small compared to other length scales in a physical system, light waves can be modeled by light rays, moving on straight-line trajectories and representing the direction of a propagating light wave.
- The law of reflection states that the angle of incidence is equal to the angle of reflection.
- Mirrors can focus light and produce images governed by the mirror equation, which states that the inverse of the object distance plus the inverse of the image distance equals the inverse of the focal length of the mirror.
- Light is refracted (changes direction) when it is incident on a boundary between two optically transparent media.
- Snell's Law governs refraction at the boundary between different transparent materials. It relates the angles of incident and refracted light rays and the indices of refraction of the two materials.
- When light crosses the boundary between two media, and the index of refraction of the second medium is less than the index of refraction of the first medium, there is a critical angle of incidence above which refraction cannot take place. Instead, the light is totally reflected.
- We will learn to use the laws of geometrical optics for a wide variety of applications, from simple bathroom mirrors to optical fibers in endoscopes to rainbows.

32.1 Light Rays and Shadows

In Chapter 31, we saw that electromagnetic waves spread spherically from a point source. The concentric yellow spheres in Figure 32.2 represent the spreading of spherical **wave fronts** of the light emitted from a light bulb. (A *front* is a locus of points that have the same instantaneous value for the electric field.) The black arrows are the **light rays,** which are perpendicular to the wave fronts at every point in space and point in the direction of propagation of the light. The undulating red lines represent the oscillating electric field.

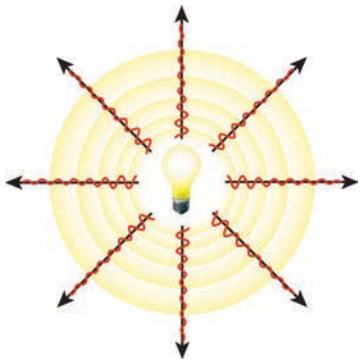

FIGURE 32.2 Light spreading from a source. Yellow: spherical wave fronts; red: oscillating electric field; black: rays.

Light waves far away from their source can be treated as plane waves whose wave fronts are traveling in a straight line (Figure 32.3). These traveling plane waves can be represented by parallel arrows perpendicular to the surface of the planes. In this chapter, we will treat light as a ray traveling in a straight line while in a homogeneous medium. Viewing light as rays will enable us to

analyze and solve a broad range of practical problems, both geometrically and by means of various constructions.

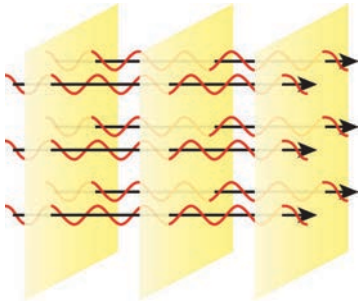

FIGURE 32.3
Planes representing wave fronts of a traveling light wave. The red sinusoidal oscillations represent the oscillating electric or magnetic field. The black arrows are the corresponding light rays, which are always perpendicular to the wave front.

Everyday experience tells us that light travels in a straight line. We cannot easily see that light has a wave structure or a quantum structure. The reason for this is simply that the wavelengths of visible light $(400 - 700\,\text{nm})$ are small compared to the structures that form our everyday experiences. (The few notable exceptions, including soap films, will be discussed in Chapter 34.)

A person standing outside in the bright sunshine sees shadows cast by objects in the sunlight. The edges of the shadows appear reasonably sharp, so the person theorizes that light travels in straight lines and the objects block the light rays from the Sun that strike them. A shadow is created where light is intercepted, while bright areas are created where the unintercepted light rays continue in straight lines and strike the ground or other surface. The shadow is not completely black, because light scatters from

other sources and partially illuminates the shadowed area. And the edge of the shadow is also not completely sharp, because the Sun has a diameter that is not negligible. But still, the creation of shadows lends credibility to the hypothesis of straight-line motion of light.

This observation can be made in a more controlled manner by placing a piece of cardboard containing a small hole in front of a bright projector light bulb (Figure 32.4). This produces a round bright spot on the screen (the image). A smaller hole produces a smaller image on the screen. A larger hole produces a larger image.

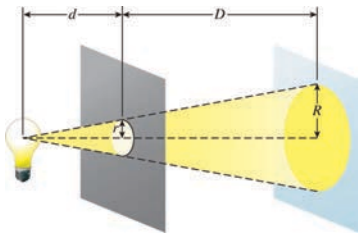

FIGURE 32.4 Light shining through an opening onto a screen.

If the size of the light source is small enough (pointlike), the similar triangles in Figure 32.4 can be used to find the relationship between the size of the hole (r), the size of the image (R), the distance between light source and the hole (d), and the distance between the hole and the screen (D):

$$\frac{r}{d} = \frac{R}{d + D}. \qquad \textbf{(32.1)}$$

This equation is sometimes referred to as the **law of rays.**

SOLVED PROBLEM 32.1 Shadow of a ball

The light from a small light bulb creates a shadow of a ball on a wall. The diameter of the ball is 14.3 cm, and the diameter of the shadow of the ball on the wall is 27.5 cm. The ball is 1.99 m away from the wall.

PROBLEM

How far is the light bulb from the wall?

SOLUTION

THINK

The light bulb is small, which means that we can neglect its size and treat it as a point source. The triangle formed by the light bulb and the ball is similar to the triangle formed by the light bulb and the shadow. The distance from the ball to the wall is given, so we can solve for the distance from the light bulb to the ball, add that distance to the distance of the ball from the wall, and obtain the distance of the light bulb from the wall.

SKETCH

Figure 32.5 shows a sketch of a light bulb casting a shadow of a ball on a wall.

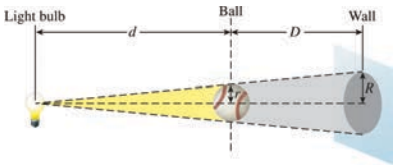

FIGURE 32.5 A light bulb casts a shadow of a ball on a wall

RESEARCH

The triangle formed by the light bulb and the ball is similar to the triangle formed by the light bulb and the shadow. Using

equation 32.1 we can write

$$\frac{r}{d} = \frac{R}{d+D},$$

where r is the radius of the ball, R is the radius of the shadow cast on the wall, d is the distance of the light bulb from the ball, and D is the distance of the ball from the wall.

SIMPLIFY

We can rearrange the law of rays to obtain

$$d + D = \frac{Rd}{r}.$$

Collecting the terms involving the distance from the light bulb to the ball on the left side gives us

$$d\left(1 - \frac{R}{r}\right) = -D.$$

Solving for the distance from the light bulb to the ball leads to

$$d = \frac{D}{\frac{R}{r} - 1} = \frac{rD}{R - r}.$$

The distance of the light bulb from the wall, $d_{\text{light bulb}}$, is then

$$d_{\text{light bulb}} = d + D = \frac{rD}{R - r} + D.$$

CALCULATE

Putting in the numerical values gives us

$$d_{\text{ light bulb}} = \frac{rD}{R-r} + D = \frac{(1.99\text{ m})(0.143\text{ m})}{(0.275\text{ m}) - (0.143\text{ m})} + 1.9$$

ROUND

We report our result to three significant figures:

$$d_{\text{light bulb}} = 4.15\text{ m}.$$

DOUBLE-CHECK

To double-check our result, we calculate the ratio r/d and compare that result with the ratio $R/(d+D)$, which must have the same value according to the law of rays (equation 32.1). We note from above that the value of d, the distance from the bulb to the ball, is 2.16 m. The first ratio is

$$\frac{r}{d} = \frac{0.143\text{ m}}{2.16\text{ m}} = 0.0662.$$

The second ratio is

$$\frac{R}{d+D} = \frac{0.275\text{ m}}{4.15\text{ m}} = 0.0663.$$

These values agree within rounding errors, so our answer seems reasonable.

As a second double-check, we can examine limiting cases and see if they support our result. What happens to our result in the limiting case where the distance d from the light bulb to the ball is large compared to the distance D from the ball to the wall? This is a case similar to sunlight hitting the ball and throwing a shadow. We know that the shadow is approximately the same size as the ball in this case. And the limiting case of our formula $r/d = R/(d+D)$ bears this out, because for $d \gg D$ we see that $r/d = R/(d+D) \approx R/d$, and so $r \approx R$.

What happens in the reverse case, where $d \ll D$, that is, the light bulb is very close to the ball, as compared to the distance

between ball and wall? The size of the shadow diverges. Our formula also shows this limiting case, because in this case $R = (d + D)r/d \approx rD/d \gg r$, that is the radius of the shadow becomes very large relative to the radius of the ball.

Concept Check 32.1

In Solved Problem 32.1, we neglected the size of the light bulb and treated it as a point source. What happens if the light bulb is too large to make this assumption, for example, if it is larger than the baseball?

a) The shadow of the ball will not be sharp but will be fuzzy around the edge.

b) No shadow will be formed.

c) Multiple shadows will be formed.

d) It is impossible to make a general statement about this situation.

Let us finish this introductory discussion of light rays and ray tracing with a very important observation: The direction of the rays is reversible. In the following discussions of reflection off surfaces and refraction at boundaries between different media, light rays will be drawn with an implied direction, emerging from objects and then scattering or encountering a boundary between materials and refracting. But all of the drawings are equally valid if the direction of the rays is reversed. Keep this in mind as we proceed through the following examples and derivations.

32.2 Reflection and Plane Mirrors

Some objects (light bulbs, fires, the Sun, etc.) emit light and are thus primary light sources. Objects that are not primary light sources can be seen because they reflect light. There are two different kinds of reflection, diffuse and specular. In diffuse reflection, light waves hitting the object's surface are scattered randomly. In specular reflection, they are all reflected in the same way. Most objects show diffuse reflection, where the color of the reflected light is a property not just of the wavelength of the incoming light before reflection, but also of the surface properties of the object reflecting the light. The difference between diffuse and specular reflection lies in the roughness of the surface on the scale of the wavelength of the light. For a surface showing specular reflection, the local surface normal vectors (red arrows in Figure 32.6b) are aligned, whereas they are not for a surface showing diffuse reflection (Figure 32.6a).

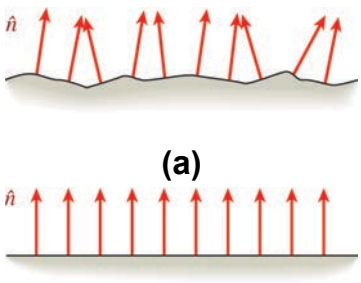

FIGURE 32.6 Orientation of surface normal vectors for a surface showing (a) diffuse reflection and one showing (b) specular reflection.

A **mirror** is a surface that reflects light in specular fashion. Here we will deal only with perfect mirrors. A *perfect mirror* is a mirror that does not absorb any light and that reflects 100% of incident light, independent of the intensity of that light. In Chapter 31 we saw that light is a type of electromagnetic wave. Visible light consists of electromagnetic waves with wavelengths of approximately 400 nm to 700 nm. For a mirror to be considered perfect, it must reflect 100% of the incoming light in at least this range of wavelengths. Mirror perfection is not easily achieved.

Conventional bathroom mirrors consist of a piece of glass with a metal coating on the back side. They are usually sufficient for our purposes, but they are not perfect mirrors. You can see this with the aid of a medicine cabinet with three mirrored doors. Fold out the left and right doors to the point where they are facing each other and look parallel, and then stick your head between them. You will see a huge number of your own reflections, with the light emitted from your head bouncing back and forth many times between the two mirrors until it reaches your eyes. The images formed from light that has undergone multiple reflections are noticeably dimmer (Figure 32.7). The reason is that each reflection absorbs a fraction of the intensity of the incoming light, perhaps on the order of 1%.

FIGURE 32.7 Light reflection between two almost exactly parallel plane mirrors.

W. Bauer and G. D. Westfall

In 1998 Yoel Fink, then a graduate student at MIT, invented the *omnidirectional dielectric mirror*, which can be considered perfect in the sense defined above, with absorption losses of less than 0.0001%. He did this by using many alternating, approximately 1 μm thick, layers of a polymer and a semiconducting glass. While initially developed with a grant from the Defense Advanced Research Projects Agency (DARPA), this technology has been used to create vastly improved laser surgery tools. This is yet another example of how modern advanced physics research continues to lead to stunning technological breakthroughs, even in a field as long-established as geometric optics.

Let's start with flat, plane mirrors. For reflection of light rays incident on the surface of a plane mirror, there is a simple rule, known as the **law of reflection:** The angle of incidence, θ_i, is equal to the angle of reflection, θ_r. These angles are always measured from the surface normal, which is defined to be a line perpendicular to the surface of the plane mirror. In addition, the incident ray, the normal, and the reflected ray all lie in the same plane (Figure 32.8).

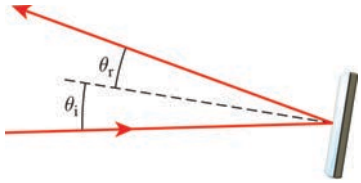

FIGURE 32.8 The angle of incidence equals the angle of reflection for reflection of light off a plane mirror. The dashed line is normal (perpendicular) to the mirror.

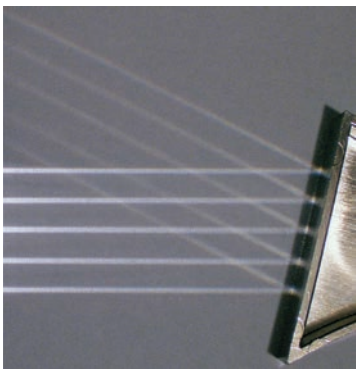
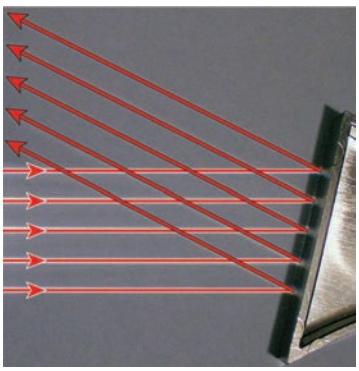
Mathematically, the law of reflection is given by

$$\theta_r = \theta_i. \qquad \textbf{(32.2)}$$

Parallel rays incident on a plane mirror are reflected in such a way that the reflected rays are also parallel (Figure 32.9), because every normal to the surface (dashed line in Figure 32.8) is parallel to other normals.



(a)



(b)

FIGURE 32.9 (a) Parallel light rays reflect off a plane mirror. (b) Arrows superimposed on the light rays.

W. Bauer and G. D. Westfall

Image Formed by a Plane Mirror

An **image** can be formed by light reflected from a plane mirror. For example, when you stand in front of a mirror, you see an image of yourself that appears to be behind the mirror. This perception occurs because the brain assumes that light rays reaching the eyes have traveled in straight lines with no change in direction. Thus, if light rays appear to originate at a point (say, behind the mirror), the eye (or a camera) sees a source of light at that point,whether or not an actual light source is there. This type of image, from which the light does not emanate, is referred to as a **virtual image**. By their nature, virtual images cannot be displayed on a screen. In contrast, **real images** are formed at a location at which you could physically put an object, like a screen or a charge-coupled device (CCD) from a camera.

An example will clarify the notion of a virtual image. In Figure 32.10, every point on the surface of the candle flame emits light, with the light rays moving out in radial directions. An observer can locate the candle flame in space by tracing the light rays back to the point where they intersect. Most of these light rays are drawn in gray. The rays that hit the mirror are highlighted in black. Each of them gets reflected according to the law of reflection (equation 32.2), with the angle of reflection relative to the surface normal being equal to the angle of incidence. The reflected rays also have a point at which they intersect. This point is found by continuing the reflected rays behind the mirror (dashed black lines). Therefore, for the observer, the light seems to come from a point behind the mirror. This point is the location of the image formed by the mirror.

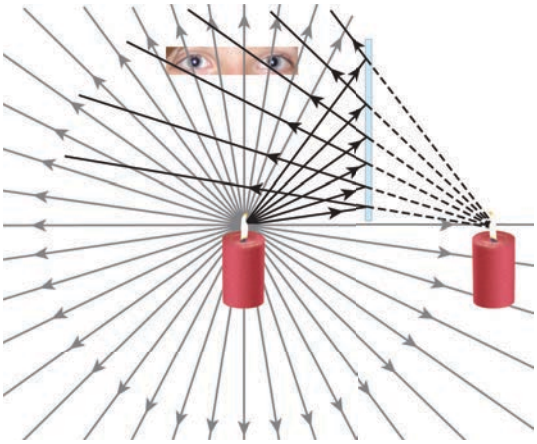


FIGURE 32.10 Image of a candle, as seen in a mirror (blue line).

W. Bauer and G. D. Westfall

Images formed by plane mirrors are left-right reversed because the light rays incident on the surface of the mirror are reflected back on the other side of the normal. Thus, we have the term *mirror image*. We will explore this point a bit more below, with the aid of Figure 32.12 and Figure 32.13.

But first let's consider quantitatively the process of forming images with a plane mirror (Figure 32.11) by using the technique of ray tracing. It turns out that a few rays are sufficient to construct an image, and we are free to select the most convenient ones.

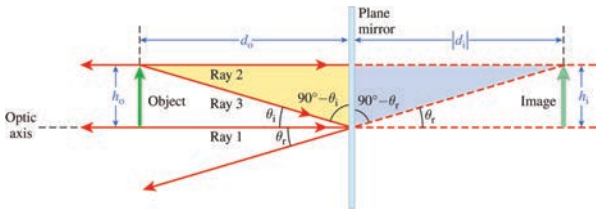

FIGURE 32.11 Ray diagram for the image formed by a plane mirror.

For this image construction, we choose the case where an object with height h_o is placed a distance d_o from a plane mirror. Following the common convention, the object is represented by an arrow, which indicates the object's height and orientation. The object is oriented so that the tail of the arrow is on the **optic axis**, which is defined as a normal to the plane of the mirror. (For a

plane mirror, the optic axis can be shown as going through any point on the mirror, but later when we examine curved mirrors, we will find that there is a unique location for the optic axis.) Three light rays determine where the image is formed.

1. The first light ray emanates from the bottom of the arrow along the optic axis. This ray is reflected directly back on itself. The extrapolation of this reflected ray along the optic axis to the right of the mirror indicates that the bottom of the image is located on the optic axis.
2. The second light ray starts from the top of the arrow parallel to the optic axis and is reflected directly back on itself. The extrapolation of this ray past the mirror is shown in Figure 32.11 as a dashed line.
3. The third ray starts from the top of the arrow, strikes the mirror where the optic axis intersects the mirror, and is reflected with an angle equal to its angle of incidence. The extrapolation of the reflected ray is shown as a dashed line in Figure 32.11.

The extrapolations of these last two rays intersect at the point where the top of the image forms (Figure 32.11). It turns out that extrapolations of all rays from the arrow tip that hit the mirror—not just the two rays shown here—intersect at the top of the image. Thus, the mirror produces a virtual image on the opposite side of the mirror. This image has a height h_i and is located a distance d_i to the right of the mirror. In Figure 32.11, the yellow triangle is congruent with the blue triangle. Thus,

$$h_\mathrm{i} = h_\mathrm{o} \qquad \textbf{(32.3)}$$

and

$$|d_i| = |d_o|. \qquad \textbf{(32.4)}$$

By convention, the sign of the image distance for a virtual image produced by a mirror is negative. Thus, we use the absolute value of the image distance in equation 32.4. The image produced by a plane mirror appears to be the same distance behind the mirror as the object is in front of the mirror. In addition, the image appears upright and the same size as the object.

Why are mirror images left-right reversed but not up-down reversed? A person standing in front of a plane mirror sees an image of herself standing at the same distance behind the mirror as she is standing in front of the mirror (Figure 32.12). The image seen by the person can be constructed with two light rays as shown, but of course light rays are coming from every visible point of the person. The image is upright (it has the same orientation as the object, not upside-down) and virtual (the image is formed behind the surface of the mirror).

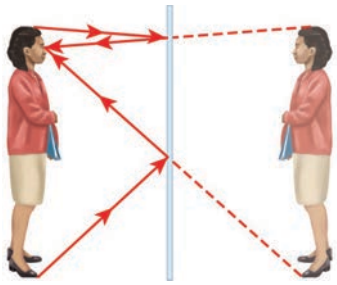

FIGURE 32.12 A person standing in front of a mirror sees a virtual image of herself.

What about the left-right reversal? In Figure 32.13, the virtual image is again constructed with two rays, but all other rays behave the same way. The figure shows that the mirror actually does a front-to-back reversal, not a left-right or top-bottom reversal. If you hold an arrow pointing to the right and look in the mirror, the arrow still points to the right! You can see that the real person in Figure 32.13 has his watch on his right arm. He perceives that his

virtual self has the watch on the left arm only because his brain imagines that the image is formed by a 180° rotation through a vertical axis, and not by a front-to-back reversal. If you find this too complicated, perhaps the following visualization will help you: Suppose you paint the letters representing your university's name on your forehead to get yourself ready for the big game. Then you put a length of clear packaging tape over the letters. As you pull the tape off, some of the paint sticks to it. If you pull the tape straight away from you, you see the back side of the tape that contacted the paint, and the letters are on it mirror-reversed. Looking at your image in the mirror is just like looking at the back side of the tape.

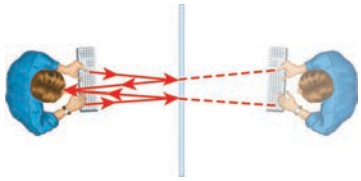

FIGURE 32.13 A person sitting in front of a mirror sees a mirror image of himself.

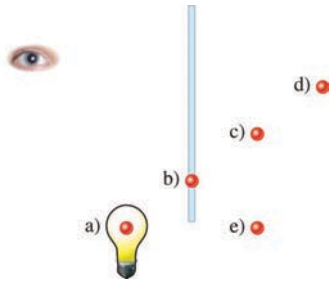
If you look at an image of yourself using a webcam on your computer, you see yourself as other people see you—the image from the webcam is not reversed front-to-back. This image is confusing after your long experience with seeing yourself in a mirror. Every movement you make seems to be made by your image in the opposite direction from what you expect. For this reason, some videoconferencing software now presents images that incorporate the front-to-back reversal inherent in mirror images, which makes for a more natural experience.

Concept Check 32.2

An observer (represented by the eye in the figure) is looking at a light bulb reflected in a plane mirror. To the observer, where does the image of the light bulb appear to be?



EXAMPLE 32.1 Full-Length Mirror

PROBLEM

A person who is 184 cm (6 ft $\frac{1}{2}$ in) tall wants to buy a mirror in which he can see his entire body. His eyes are 8 cm from the top of his head. What is the minimum height of the mirror that is needed?

SOLUTION

For simplicity, we represent the person as a pole 184 cm tall with "eyes" 8 cm from the top (this number does not matter, as the discussion below will show), as shown in Figure 32.14.

Page 986

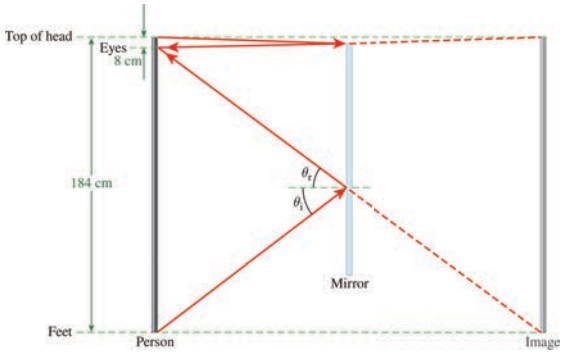


FIGURE 32.14 Distances and angles for a person standing in front of a mirror.

First, consider where the light from the person's feet must travel to reach his eyes. The light leaving the feet is represented by a red arrow in Figure 32.14. The angle of incidence on the mirror, θ_i, is equal to the angle of reflection from the mirror, θ_r. We can draw two triangles that include these angles (Figure 32.15).

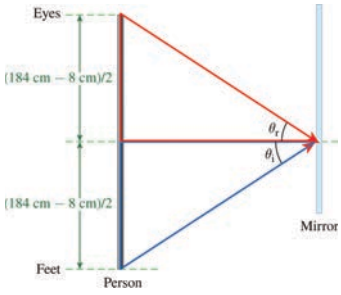

FIGURE 32.15
Two congruent triangles formed by the light from the person's feet.

These two triangles are congruent because $\theta_i = \theta_r$, they each have a right angle, and they share a common side. Thus, the vertical sides of each triangle must have the same length. The sum of these two sides is equal to the height of the person minus the distance from the top of the person's head to his eyes. Therefore, the vertical side of each triangle has the length $(184\text{ cm} - 8\text{ cm})/2$, as indicated in Figure 32.15.

We can now see that the bottom edge of the mirror needs to be at a height of $(184\text{ cm} - 8\text{ cm})/2 = 88\text{ cm}$ above the floor. A similar analysis of two congruent triangles gives us the location of the top edge of the mirror, which needs to be $(8\text{ cm})/2 = 4\text{ cm}$ below the top of the person's head. Therefore, the minimum height of the mirror is $184\text{ cm} - 4\text{ cm} - 88\text{ cm} = 92\text{ cm}$. This height is exactly half the height of the person. Thus, a mirror that is half a person's height affords the person a full-length view. This result does not depend on the distance of the eyes from the top of the person's head or on how close to the mirror the person stands. However, it does depend on how the mirror is hung: The top of the mirror must be halfway between the eyes and the top of the head.

32.3 Curved Mirrors

When light is reflected from the surface of a curved mirror, the light rays follow the law of reflection at each point on the surface. The light rays that are parallel before they strike the mirror are reflected in different directions, depending on the part of the mirror that they strike. Depending on whether the mirror is concave or convex, the light rays can converge or diverge. What kind of curved mirrors are most useful? Parabolic mirrors work best in precise optical devices, as we will see later. However, spherical mirrors are used in many practical applications. Since geometrical constructions are somewhat simpler with spherical mirrors, we start with them. We will see that geometric optics for these mirrors is valid only for small angle scattering and that spherical aberration arises with larger angles.

Focusing Spherical Mirrors

Consider a spherical mirror with a reflecting surface on its inside. This is a **concave mirror.** Figure 32.16 represents this spherical reflecting surface as a segment of a circle. The optic axis of the mirror, represented in the figure by a horizontal dashed line, is a line through the center of the sphere, which is labeled *C*. Imagine that a horizontal light ray above and parallel to the optic axis is incident on the surface of the mirror. The law of reflection applies at the point where the light ray strikes the mirror. The normal to the surface at this point, a dashed line in Figure 32.16, is a radial line that goes through the center of the sphere. For the isosceles triangle in Figure 32.16, you can see that each short side is about half the length of the long side, provided that θ_r is small. Thus, the reflected ray crosses the optic axis approximately halfway between the mirror and point *C*.

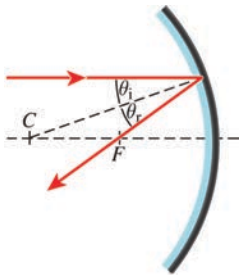

FIGURE 32.16 A horizontal light ray is reflected through the focal point of a concave mirror.

Now suppose there are many horizontal light rays incident on this spherical mirror (Figure 32.17). Each light ray obeys the law of reflection at the point where it strikes the mirror. Thus, each ray will cross the optic axis halfway between the mirror and point *C*. This crossing point, *F*, is called the **focal point.** Note that only horizontal rays incident on the mirror close to the optic axis will be reflected through the focal point, because only for such rays is the

condition of a small reflection angle satisfied. (The distance of the incident ray from the optic axis in Figure 32.16 is probably the upper limit for satisfying that condition.) Unless otherwise specified, all horizontal rays are assumed to be close enough to the optic axis to pass through F on reflection.

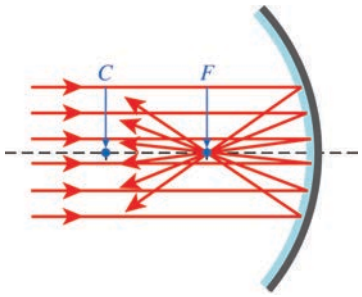

FIGURE 32.17
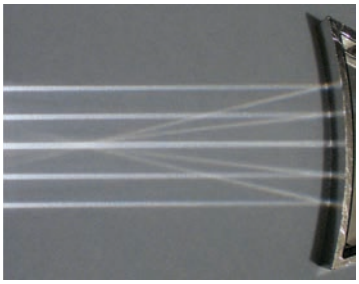
Many parallel light rays reflected through the focal point of a concave mirror.

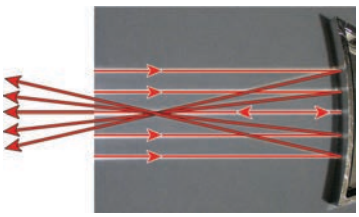
Point F is halfway between point C and the surface of the mirror. Point C is located at the center of the sphere, so the distance of C from the surface of the mirror is just the radius of the mirror, R. The **focal length** is the distance along the optical axis between the mirror's surface and the focal point. Therefore the focal length f of a converging spherical mirror is

$$f = \frac{R}{2} \quad \text{(converging mirror)}. \qquad \textbf{(32.5)}$$

Light rays incident on an actual converging mirror are shown in Figure 32.18.



(a)



(b)

FIGURE 32.18 (a) Parallel light rays reflected to the focal point by a converging mirror. (b) Same image with arrows superimposed.

W. Bauer and G. D. Westfall

Now let's consider forming images with a converging mirror, such as the one in Figure 32.19. An object with height h_o is placed a distance d_o from the mirror, where $d_0 > f$. The object is represented by an arrow, which indicates the height and orientation of the object. The object is oriented so that the tail of the arrow is on the optic axis, which, as before, is a normal to the surface of the spherical mirror along a line passing through the center C of the sphere. Four light rays determine where the image is formed.

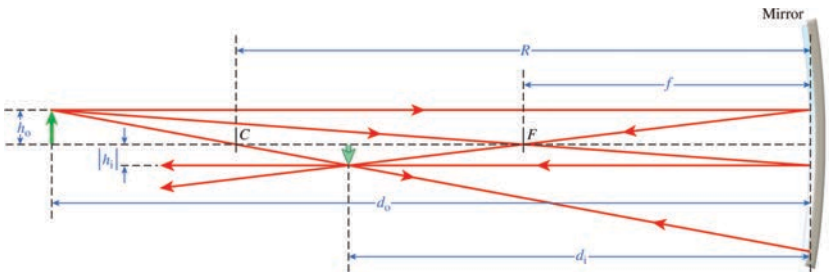


FIGURE 32.19 Image produced by a converging mirror when the object distance is greater than the focal length of the mirror.

1. The first light ray emanates from the bottom of the arrow along the optic axis and is usually not shown. This ray merely indicates that the bottom of the image is located on the optic axis.
2. The second light ray starts from the top of the arrow, is parallel to the optic axis, and is reflected through the focal point of the mirror.
3. The third ray starts from the top of the arrow, passes through the center of the sphere, *C*, and is reflected back on itself.
4. The fourth ray starts from the top of the arrow, passes through the focal point, *F*, and is reflected back parallel to the optic axis.

The last three reflected rays intersect at the point where the image of the top of the object is formed (Figure 32.19). It turns out that all rays from the arrow tip that strike the mirror—not just the three shown here—intersect at the top of the image when they are reflected. Thus, we say that the mirror focuses the rays to form the image.

The reconstruction of the special case shown in Figure 32.19 shows a real image (on the same side of the mirror as the object, not behind the mirror) with height h_i at a distance d_i from the surface of the mirror. The image height, h_i, is assigned a negative value to denote that the image is inverted. By convention, the

image distance, d_i, is defined as positive because the image is on the same side of the mirror as the object. The image is inverted and in this case is reduced in size relative to the object. An image is called real when a screen placed at the image location can display a sharp projection of the image. For a virtual image, the light rays do not go through the image and thus no light reaches a screen placed at the image location.

Now let's reconstruct another case for a converging mirror, where $d_o < f$ (Figure 32.20). The object stands on the optic axis, and three light rays determine where the image is formed.

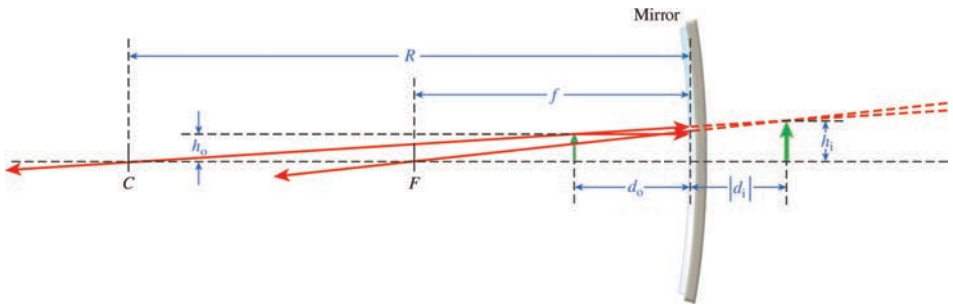

FIGURE 32.20 Image produced by a converging mirror when the object distance is less than the focal length of the mirror.

1. The first ray merely indicates that the tail of the image lies on the optic axis and is usually not shown.
2. The second ray starts from the top of the object, is parallel to the optic axis, and is reflected through the focal point.
3. The third ray leaves the top of the object along a radius and is reflected back on itself through the center of the sphere.

The reflected rays are clearly diverging. To determine the location of the image, we must extrapolate the reflected rays to the other side of the mirror. These extrapolations intersect at a distance d_i from the surface of the mirror, producing an image with height h_i.

In this case, the image is formed on the opposite side of the mirror from the object, a virtual image. (By convention, the distance d_i is assigned a negative value to denote that the image is virtual.) To an observer, the image appears to be behind the mirror, as with a plane mirror. The image is upright and larger than the

object. These results for $d_o < f$ are quite different from those for $d_o > f$. Mirrors used for shaving or applying cosmetics are usually converging mirrors; the user puts his or her face closer than the focal length, producing a large, upright image.

Before treating diverging mirrors, let's formalize the sign conventions for distances and heights.

1. All distances on the same side of the mirror as the object are defined to be positive, and all distances on the opposite side of the mirror from the object are defined to be negative. Thus, *f* and d_o are positive for converging mirrors.
2. For real images, d_i is positive. For virtual images, d_i is negative.
3. If the image is upright, then h_i is positive; if the image is inverted, h_i is negative.

We can derive the **mirror equation** (equation 32.6), which relates the object distance, d_o, the image distance, d_i, and the focal length of a mirror, *f*:

$$\frac{1}{d_o} + \frac{1}{d_i} + \frac{1}{f}. \qquad \textbf{(32.6)}$$

The signs of the terms in this equation are based on the conventions just defined.

DERIVATION 32.1 Spherical-Mirror Equation

The spherical-mirror equation can be derived by starting with a converging mirror that has a focal length f. An object h_o tall stands at a distance d_o from the surface of the mirror on the optic axis (Figure 32.21).

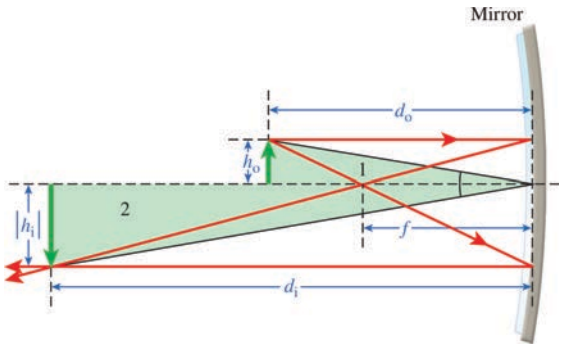

FIGURE 32.21 The two similar triangles 1 and 2 in the derivation of the spherical-mirror equation.

Trace a ray from the top of the object parallel to the optic axis and reflect it through the focal point. Trace a second ray from the top of the object through the focal point and reflect it parallel to the optic axis. The image is formed with height h_i at distance d_i from the mirror. Form a right triangle with height h_o and base d_o (green triangle 1 in Figure 32.21). Form a second right triangle with $-h_i > 0$ as the height and d_i as the base (green triangle 2 in Figure 32.21). From the law of reflection for a ray striking the mirror on the optic axis, the indicated angles in the two triangles are the same, so the two triangles are similar. Thus,

$$\frac{h_o}{d_o} = \frac{-h_i}{d_i} \quad \text{or} \quad \frac{-h_i}{h_o} = \frac{d_i}{d_o}. \qquad \text{(i)}$$

Now let us look at the geometry for two different triangles. One right triangle (yellow triangle 4 in Figure 32.22) is defined by the height $-h_i$ and the base length $d_i - f$. The second triangle (yellow triangle 3 in Figure 32.22) is defined by the height h_o and the base f. The two triangles are similar, so

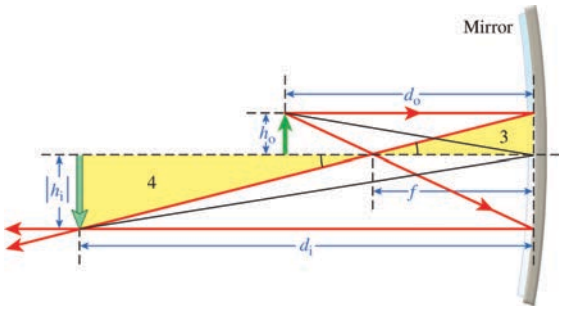

FIGURE 32.22 The two similar triangles 3 and 4 in the derivation of the spherical-mirror equation.

$$\frac{h_o}{f} = \frac{-h_i}{d_i - f} \quad \text{or} \quad \frac{-h_i}{h_o} = \frac{d_i - f}{f}.$$

Substituting from equation (i) for the ratio of the heights gives

$$\frac{d_i}{d_o} = \frac{d_i - f}{f}.$$

Multiplying both sides of this equation by f yields

$$\frac{fd_i}{d_o} = d_i - f \Rightarrow \frac{fd_i}{d_o} + f = d_i.$$

Finally, dividing both sides of this equation by the product fd_i leads to the spherical-mirror equation:

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}.$$

Concept Check 32.3

The mirror equation tells us that

a) moving an object farther from a converging mirror means that the image will be formed farther from the mirror.

b) moving an object farther from a converging mirror means that the image will be formed closer to the mirror.

c) either of the above could occur, depending on the focal length of the mirror.

The **magnification**, m, of a mirror is defined as the ratio of the size of the image to the size of the object, $m = h_\mathrm{i}/h_\mathrm{o}$. In the Derivation 32.1, we saw that this ratio is the negative of the ratio of the image distance to the object distance. Thus, we have

$$m = \frac{h_\mathrm{i}}{h_\mathrm{o}} = -\frac{d_\mathrm{i}}{d_\mathrm{o}}. \qquad \textbf{(32.7)}$$

Note that m is negative for the situation used in the derivation. Algebraically, this occurs because $h_\mathrm{i} < 0$. The significance of $m < \mathrm{o}$ is that it tells us that the image is inverted. Table 32.1 summarizes the characteristics of images formed by a converging mirror for five different classes of object distances.

Table 32.1 Image Characteristics for Converging Mirrors

Case	Image Type	Image Orientation	Magnification
$d_o < f$	Virtual	Upright	Enlarged
$d_o = f$	Real	Upright	Image at infinity
$f < d_o < 2f$	Real	Inverted	Enlarged
$d_o = 2f$	Real	Inverted	Same size
$d_o > 2f$	Real	Inverted	Reduced

Diverging Spherical Mirrors

Suppose we have a spherical mirror with the reflecting surface on the outside of the sphere (Figure 32.23). This is a **convex mirror,** and the reflected rays diverge. In Figure 32.23, this spherical reflecting surface is indicated by a semicircle. The optic axis of the mirror is a line through the center of the sphere, represented by the horizontal dashed line. Imagine that a horizontal light ray above the optic axis is incident on the surface of the mirror. At the point where the light ray strikes the mirror, the law of reflection applies.

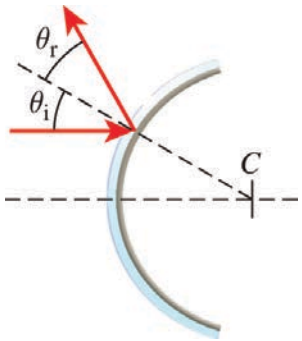

FIGURE 32.23
Reflection of a horizontal light ray from a diverging spherical mirror.

In contrast to the normal for a converging mirror, the normal to the surface of a diverging mirror points *away* from the center of the sphere. When we extrapolate the normal through the surface of the sphere, it intersects the optic axis of the sphere at the sphere's center, marked *C* in Figure 32.23. When we observe the reflected ray, it seems to be coming from inside the sphere.

Suppose many horizontal light rays are incident on this spherical mirror (Figure 32.24). Each light ray obeys the law of reflection. The rays diverge and do not seem to form any kind of image. However, if the reflected rays are extrapolated through the surface of the mirror, they all intersect the optic axis at one point. This point is the focal point of this diverging mirror.

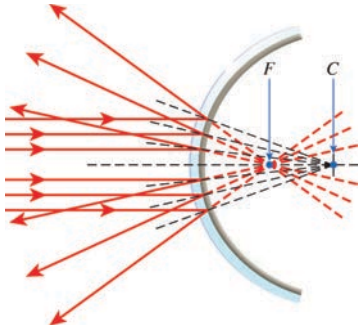

FIGURE 32.24 The reflection of parallel light rays from the surface of a diverging mirror.

Figure 32.25a shows five parallel light rays incident on an actual diverging spherical mirror. The dashed lines in Figure 32.25b represent the extrapolation of the reflected rays to show the focal point.

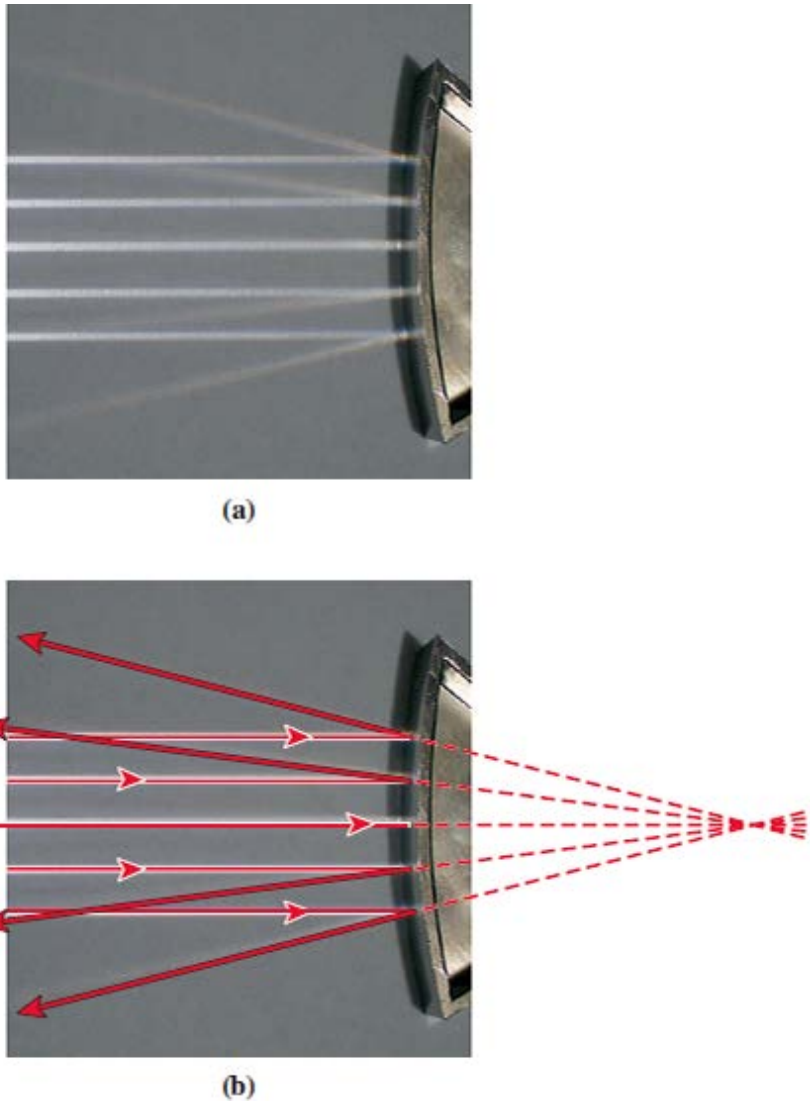

FIGURE 32.25 (a) Parallel light rays reflected from a diverging spherical mirror. (b) Arrows corresponding to the light rays, with the dashed lines representing the extrapolated reflected rays.

W. Bauer and G. D. Westfall

Now let's discuss images formed by diverging mirrors (Figure 32.26). Again we use three rays.

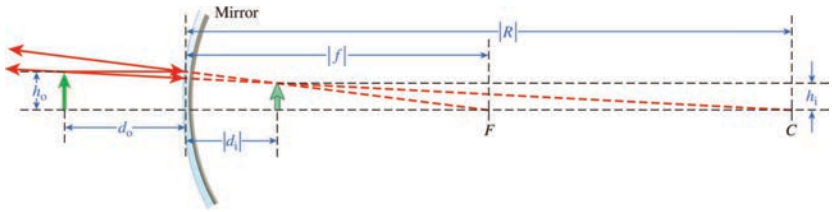

FIGURE 32.26 Image formed by an object placed in front of a diverging spherical mirror.

1. The first ray establishes that the tail of the arrow lies on the optic axis and is usually not shown.
2. The second ray starts from the top of the object, travels parallel to the optic axis, and is reflected from the surface of the mirror in such a way that its extrapolation crosses the optic axis a distance from the surface of the mirror equal to the focal length of the mirror.
3. The third ray begins at the top of the object and is directed so that its extrapolation intersects the center of the sphere. This ray is reflected back on itself.

The reflected rays diverge, but the extrapolated rays converge a distance d_i from the surface of the mirror on the side of the mirror opposite the object. The rays converge at a distance h_i above the optic axis, forming an upright, reduced image on the side of the mirror opposite the object. This image is virtual because the light rays do not actually go through it. These characteristics (upright, reduced, virtual image) are valid for all object distances for a diverging mirror. Such mirrors are often used in stores to give clerks at the front of the store a wide view down the aisles and as passenger side rear-view mirrors on cars.

In the case of a diverging mirror, the focal length, f, is negative because the focal point of the mirror is on the side opposite the object. A negative value is also assigned to the radius of a diverging mirror. Thus,

$$f = \frac{R}{2} \quad (\text{ with } R < 0 \text{ for a divering mirror}).$$

The object distance, d_o, is always taken to be positive. Rearranging the mirror equation (equation 32.6), which is also valid for a diverging mirror, gives

$$d_i = \frac{d_o f}{d_o - f}. \tag{32.8}$$

If d_o is always positive and f is always negative, d_i is always negative. Applying (equation 32.7 for the magnification, we find that m is always positive. Looking at Figure 32.26 will also convince you that the image is always reduced in size. Thus, a diverging mirror (even if if $d_o > |f|$) always produces a virtual, upright, and reduced image.

Self-Test Opportunity 32.1

You are standing 2.50 m from a diverging mirror with focal length $f = -0.500$ m. What do you see in the mirror? (The answer "myself" is not good enough!)

EXAMPLE 32.2 Image Formed by a Converging Mirror

Consider an object 5.00 cm tall placed 55.0 cm from a converging mirror with focal length 20.0 cm (Figure 32.27).

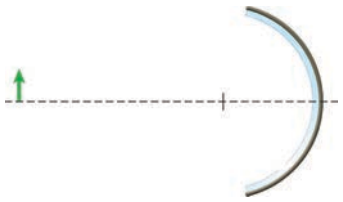

FIGURE 32.27 An object (green arrow) whose image is to be formed by a converging mirror.

PROBLEM 1

Where is the image produced?

SOLUTION 1

We can use the mirror equation to find the image distance, d_i, in terms of the object distance, d_o, and the focal length of the mirror, f:

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}.$$

The mirror is converging, so the focal length is positive. The image distance is

$$d_i = \frac{d_o f}{d_o - f} = \frac{(55.0\text{ cm})(20.0\text{ cm})}{55.0\text{ cm} - 20.0\text{ cm}} = 31.4\text{ cm}.$$

PROBLEM 2

What are the size and the orientation of the image?

SOLUTION 2

The magnification, m, is given by

$$m = \frac{h_\mathrm{i}}{h_\mathrm{o}} = \frac{d_\mathrm{i}}{d_\mathrm{o}},$$

where h_o is the height of the object and h_i is the height of the image. The image height is then

$$h_\mathrm{i} = -h_\mathrm{o}\frac{d_\mathrm{i}}{d_\mathrm{o}} = -(5.00\ \mathrm{cm})\frac{31.4\ \mathrm{cm}}{55.0\ \mathrm{cm}} = -2.85\ \mathrm{cm}.$$

The magnification is

$$m = \frac{h_\mathrm{i}}{h_\mathrm{o}} = \frac{-2.85\ \mathrm{cm}}{5.00\ \mathrm{cm}} = -0.570.$$

Thus, the image is inverted and reduced.

Concept Check 32.4

Moving the object in Example 32.2 10% closer to the mirror would produce an image that was

a) closer to the mirror and larger than before.

b) closer to the mirror and smaller than before.

c) farther from the mirror and larger than before.

d) farther from the mirror and smaller than before.

e) It is not possible to predict the image's characteristics.

Spherical Aberration

The equations we have derived for spherical mirrors $\left(\frac{1}{d_o} + \frac{1}{d_i} + \frac{1}{f} \quad \text{and} \quad m = \frac{h_i}{h_o} = -\frac{d_i}{d_o}\right)$ apply only to light rays that are close to the optic axis. If the light rays are far from the optic axis, they will not be focused through the focal point of the mirror, leading to a distorted image. Strictly speaking, there is no precise focal point in this situation. This condition is called **spherical aberration**.

Figure 32.28 shows several light rays not close to the optic axis incident on a spherical converging mirror. The rays farther from the optic axis are reflected in such a way that they cross the optic axis closer to the mirror than do rays that strike the mirror closer to the axis. As the rays approach the optic axis, they are reflected through points closer and closer to the focal point.

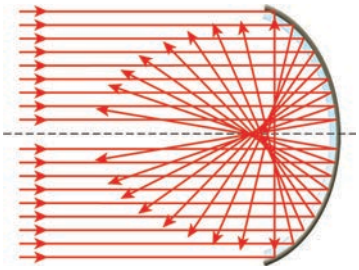

FIGURE 32.28
Parallel light rays incident on a spherical converging mirror, demonstrating spherical aberration.

DERIVATION 32.2 Spherical Aberration for Converging Mirrors

Up until now we have assumed that light rays parallel to the optic axis and close to it are reflected in such a way that they cross the optic axis at the focal point of the mirror. The focal point is at half the radius of curvature of the mirror. However, light rays that are far from the optic axis are not reflected through the focal point. To derive an expression for the point at which rays parallel to but far from the optic axis cross the axis, we use the geometry shown in Figure 32.29.

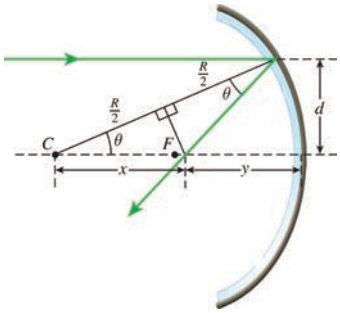

FIGURE 32.29
Geometry for the spherical aberration of a converging spherical mirror.

Start with a light ray parallel to the optic axis and at a distance d from it. The ray reflects and crosses the axis a distance y from the mirror. The ray makes an angle θ with respect to the normal to the mirror's surface, which is a radius R of the spherical mirror. The law of reflection tells us that the angle of incidence of the ray on the surface of the mirror is equal to the angle of reflection.

Define the distance from the center of the spherical mirror to the point at which the reflected ray crosses the optic axis as x. Draw a perpendicular line from the point where the ray crosses the axis to the normal. This line forms two congruent

right triangles with angle θ, hypotenuse x, and adjacent side $R/2$, such that

$$\cos\theta = \frac{R/2}{x} \Rightarrow x = \frac{R}{2\cos\theta}.$$

We can also express θ in terms of d as

$$\sin\theta = \frac{d}{R} \Rightarrow \theta = \sin^{-1}\left(\frac{d}{R}\right).$$

Page 993

The distance y is given by

$$y = R - x = R - \frac{R}{2\cos\theta} = R\left(1 - \frac{1}{2\cos\theta}\right) = R\left(1 -$$

Remembering the trigonometric identity $\cos\left(\sin^{-1}(x)\right) = \sqrt{1-x^2}$, we can rewrite our result for y as

$$y = R\left(1 - \frac{1}{2\left(\sqrt{1-\frac{d}{R}}\right)^2}\right) = \frac{R}{2}\left(2 - \frac{1}{\sqrt{1-\left(\frac{d}{R}\right)}\right.$$

We can see that for $d \ll R, 1-(d/R)^2 \approx 1$ and $y \approx R/2$, which agrees with equation 32.5. We can make a better approximation by writing the Maclaurin series expansion

$$(1-x^2)^{-1/2} \approx 1 + \frac{x^2}{2} (\text{for } x \ll 1).$$

Taking $x = (d/R) \ll 1$, we can make the approximation

$$y = \frac{R}{2}\left(2\left[1-\left(\frac{d}{R}\right)^2\right]^{-1/2}\right) \approx \frac{R}{2}\left(2-\left[1+\frac{1}{2}\left(\frac{d}{R}\right)\right.\right.$$

Thus, the amount of spherical aberration is given approximately by

$$\frac{R}{2} - y \approx \frac{d^2}{4R}\left(\text{for}\frac{d}{R} \ll 1\right).$$

Self-Test Opportunity 32.2

For a converging spherical mirror with $R = 7.20$ cm, assume that the incident light rays are not close to the optic axis of the mirror but are parallel to the axis. Calculate the position at which the reflected light ray intersects the optic axis if the incident ray is

a) 0.720 cm away from the optical axis.

b) 0.800 cm away from the optical axis.

c) 1.80 cm away from the optical axis.

d) 3.60 cm away from the optical axis.

Parabolic Mirrors

Parabolic mirrors have a surface that reflects light from a distant source to the focal point from anywhere on the mirror. Thus, the full size of the mirror can be used to collect light and form images that do not suffer from spherical aberrations. Figure 32.30 shows vertical light rays incident on a parabolic mirror. All rays are reflected through the focal point of the mirror.

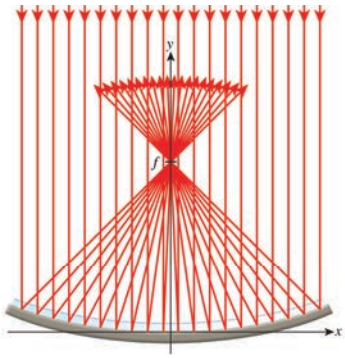

FIGURE 32.30
Light rays reflected by a parabolic mirror.

If the surface of a parabolic mirror is described by the equation $y(x) = ax^2$, then its focal point is located at the point $(x = 0, y = 1/(4a))$. Its focal length is therefore

$$f = \frac{1}{4a}. \qquad \textbf{(32.9)}$$

Parabolic mirrors are more difficult to produce than spherical mirrors and are accordingly more expensive. Most large reflecting telescopes use parabolic mirrors in order to avoid spherical aberration. Many automobile headlights use parabolic reflectors for the same reason, but these send light in the opposite direction: The light source is placed at the focal point, and the reflector sends the light out in a strong beam parallel to the optic axis, as illustrated in Figure 32.31. (However, incandescent headlights are

likely to be replaced with LED headlights, which will use small lenses to accomplish the same thing.)

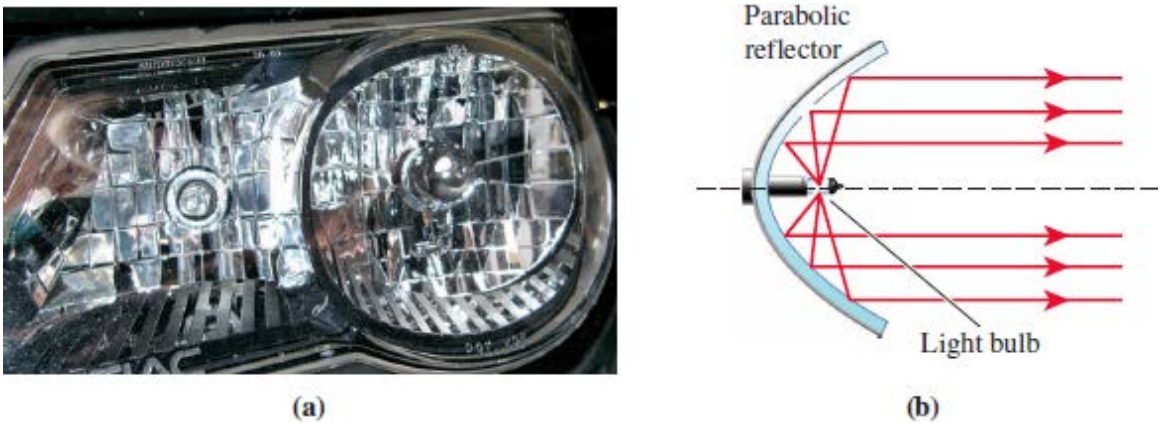

FIGURE 32.31 (a) Headlight assembly for a car. The left light is the low-beam headlight, and the right light is the high-beam headlight. (b) Diagram of the high-beam headlight showing the light bulb at the focus of the parabolic reflector.

a: W. Bauer and G. D. Westfall

Figure 32.31a shows the low-beam and high-beam headlights for a car. The parabolic reflectors for headlights are faceted. A facet is a flat area on the reflector. These facets help produce the light distribution desired for the headlight. Figure 32.31b shows the light bulb for the high-beam headlight at the focus of a parabolic mirror that functions as a reflector for the light produced by the light bulb, producing a focused parallel beam of light.

The satellite TV antennas (“dishes”) found on many rooftops are also parabolic in shape. These satellite dishes are not mirrors in the sense that they do not reflect visible light in specular fashion. But they are parabolic reflectors for radiation in the wavelength range used for satellite TV transmission.

Rotation Parabolas

For precise optical applications, clearly it is best to use parabolic mirrors. For example, in Chapter 33, we will see that huge parabolic mirrors are used in telescopes. One very interesting way to create a parabolic mirror is to put a liquid into rotational motion. At every point on the surface of the liquid, the surface will be perpendicular to the force from the fluid acting on that surface element. This force, $\overrightarrow{F}$, adds to the force of gravity acting on the surface element, $-mg\hat{y}$, to provide the net centripetal force, which is needed to keep the surface element on a circular path (Figure 32.32). In the xy-coordinate system chosen here, the centripetal force is $-m\omega^2 x\hat{x}$ (refer to Chapter 9 on circular motion).

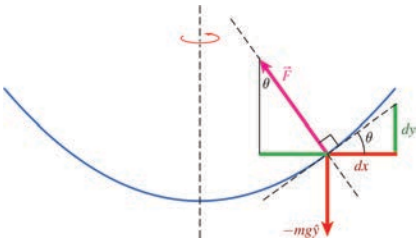

FIGURE 32.32
Geometry of a rotational parabola and free-body diagram for a fluid surface element. The force $\overrightarrow{F}$ exerted by the fluid on a surface element is shown in magenta. It needs to balance the force of gravity (red) and provide the centripetal force (green) necessary to keep the surface element moving in a circular path.

The angle θ of the surface element with respect to the horizontal is given by $\tan\theta = dy/dx$(see Figure 32.32). The same angle also can be used to express the components of the force $\vec{F}$. The vertical component of $\vec{F}$ has to balance the force of gravity, and the horizontal component has to provide the net centripetal force:

$$\begin{aligned} F\cos\theta &= mg \\ F\sin\theta &= m\omega^2 x. \end{aligned}$$

Self-Test Opportunity 32.3

Show that the derivation of $y(x) = \left(\omega^2/2g\right)x^2$ for the surface of a rotating liquid can be accomplished using energy considerations.

Dividing these two equations by each other leads to $\tan\theta = \left(\omega^2/g\right)x$. Previously we showed that $\tan\theta = dy/dx$, so

$$\frac{dy}{dx} = \frac{\omega^2}{g}x.$$

Integration then results in the desired shape of the surface

$$y(x) = \frac{\omega^2}{2g}x^2,$$

which is a parabola. Because the focal length of a parabola of the form $y = ax^2$ is $f = 1/(4a)$, the focal length of this parabolic mirror made of a rotating liquid is

$$f = \frac{g}{2\omega^2}.$$

Rotation of liquid surfaces has been successfully used to construct large telescope mirrors. One such mirror is shown in Figure 32.33. A very large version of such a telescope has been designed to be installed on the Moon. While this may sound like science fiction at the present, such a telescope would be much cheaper to construct than one with a solid mirror. Since the Moon has no atmosphere, the telescope would not suffer from the atmospheric distortions that all ground-based telescopes suffer from on Earth. And it could be constructed on a much larger scale than what is possible with satellite-based telescopes like the Hubble Space Telescope. (We will cover telescopes in much greater detail in Chapter 33.)

Concept Check 32.5

Suppose you have a liquid-mirror telescope with focal length f_1, and you want to double this focal length. What adjustment do you have to make to the rotational angular velocity of the liquid?

a) reduce it by a factor of 0.5

b) reduce it by a factor of 0.707

c) keep it the same

d) increase it by a factor of 0.707

e) increase it by a factor of 2

FIGURE 32.33

Concentrating Solar Power

The energy contained in solar radiation can be harnessed by solar power plants, which accomplish this in two different ways. One involves photovoltaic processes, which we will discuss in Chapter 36. The other method focuses the Sun's rays onto a focal point, where their energy can be used for heating water and/or generating steam, which in turn can be used for electricity production.

One ray-focusing design uses parabolic troughs (see Figure 32.34). The cross section of one of these troughs looks like Figure 32.30. At the focal point of the parabola is a liquid-filled heat transfer tube, which captures the solar energy for processing into electricity. As the Sun moves across the sky during the day, the parabolic troughs have to be rotated so that their optical axes point in the direction of the Sun.

FIGURE 32.34
Large-scale solar farm utilizing parabolic troughs.

RGB Ventures/SuperStock/Alamy Stock Photo

Another design for a solar power plant uses a large array of flat mirrors to focus the Sun's rays on a focal point at the top of a tower (see Figure 32.35). At that focal point, temperatures of a few thousand degrees can be reached, allowing for very efficient conversion of solar energy into electricity.

FIGURE 32.35 The world's first commercial tower solar farm, an 11-MW installation in Sanlúcar la Mayor, Spain.

Denis Doyle/Getty Images

Self-Test Opportunity 32.4

The parabolic troughs of the solar farm shown in Figure 32.34 can only be rotated about their long axes. Does such rotation keep the maximum amount of solar radiation incident on the troughs' inner surfaces at all times? If not, what, if anything, could be done to maximize the incident radiation?

Concept Check 32.6

Using flat mirrors to focus the Sun's rays at the top of a tower, as is done by the power plant shown in Figure 32.35, is only possible because

a) the Sun is essentially infinitely far away, so its rays are parallel when they strike the mirrors.

b) the orientations of the flat mirrors are continuously and individually adjusted by computerized controls.

c) the mirrors are located in a parabolic bowl.

d) the Sun is directly overhead in Spain for several hours each day.

e) the Earth is a sphere with a very large radius of curvature.

32.4 Refraction and Snell's Law

Light travels at different speeds in different optically transparent materials. The ratio of the speed of light in vacuum to the speed of light in a material is called the **index of refraction** of the material. The index of refraction, n, is therefore defined as

$$n = \frac{c}{v}, \tag{32.10}$$

where c is the speed of light in vacuum and v is the speed of light in the material. The speed of light in a physical medium such as glass is always less than the speed of light in vacuum. Thus, the index of refraction of a material is always greater than or equal to 1, and by definition the index of refraction of vacuum is 1. Table 32.2 lists the indices of refraction for some common materials. In general, the index of refraction is a function of the wavelength of the light, but the table gives typical average values for visible light. We will return to the wavelength dependence of the index of refraction in a later subsection on chromatic dispersion.

Table 32.2 Indices of Refraction for Some Common materials*

Material	Index of Refraction
Gases	
Air	1.000271
Helium	1.000036
Carbon dioxide	1.00045
Liquids	
Water	1.333
Methyl alcohol	1.329
Ethyl alcohol	1.362
Glycerine	1.473
Benzene	1.501
Typical oil	1.5
Solids	
Ice	1.310
Calcium fluoride	1.434
Fused quartz	1.46
Salt	1.544
Polystyrene	1.49
Typical Lucite	1.5
Typical glass	1.5
Quartz	1.544
Diamond	2.417

*For light with wavelength 589.3 nm

When light crosses the boundary between two transparent materials, some of it is reflected, but usually some of it crosses the boundary into the other material and in the process is refracted. **Refraction** means that the light rays do not travel in a straight line across the boundary, but change direction. When light crosses a boundary from a medium with a lower index of refraction, n_1, to a medium with a higher index of refraction, n_2, the light rays change their direction and bend *toward* the normal to the boundary (Figure 32.36). The change in direction toward the normal means that the angle of refraction, θ_2, is less than the angle of incidence, θ_1.

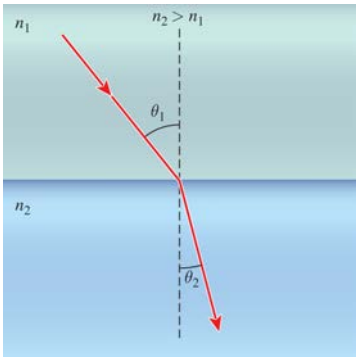

FIGURE 32.36
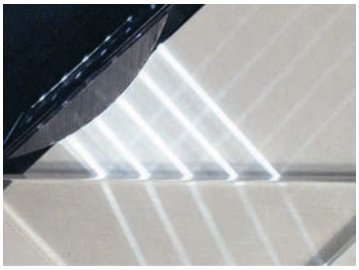
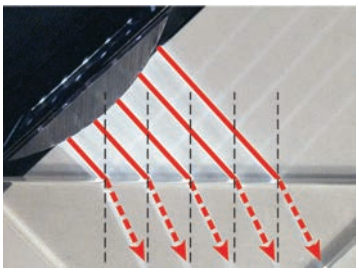
Light rays refracted at the boundary between two optical media with $n_1 < n_2$. (The reflected light ray is not shown.)

Figure 32.37 shows actual light rays in air incident on the boundary between air and glass. The light rays are refracted toward the normal. (The reflected light is also observable.)



(a)



(b)

FIGURE 32.37 (a) Light rays refracted when crossing the boundary between air and glass. (b) Arrows superimposed on the light rays. The dashed lines are normal to the boundary.

W. Bauer and G. D. Westfall

When light crosses a boundary from a medium with a higher index of refraction n_1 to a medium with a lower index of refraction n_2, the light rays are bent *away* from the normal (Figure 32.38). Bending away from the normal means that $\theta_2 > \theta_1$.

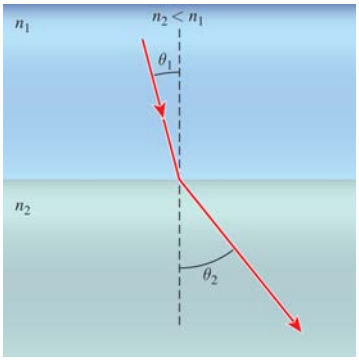


FIGURE 32.38
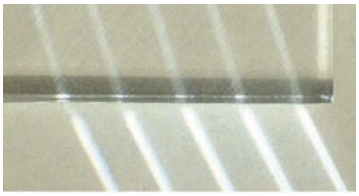
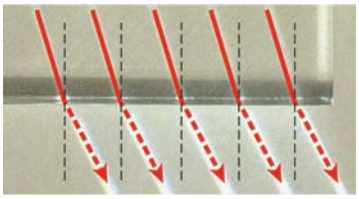
Light rays refracted at the boundary between two optical media with $n_1 > n_2$.

Figure 32.39 shows actual light rays in glass incident on the boundary between glass and air. The light rays are refracted away from the normal.



(a)



(b)

FIGURE 32.39 (a) Light rays refracted when crossing the boundary between glass and air. (b) Arrows superimposed on the light rays. The dashed lines are normal to the boundary.

W. Bauer and G. D. Westfall

From measurements of the angles of incident and refracted rays in media with different indices of refraction, we can construct a law of refraction. This law of refraction based on empirical observations can be expressed as

$$n_1 \sin\theta_1 = n_2 \sin\theta_2, \qquad \textbf{(32.11)}$$

where n_1 and θ_1 are the index of refraction and angle of incidence (relative to the surface normal) in the first medium, and n_2 and θ_2 are the index of refraction and angle of the transmitted ray (relative

to the surface normal) in the second medium. This law of refraction is also called **Snell's Law**. It cannot be proven using ray optics alone; however, in Chapter 34 this law is derived using wave optics.

The index of refraction of air is very close to 1, as shown in Table 32.2, and in this book we will always assume that the index of refraction of air is $n_{\text{air}} = 1$. It is very common for light to be incident on various media from air, so we can write the formula for refraction of light incident on a surface of a medium with index of refraction n_{medium} as

$$n_{\text{medium}} = \frac{\sin\theta_{\text{air}}}{\sin\theta_{\text{medium}}}, \qquad \textbf{(32.12)}$$

where θ_{air} is the angle of incidence (relative to the surface normal) for light in air and θ_{medium} is the angle of the refracted light (relative to the surface normal) in the medium. Note that θ_{air} is always greater than θ_{medium}!

Also note that for light coming out of a medium into air, the refraction formula is the same (equation 32.12)! This is a special case of the general statement advanced earlier: All ray-tracing figures remain valid if the direction of the light rays is reversed. For example, changing the direction of the arrows on the red line in Figure 32.38 still yields a physically valid path for a light ray crossing the boundary between the two media.

Fermat's Principle

We have just stated that Snell's Law cannot be proven using ray optics alone. But there is a qualifier to this statement: If you accept Fermat's Principle, then Snell's Law emerges automatically. **Fermat's Principle,** or the **principle of least time,** as expressed by Fermat in 1657, states that the path taken by a ray of light between two points in space is the path that takes the least time.

How can we prove Snell's Law this way? The key is the connection between the speed of light in a medium, v, and the medium's index of refraction, n, which was established in equation 32.10. If light moves at different speeds in two media, then Fermat's Principle is analogous to the logic used in determining who won the aquathlon race, which we did in Example 2.6 and the following text. In that problem, we calculated the angle at which a contestant must swim to shore in a race that consists of a swim to shore (with one given speed) and a run along the shore (with another speed). Winning the race means taking the minimum time, which is exactly what Fermat's Principle postulates.

If you accept Fermat's Principle and you want to prove Snell's Law, then all you have to do is to revisit the solution to Example 2.6. But of course you can ask where Fermat's Principle comes from. Using the minimum time to win a race seems obvious. But what makes the light rays understand that they should take the minimum time to get from point A to point B? The answer to this can be found in Huygens's Principle. However, to gain an understanding of the physics underlying that principle, you need to wait until Chapter 34, when we revisit the model of light as a wave.

EXAMPLE 32.3 Apparent Depth

You are standing on the edge of a pond and looking at the water at an angle of $\theta_2 = 45.0^\circ$ to the vertical, as shown in Figure 32.40. You see a fish in the pond. The actual depth of the fish is $d_{\text{actual}} + 1.50$ m.

PROBLEM

What is the apparent depth of the fish from your vantage point?

SOLUTION

Light rays from the fish are refracted at the surface of the water into your eyes at a 45.0°. angle as shown in Figure 32.40. In the figure we show a central ray as representative of a collection of rays emitted from one point on the body of the fish (semitransparent cone). Where the eyes see these rays intersect is where you locate the fish.

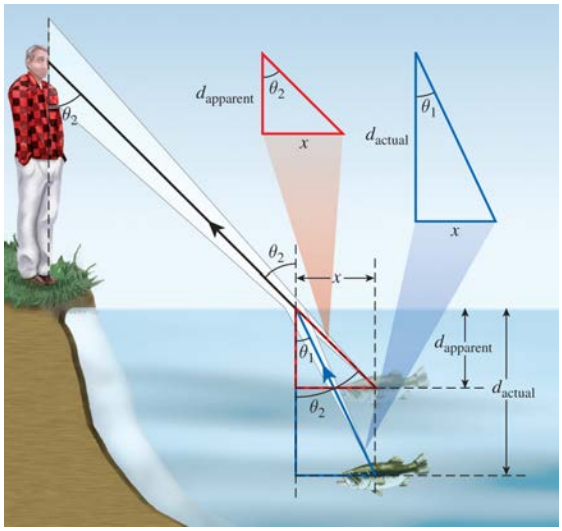


FIGURE 32.40 You are looking at the surface of a pond at an angle of $\theta_2 = 45.0^\circ$, and you see a fish under the water. The rays that are emitted from one point on the body of the fish are shown as a semitransparent cone, with the center line of the cone represented by a solid ray.

The apparent depth of the fish is located along the upper dashed horizontal line in Figure 32.40, extrapolated from the direction of the light rays as they enter your eye. This extrapolated line makes an angle $\theta_2 = 45.0^\circ$, with the normal to the surface of the water.

Using Snell's Law, we can calculate the angle θ_1 that the light rays from the fish must make at the surface of the water:

$$n_{\text{air}} \sin \theta_2 = n_{\text{water}} \sin \theta_1.$$

Taking $n_{\text{air}} = 1.00$ and $n_{\text{water}} = 1.333$ from Table 32.2, we can calculate θ_1:

$$\theta_1 = \sin^{-1}\left(\frac{\sin\theta_2}{n_{\text{water}}}\right) = \sin^{-1}\left(\frac{\sin\ 45.0^\circ}{1.333}\right) = 32.0^\circ.$$

We define the horizontal distance between the point where the light rays intersect the surface of the water and a point on the back of the fish as x, as shown in Figure 32.40. We can then define the red triangle and the blue triangle. From the red triangle, we get

$$\tan\theta_2 = \frac{x}{d_{\text{apparent}}},$$

and from the blue triangle, we obtain

$$\tan\theta_1 = \frac{x}{d_{\text{actual}}}.$$

Solving each of these two equations for x and setting the resulting expressions equal to each other gives us

$$d_{\text{actual}}\tan\theta_1 = d_{\text{apparent}}\tan\theta_2,$$

which we can solve for the apparent depth of the fish:

$$d_{\text{apparent}} = \frac{d_{\text{actual}}\tan\theta_1}{\tan\theta_2} = \frac{(1.50\ \text{m})\tan(32.0^\circ)}{\tan(45.0^\circ)} = 0.937$$

Thus, the fish appears to be closer to the water surface than it actually is.

Concept Check 32.7

If the same fish swimming at the same depth is seen by a different observer whose line of sight is at an angle larger than that given in Example 32.3, then, to that observer, the fish's apparent depth will be

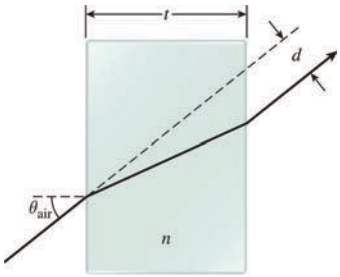
a) larger than that calculated in Example 32.3.

b) the same as that calculated in Example 32.3.

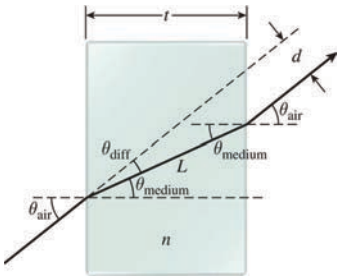
c) smaller than that calculated in Example 32.3.

SOLVED PROBLEM 32.2 Displacement of Light Rays in Transparent Material

A light ray in air is incident on a sheet of transparent material with thickness $t = 5.90\,\text{cm}$ and with index of refraction $n = 1.50$. The angle of incidence is $\theta_{\text{air}} = 38.5^\circ$ (Figure 32.41a).



(a)



(b)

FIGURE 32.41 (a) Light ray incident on a sheet of transparent material with thickness *t* and index of refraction *n*. (b) Angles of incidence and refraction as the ray enters and exits the sheet.

PROBLEM

What is the distance d that the light ray is displaced after it has passed through the sheet?

SOLUTION

THINK

The light ray refracts toward the normal as it enters the transparent sheet and refracts away from the normal as it exits the transparent sheet. After passing through the sheet, the light ray is parallel to the incident light ray, but is displaced. Using Snell's Law, we can calculate the angle of refraction in the transparent sheet. Having that angle, we can use trigonometry to calculate the displacement of the light ray after passing through the sheet.

SKETCH

Figure 32.41b shows the geometry for the light ray passing through the transparent sheet.

RESEARCH

The light ray is incident on the sheet with an angle θ_{air}. Snell's Law relates the incident angle to the refracted angle, θ_{medium}, through the index of refraction of the transparent material, n:

$$n = \frac{\sin\theta_{\text{air}}}{\sin\theta_{\text{medium}}}.$$

We can solve this equation for the refraction angle:

$$\theta_{\text{medium}} = \sin^{-1}\left(\frac{\sin\theta_{\text{air}}}{n}\right). \qquad \text{(i)}$$

The distance the light ray travels in the transparent sheet is L. Using Figure 32.41b, we can relate the thickness of the sheet, t, to the refraction angle:

$$\cos\theta_{\text{medium}} = \frac{t}{L}. \qquad \text{(ii)}$$

If θ_{diff} is the difference between the incident angle and the refraction angle, as shown in Figure 32.41b, then

$$\theta_{\text{diff}} = \theta_{\text{air}} - \theta_{\text{medium}}. \qquad \text{(iii)}$$

We can see in Figure 32.41b that the displacement of the light ray, d, can be related to the distance the light ray travels in the sheet and the difference between the incident angle and the refracted angle:

$$\sin\theta_{\text{diff}} = \frac{d}{L}. \qquad \text{(iv)}$$

SIMPLIFY

We can combine equations (ii), (iii), and (iv) to obtain

$$d = L\sin\theta_{\text{diff}} = \frac{t}{\cos\theta_{\text{medium}}}\sin(\theta_{\text{air}} - \theta_{\text{medium}}), \text{(v)}$$

where, from equation (i),

$$\theta_{\text{medium}} = \sin^{-1}\left(\frac{\sin\theta_{\text{air}}}{n}\right).$$

CALCULATE

We first calculate the angle of refraction, using equation (i):

$$\theta_{\text{medium}} = \sin^{-1}\left(\frac{\sin(38.5^\circ)}{1.50}\right) = 24.5199^\circ.$$

Then we calculate the displacement of the light ray, using equation (v)

$$d = \frac{5.90\text{ cm}}{\cos(24.5199^\circ)}\sin(38.5^\circ - 24.5119^\circ) = 1.56663\text{ cm}.$$

ROUND

We report our result to three significant figures:

$$d = 1.57\text{ cm}.$$

DOUBLE-CHECK

If the light ray were incident perpendicularly on the sheet ($\theta_{\text{air}} = 0^\circ$), the displacement of the ray would be zero. To calculate what the displacement would be in the limit as the incident angle approaches $\theta_{\text{air}} = 90^\circ$, we can rewrite equation (v) as

$$d = \frac{t\sin(\theta_{\text{air}} - \theta_{\text{medium}})}{\cos\theta_{\text{medium}}} = t\frac{\sin\theta_{\text{air}}\cos\theta_{\text{medium}} - \cos\theta_{\text{air}}}{\cos\theta_{\text{medium}}}$$

using the trigonometric identity $\sin(\alpha - \beta) = \sin\alpha\cos\beta - \cos\alpha\sin\beta$. Taking $\theta_{\text{air}} = 90^\circ$, we get

$$d = t\frac{1(\cos\theta_{\text{medium}}) - 0(\sin\theta_{\text{medium}})}{\cos\theta_{\text{medium}}} = t.$$

Thus, our result must be between zero and the thickness of the sheet. Our result is $d = 1.57$ cm, while $d = 5.90$ cm for

$\theta_{\text{air}} = 90^\circ$, so our result seems reasonable.

Concept Check 32.8

In Solved Problem 32.2, the sheet of transparent material was surrounded by air. If the sheet were surrounded by water instead, what would happen to the displacement of the light ray with the same angle of incidence? (Assume that the index of refraction of the transparent material is still larger than that of water.)

a) It would be larger.

b) It would be the same.

c) It would be smaller.

Total Internal Reflection

Now let's consider light traveling in an optical medium with index of refraction n_1 and crossing a boundary into another optical medium with a lower index of refraction n_2 such that $n_2 < n_1$. In this case, the light is bent away from the normal. As we increase the angle of incidence, θ_1, the angle of the transmitted light, θ_2, can approach 90°. When θ_1 exceeds the angle for which $\theta_2 = 90^\circ$, **total internal reflection** takes place instead of refraction; all of the light is reflected internally. The critical angle, θ_c, at which total internal reflection takes place is given by

$$\frac{n_2}{n_1} = \frac{\sin\theta_1}{\sin\theta_2} = \frac{\sin\theta_\text{c}}{\sin 90^\circ}$$

or, because $\sin 90^\circ = 1$,

$$\sin\theta_\text{c} = \frac{n_2}{n_1} (\text{for } n_2 \leq n_1). \qquad \textbf{(32.13)}$$

You can see from this equation that total internal reflection can occur only for light traveling from a medium with a higher index of refraction into a medium with a lower index of refraction, because the sine of an angle cannot be greater than 1. At angles less than θ_c, some light is reflected and some is transmitted. At angles greater than θ_c, all the light is reflected and none is transmitted.

Concept Check 32.9

At the boundary between water and air, the critical angle for total internal reflection in the water is 48°. What does a diver in a swimming pool see when looking from under the water toward the surface at an angle greater than 48°?

a) the sky above the pool

b) the reflection of the floor of the pool

c) a superposition of the sky and the reflection of the floor

d) nothing, because no light can reach the eyes of a diver looking toward the surface at this angle

If the second medium is air, then we can take $n_2 = 1$ and obtain an expression for the critical angle for total internal reflection for light leaving a medium with index of refraction n and entering air:

$$\sin\theta_c = \frac{1}{n}. \qquad \textbf{(32.14)}$$

Total internal reflection is illustrated in Figure 32.42. In this figure, light rays are traveling in glass with index of refraction n from lower right to upper left. In Figure 32.42a, light rays are incident on the boundary between glass and air and are refracted according to Snell's Law. In Figure 32.42b, light rays are incident on the boundary at the critical angle of total internal reflection, θ_c. At this angle, the refracted rays would have an angle of $\theta_2 = 90^\circ$, as depicted by the dashed arrow. Light rays in Figure 32.42c are incident on the boundary with an angle greater than the critical angle of total internal reflection, $\theta_1 > \theta_c$, so all the light is reflected

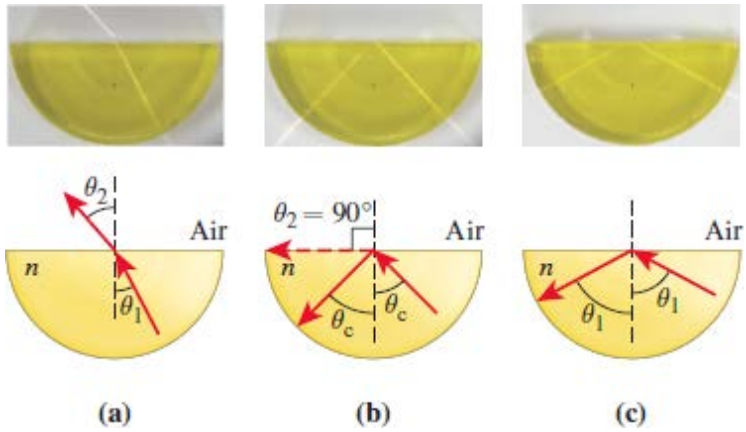


FIGURE 32.42 Light rays traveling through glass with index of refraction n from the lower right to the upper left are incident on the boundary between glass and air. The top panels are photographs and the lower panels are drawings illustrating the paths of the light rays. (a) Light is reflected at the boundary. (A small amount of light is also reflected by the boundary, but is too weak to show up in the photograph.) (b) Light is incident on the boundary at the critical angle for total internal reflection. (c) Light is totally internally reflected at the boundary.

W. Bauer and G. D. Westfall

Optical Fibers

An important application of total internal reflection is the transmission of light in **optical fibers**. Light is shone into a fiber so that the angle of incidence at the end surface of the fiber is greater than the critical angle for total internal reflection. The light is then transported the length of the fiber as it bounces repeatedly from the inner surface. Thus, optical fibers can be used to transport light from a source to a destination. Figure 32.43 shows a bundle of optical fibers with their ends open to the camera. The other end of each fiber is optically connected to a light source. Note that optical fibers can transport light in directions other than a straight line. The fiber may be bent, as long as the radius of curvature of the bend is not small enough to allow the light traveling in the fiber to have angles of incidence θ_{i} less than θ_{c}. If $\theta_i < \theta_c$, the light will be absorbed by the cladding around the core of the fiber. These arguments are applicable to optical fibers with core diameters greater than 10 μm. that is, large compared to the wavelength of light. Charles Kao received the 2009 Nobel Prize in Physics, along with with Willard Boyle and George Smith, for his pioneering work on optical fibers.

FIGURE 32.43
Light transported from a light source by optical fibers.

W. Bauer and G. D. Westfall

One type of optical fiber used for digital communications consists of a glass core surrounded by cladding, which is composed of glass with a lower index of refraction than the core. The cladding is coated to prevent damage (Figure 32.44).

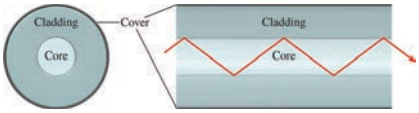

FIGURE 32.44 The structure of an optical fiber incorporating total internal reflection.

For a typical commercial optical fiber, the core material is silicon dioxide (SiO_2) doped with germanium (Ge) to increase its index of refraction. The typical commercial fiber can transmit light 500 m with small losses. The light is generated using light-emitting diodes (LEDs) that produce light with a long wavelength. The light is generated as short pulses. Small light losses do not affect digital signals because digital signals are transmitted as binary bits rather than as analog signals. As long as the bits are registered correctly, the information is transmitted flawlessly, as opposed to analog signals, which would be directly degraded by any signal loss. Every 500 m the signals are received, amplified, and retransmitted. Thus, data immune to interference can be transmitted at very high rates over long distances. These advantages explain why fiber optics forms the backbone of the modern Internet.

Optical fibers are also used for analog signal transmission, if the distance over which the signal has to be transported is not too long, up to a few meters. Applications in which optical fibers are used for analog signal transmission include the endoscope and related devices such as the borescope. An endoscope is used to look inside the human body without performing surgery, while a borescope is used to view hard-to-reach places in machinery. A typical endoscope is shown in Figure 32.45a. An endoscope uses a small lens to produce an image of the area of interest. The image produced by the lens is focused on one end of a bundle of thousands of optical fibers. The fiber-optics bundle is small enough in diameter and flexible enough to be inserted into the human body through an orifice such as the esophagus. Each fiber transports one pixel of the image to the other end of the bundle of fibers, where a

second lens reproduces the image for viewing by the health professional. An endoscope may have 7,000 to 25,000 image-producing fibers. In addition, another set of optical fibers carries light to illuminate the region of interest. Often the lens end of the endoscope can be moved (articulated) remotely to view the desired area.

SOLVED PROBLEM 32.3 Optical Fiber

Consider a long optical fiber with index of refraction $n = 1.265$ that is surrounded by air. (There is no cladding.) The end of the fiber is polished so that it is flat and perpendicular to the length of the fiber. A light ray from a laser is incident from air onto the center of the circular face of the end of the fiber.

PROBLEM

What is the maximum angle of incidence for this light ray such that it will be confined and transported by the optical fiber? (Neglect any reflection as the light ray enters the fiber.)

SOLUTION

THINK

The light ray will refract as it enters the optical fiber. If the angle of incidence on the end surface of the optical fiber is greater than the critical angle for total internal reflection, then the light is transmitted in the fiber without loss.

SKETCH

Figure 32.46 shows a sketch of the light ray entering the optical fiber and reflecting off its inner surface.

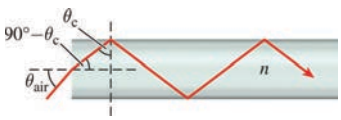

FIGURE 32.46
Light entering an optical fiber and undergoing total internal reflection.

RESEARCH

The critical angle for total internal reflection, θ_c, in the fiber for light entering from air is given by

$$\sin\theta_c = \frac{1}{n}, \qquad \text{(i)}$$

where n is the index of refraction of the optical fiber. For the light entering the optical fiber, Snell's Law tells us that, since $n_{\text{air}} = 1$,

$$\sin\theta_{\text{air}} = n\sin\theta_{\text{medium}}, \qquad \text{(ii)}$$

where θ_{medium} is the angle of the refracted light ray in the fiber. From Figure 32.46 we can see that

$$\theta_{\text{medium}} = 90^\circ - \theta_c. \qquad \text{(iii)}$$

SIMPLIFY

We can solve equation (ii) to obtain the maximum angle of incidence,

$$\theta_{\text{air}} = \sin^{-1}(n\sin\theta_{\text{medium}}).$$

Using equation (iii) we can write

$$\theta_{\text{air}} = \sin^{-1}(n\sin(90^\circ - \theta_c)) = \sin^{-1}(n\cos\theta_c),$$

where we have used the trigonometric identity $\sin(90^\circ - \alpha) = \cos\alpha$. We can then use equation (i) to obtain

$$\theta_{\text{air}} = \sin^{-1}\left(n\cos\left(\sin^{-1}\left(\frac{1}{n}\right)\right)\right).$$

CALCULATE

Putting in the numerical values, we get

$$\theta_{\text{air}} = \sin^{-1}\left((1.265)\ \cos\left(\sin^{-1}\left(\frac{1}{1.265}\right)\right)\right) = 50.7816^{\circ}$$

ROUND

We report our result to four significant figures, because the index of refraction was given with this accuracy:

$$\theta_{\text{air}} = 50.78^{\circ}.$$

DOUBLE-CHECK

The critical angle of total internal reflection for the optical fiber is

$$\theta_{\text{c}} = \sin^{-1}\left(\frac{1}{1.265}\right) = 52.23^{\circ}.$$

Applying Snell's Law at the end surface of the optical fiber gives us

$$\theta_{\text{medium}} = \sin^{-1}\left(\frac{\sin(50.78^{\circ})}{1.265}\right) = 37.77^{\circ}.$$

Thus, $\theta_{\text{medium}} = 37.77^{\circ} = 90^{\circ} - \theta_{c} = 90^{\circ} - 52.23^{\circ} = 37.77^{\circ}$, and our result appears reasonable.

Mirages

A mirage is often associated with traveling in the desert. You seem to see an oasis with water in the distance. As you approach the welcome sight, it disappears. However, you don't have to be traveling in the desert to observe this phenomenon. You can often see a mirage when traveling on a long, straight highway on a hot day. An example of such a mirage is shown in Figure 32.47a.

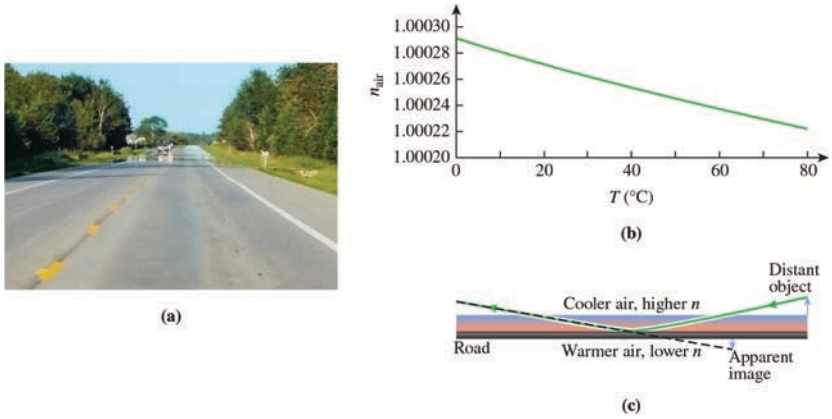

FIGURE 32.47 (a) A mirage on a hot road. There appears to be water on the road and objects appear to be reflected from the surface of that water. (b) The index of refraction of air as a function of temperature. (c) A ray diagram showing light from a distant object being refracted in the air layer near a hot road surface.

a: W. Bauer and G. D. Westfall

The mirage is caused by refraction in the air near the surface of the hot road. The air near the surface of the road is warmer than the air farther from the surface. As shown in Figure 32.47b, the index of refraction of air goes down as its temperature goes up. Thus, the air near the road has a lower index of refraction than the cooler air above it. As light from distant objects passes through the warmer air layer, it is refracted upward, as illustrated inFigure 32.47c. The appearance of water is created by light refracted from

the sky. You see what seems to be light reflected off the surface of water, as shown in Figure 32.47a. Other objects are also visible in the mirage shown in Figure 32.47a, such as trees and car headlights. As you keep driving, you soon find that there is no water standing on the road.

Chromatic Dispersion

The index of refraction of an optical medium depends on the wavelength of the light traveling in that medium. This dependence of the index of refraction on the wavelength of the light means that light of different colors is refracted differently at the boundary between two optical media. This effect is called **chromatic dispersion**.

In general, the index of refraction for a given optical medium is greater for shorter wavelengths than for longer wavelengths. Therefore, blue light is refracted more than red light. We can see that $\theta_b < \theta_r$ in Figure 32.48.

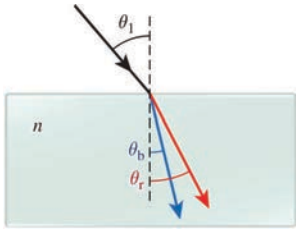

FIGURE 32.48 Chromatic dispersion for light refracted across the boundary of two optical media.

White light consists of a superposition of all visible wavelengths. When a beam of white light is projected onto a glass prism (Figure 32.49), the incident white light separates into the different visible wavelengths, because each wavelength is refracted at a different angle. Figure 32.49 shows three refracted light rays, for red, green, and blue light, but of course white light contains a continuum of wavelengths, as can be seen in a rainbow.

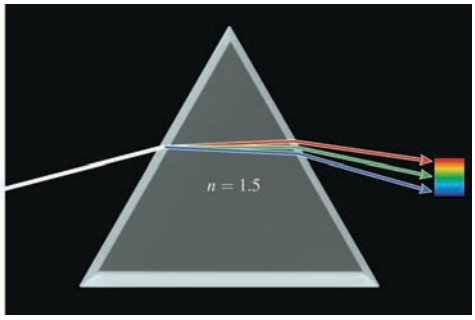

FIGURE 32.49 White light incident on a glass prism is separated into its component colors by chromatic dispersion.

A rainbow is a common example of chromatic dispersion (Figure 32.50). When water drops are suspended in the air and you observe them with the Sun at your back, you see a rainbow. The white light from the Sun enters a water drop, refracts at the surface of the drop, and is transmitted through the drop to the far side. Here it is totally internally reflected and is then transmitted again to the surface of the drop, where it exits the drop and is refracted again. In the two refraction steps, the index of refraction is different for different wavelengths. The index of refraction for green light in water is 1.333, while the index of refraction for blue light is 1.337, and for red light it is 1.331. The indexes of refraction for all the colors form a continuum of values.

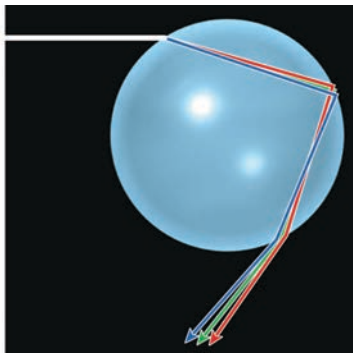

FIGURE 32.50 Chromatic dispersion in a spherical drop of water produces a rainbow.

A typical rainbow is shown in Figure 32.1. You can see the blue light along the inner curve of the rainbow and the red light on the outer curve. The arc of the rainbow represents an average 42° angle from the direction of the sunlight. Another feature of rainbows is evident in this photograph: The region inside the arc of the rainbow appears to be brighter than the region outside the arc. You can understand this phenomenon by looking at the path light rays take as they are refracted and reflected in the raindrops (Figure 32.51).

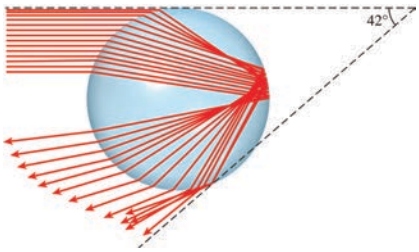

FIGURE 32.51 The paths taken by parallel light rays in a spherical drop of water.

You can see from this diagram that most of the light that is refracted and reflected back to the observer has an angle less than 42° from the direction of the sunlight. At angles smaller than 42°, most of the light is refracted and reflected back to the observer, although no separation of the different wavelengths is observed because dispersed colors from one ray merge with those from another ray and form white light. At larger angles, no light is sent back to an observer—thus, outside the arc of the rainbow, much less light appears. However, some light still appears there because it is scattered from other sources.

Figure 32.1 also contains a secondary rainbow. The secondary rainbow appears at a larger angle than the primary rainbow, and in it the order of the colors is reversed. The secondary rainbow is created by light that reflects twice inside the raindrop (Figure 32.52). In contrast to the situation shown in Figure 32.50, when

the ray in Figure 32.52 strikes the drop surface the third time (after one refraction and one reflection), not all of the light gets refracted and leaves the drop. Instead some of it gets internally reflected again and then refracted out of the drop, forming the secondary rainbow. In Figure 32.52, you can see that the angles of the emerging blue and red light are reversed compared to the blue and red light shown in Figure 32.50 for the primary rainbow. (For the secondary rainbow there is also a preferred angle, in this case approximately 50°, at which parallel rays entering the drop scatter for the secondary rainbow.)

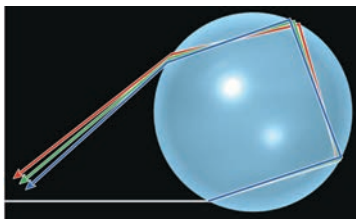

FIGURE 32.52
Chromatic dispersion and double reflection in a raindrop to produce a secondary rainbow.

Finally, combining our observations for the primary and secondary rainbows yields a quantitative understanding of the physical phenomena underlying Figure 32.1. The observed angles of the primary and secondary rainbows with respect to the sunlight are sketched in Figure 32.53.

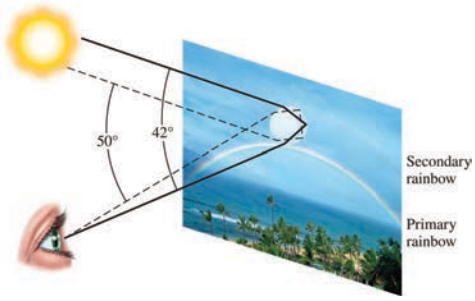

FIGURE 32.53 Geometry of the scattering of light in forming primary and secondary rainbows.

W. Bauer and G. D. Westfall

Polarization by Reflection

The phenomenon of polarization was described in Chapter 31. Here we deal with a special way to create polarized, or at least partially polarized, light. When light is incident from air on an optical medium such as glass or water, some light is reflected and some light is refracted. The light reflected in this situation is partially polarized. When light is reflected at a certain angle, called the **Brewster angle** θ_B, the reflected light is completely horizontally polarized, as illustrated in Figure 32.54.

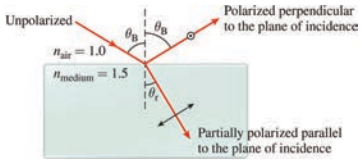

FIGURE 32.54
Unpolarized light is incident from air on a surface. When the incident angle is equal to the Brewster angle, θ_B, the reflected light is 100% polarized perpendicular to the plane of incidence. The refracted light is partially polarized parallel to the plane of incidence.

The Brewster angle is named after Scottish physicist Sir David Brewster (1781–1868), who demonstrated this effect in 1815. The Brewster angle occurs when the reflected rays are perpendicular to the refracted rays. Snell's Law tells us that

$$n_{\text{air}} \sin \theta_B = n_{\text{medium}} \sin \theta_r,$$

where θ_r is the angle of the refracted ray. Figure 32.54 shows that

$$180^\circ = \theta_\text{B} + \theta_\text{r} + 90^\circ$$

because the reflected rays and the refracted rays are perpendicular to each other. This relationship between the angles can be rewritten as

$$\theta_\text{r} = 90^\circ - \theta_\text{B}.$$

Substituting this result into Snell's Law gives

$$n_\text{air} \sin\theta_\text{B} = n_\text{medium} \sin(90^\circ - \theta_\text{B}) = n_\text{medium} \cos\theta_\text{B},$$

which can be rearranged to finally obtain

$$\frac{n_\text{medium}}{n_\text{air}} = \tan\theta_\text{B}, \qquad \textbf{(32.15)}$$

where we have made use of the trigonometric identity $\tan\theta = \sin\theta/\cos\theta$. Equation 32.15 is called **Brewster's Law**.

The fact that light in air reflected off the surface of water is partially horizontally polarized means that the glare of sunlight off surfaces of water can be blocked by sunglasses that are covered with a polarization filter that allows only vertically polarized light to pass through.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- The angle of incidence equals the angle of reflection, $\theta_{\mathrm{i}} = \theta_{\mathrm{r}}$.
- The focal length of a spherical mirror is equal to half its radius of curvature, $f = \frac{1}{2}R$. The radius, R, is positive for converging (concave) mirrors and negative for diverging (convex) mirrors.
- For images formed by spherical mirrors, the object distance, the image distance, and the focal length of the mirror are related by the mirror equation, $\frac{1}{d_0} + \frac{1}{d_{\mathrm{i}}} = \frac{1}{f}$. Here d_{o} is always positive, while d_{i} is positive if the image is on the same side of the mirror as the object and negative if the image is on the other side. The focal length f, is positive for converging (concave) mirrors and negative for diverging (convex) mirrors.
- The index of refraction of a medium is defined as the ratio of the speed of light in vacuum to the speed of light in the medium, $n = c/v$.
- Light is refracted (changes direction) as it crosses the boundary between two media with different indices of refraction. This refraction is governed by Snell's Law: $n_1 \sin\theta_1 = n_2 \sin\theta_2$.
- The critical angle for total internal reflection at the boundary between two media with different indices of refraction is given by $\sin\theta_{\mathrm{c}} = \frac{n_2}{n_1}$ (for $n_2 \leq n_1$).
- The Brewster angle, θ_{B}, is the angle of incidence of light from air to a medium with a higher index of refraction at which the reflected light is completely horizontally polarized. The angle is given by Brewster's Law: $\tan\theta_{\mathrm{B}} = n_{\mathrm{medium}}/n_{\mathrm{air}}$.

ANSWERS TO SELF-TEST OPPORTUNITIES

32.1
$$d_{\mathrm{i}} = \frac{d_0 f}{d_0 - f} = \frac{(2.50\ \mathrm{m})(-0.500\ \mathrm{m})}{(2.50\ \mathrm{m}) - (-0.500\ \mathrm{m})} = -0.417\ \mathrm{m},$$
$$m = -\frac{d_{\mathrm{i}}}{d_o} = -\frac{-0.417\ \mathrm{m}}{2.50\ \mathrm{m}} = 0.167.$$

Thus, you see an upright, smaller version of yourself.

32.2 We can use this result from Derivation 32.2:

$$y = R\left(1 - \frac{1}{2\cos\left(\sin^{-1}(d/R)\right)}\right).$$

As the position gets closer to the optic axis, the distance for the crossing point gets closer to the focal length, $f = R/2 = 3.60$ cm.

Distance from Axis (cm)	**Distance from Mirror (cm)**
0.720	3.58
0.800	3.58
1.80	3.48
3.60	3.04

32.3 Kinetic energy of rotation is $K = \frac{1}{5}m\omega^2x^2$; potential energy is $U = mgy$. Set them equal and find $y = x^2\omega^2/2g$.

32.4 Depending on the time of day and of the year, the Sun moves across the sky on a path that depends on the azimuthal and polar angles. So, in general, one axis of rotation is not sufficient to keep the Sun's incident rays always normal to a surface. However,

rotation about the long axis is sufficient to keep the Sun in the plane created by the optical axis of the parabola and the rotation axis. The variation in the radiation intensity is then a function of the cosine of the angle of the Sun relative to the optical axis in that plane. However, rotating the parabolic troughs about an axis perpendicular to their long axis would be very expensive. So the loss of the intensity of sunlight has to be accepted for economic reasons.

PROBLEM-SOLVING GUIDELINES

1. Drawing a clear, well-labeled diagram should be the first step in solving almost any optics problem. Include all the information you know and all the information you need to find. Remember that angles are measured from the normal to a surface, not to the surface itself.

2. You normally need to draw only two principal rays to locate an image formed by mirrors, but you should draw a third ray as a check that the first two are drawn correctly. Even if you need to solve a problem using the mirror equation, an accurate drawing can help you approximate the answers as a check on your calculations.

3. When you calculate distances for mirrors, remember the sign conventions and be careful to use them correctly. If a diagram indicates an inverted image, say, but your result does not have a negative sign, go back to the starting equation and check the signs of all distances and focal lengths.

4. Remember that when a ray diagram for refraction shows a light ray crossing the boundary from a medium with a lower index of refraction into a medium with a higher index of refraction, the refracted ray will be closer to the normal than the incident ray.

MULTIPLE-CHOICE QUESTIONS

32.1 Legend says that Archimedes set the Roman fleet on fire as it was invading Syracuse. Archimedes created a huge _____ mirror and used it to focus the Sun's rays on the Roman vessels.

a) plane

b) parabolic diverging

c) parabolic converging

32.2 Which of the following interface combinations has the smallest critical angle?

a) light traveling from ice to diamond

b) light traveling from quartz to Lucite

c) light traveling from diamond to glass

d) light traveling from Lucite to diamond

e) light traveling from Lucite to quartz

32.3 For specular reflection of a light ray, the angle of incidence

a) must be equal to the angle of reflection.

b) is always less than the angle of reflection.

c) is always greater than the angle of reflection.

d) is equal to 90°—the angle of reflection.

e) may be greater than, less than, or equal to the angle of reflection.

32.4 Standing by a pool filled with water, under what condition will you see a reflection of the scenery on the opposite side through total internal reflection of the light from the scenery?

a) Your eyes are level with the water.

b) You observe the pool at an angle of 41.8°.

c) There is no condition under which this can occur.

d) You observe the pool at an angle of 48.2°.

32.5 You are using a mirror and a camera to make a self-portrait. You focus the camera on yourself through the mirror. The mirror is a distance D away from you. To what distance should you set the range of focus on the camera?

a) D

b) $2D$

c) $D/2$

d) $4D$

32.6 What is the magnification for a plane mirror?

a) +1

b) -1

c) greater than +1

d) not defined for a plane mirror

32.7 A small object is placed in front of a converging mirror with radius $R = 7.50$ cm so that the image distance equals the object distance. How far is this object from the mirror?

a) 2.50 cm

b) 5.00 cm

c) 7.50 cm

d) 10.0 cm

e) 15.0 cm

32.8 Sunlight strikes a piece of glass at an angle of incidence of $\theta_{\text{i}} = 33.4^\circ$. What is the difference between the angle of refraction of a red light ray ($\lambda = 660.0$ nm) and that of a violet light ray ($\lambda = 410.0$ nm)? The glass's index of refraction is $n = 1.520$ for red light and $n = 1.538$ for violet light.

a) 0.03°

b) 0.12°

c) 0.19°

d) 0.26°

e) 0.82°

32.9 The image of yourself that you see in a bathroom mirror is

a) left-right inverted.

b) front-to-back inverted.

c) bottom-to-top inverted.

d) not inverted.

32.10 Where do you have to place an object in front of a concave mirror with focal length *f* for the image to be the same size as the object?

a) at $d_0 = 0.5f$

b) at $d_0 = f$

c) at $d_0 = 2f$

d) at $d_0 = 2.5f$

e) none of the above

32.11 You are looking down into a swimming pool at an angle of 20° relative to the vertical, and you see a coin at the bottom of the pool. This coin appears to you to be at

a) a lesser depth than it really is.

b) the same depth as it really is.

c) a greater depth than it really is.

32.12 You are looking straight down into a swimming pool, that is, at an angle of 0° relative to the vertical, and you see a coin at the bottom of the pool. This coin appears to you to be at

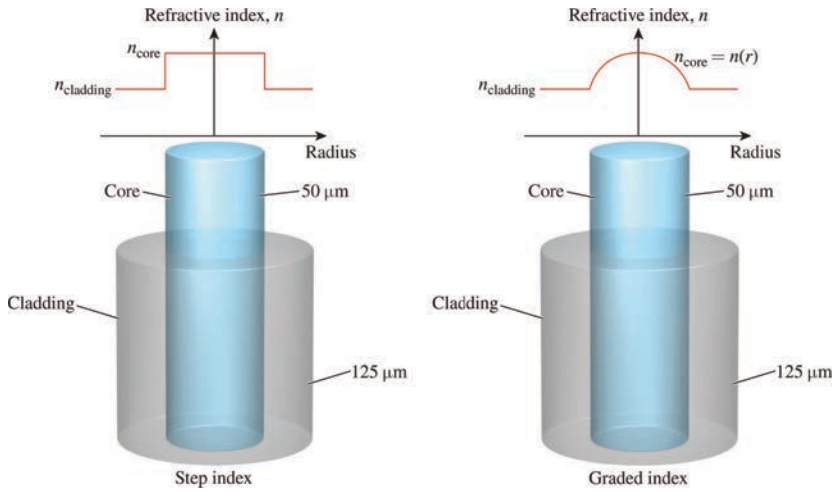
a) a lesser depth than it really is.

b) the same depth as it really is.

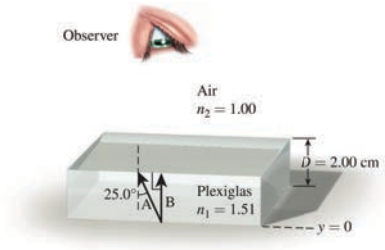
c) a greater depth than it really is.

CONCEPTUAL QUESTIONS

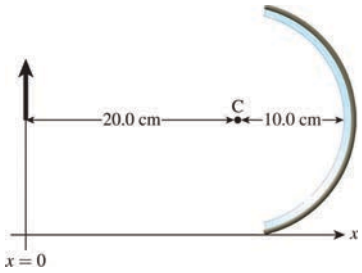
32.13 The figure shows the difference between the refractive index profile of a *step index fiber* and the refractive index profile of a *graded index fiber*. Applying geometric optics principles, comment on the path followed by a light ray entering each of the optic fibers.



32.14 A slab of Plexiglas 2.00 cm thick with index of refraction 1.51 is placed over a physics textbook. The slab has parallel sides. The text is at height $y = 0$. Consider two rays of light, A and B, that originate at the letter "t" in the text under the Plexiglas and travel toward an observer who is above the Plexiglas, looking down. **Draw** on the figure the apparent y-position of the letter under the Plexiglas as seen by the observer. (*Hint:* From where in the Plexiglas do the two rays appear to originate for the observer?) You can easily do this experiment yourself. If you do not have a block of glass or Plexiglas, you can try placing a flat-bottomed drinking glass over the text.



32.15 A concave spherical mirror is used to create an image of an object 5.00 cm tall that is located at position $x = 0$ cm, which is 20.0 cm from point *C*, the center of curvature of the mirror, as shown in the figure. The magnitude of the radius of curvature of the mirror is 10.0 cm. Without changing the mirror, how can you reduce the spherical aberration produced by it? Are there any disadvantages to your approach to reducing the spherical aberration?



32.16 If you look at an object at the bottom of a pool, the pool looks less deep than it actually is.

a) From what you have learned, calculate how deep a pool seems to be if it is actually 4 feet deep and you look directly down on it. The index of refraction of water is 1.33.

b) Would the pool look more or less deep than it actually is if you looked at it from an angle other than vertical? Answer this qualitatively, without using an equation.

32.17 Why does refraction occur? That is, what is the physical reason a wave moves with a different velocity when it passes from one medium into another?

32.18 Many optical fibers have minimum specified bending radii. Why?

32.19 A physics student is eying a steel drum, the top part of which has the approximate shape of a concave spherical surface. The

surface is sufficiently polished that the student can just make out the reflection of her finger when she places it above the drum. As she slowly moves her finger toward the surface and then away from it, you ask her what she is doing. She replies that she is estimating the radius of curvature of the drum. How can she do that?

32.20 State whether the following is true or false and explain your answer: The wavelength of He-Ne laser light in water is less than its wavelength in air. (The index of refraction of water is 1.33.)

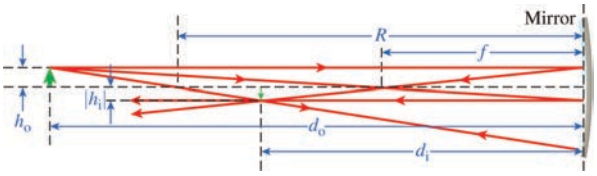
32.21 Among the instruments Apollo astronauts left on the Moon were reflectors for bouncing laser beams back to Earth. These made it possible to measure the distance from the Earth to the Moon with unprecedented precision (uncertainties of a few centimeters in 384,000 km), for the study of both celestial mechanics and Earth's plate tectonics. The reflectors consist not of ordinary mirrors, but of arrays of *corner cubes,* each constructed of three square plane mirrors fixed perpendicular to each other, as adjacent faces of a cube. Why? Explain the functioning and advantages of this design.

32.22 A 45°-45°-90° triangular prism can be used to reverse a light beam: The light enters perpendicular to the hypotenuse of the prism, reflects off each leg, and emerges perpendicular to the hypotenuse again. The surfaces of the prism are *not* silvered. If the prism is made of glass with index of refraction $n_{glass} = 1.520$ and is surrounded by air, the light beam will be reflected with a minimum loss of intensity (there are reflection losses as the light enters and leaves the prism).

a) Will this work if the prism is *under water,* which has the index of refraction $n_{\mathrm{H_2O}} = 1.333$?

b) Such prisms are used, in preference to mirrors, to bend the optical path in quality binoculars. Why?

32.23 An object is imaged by a converging spherical mirror as shown in the figure. Suppose a black cloth is put between the object and the mirror so that it covers everything above the optic axis. How will the image be affected?



32.24 You are under water in a pond and look up through the smooth surface of the water at the Sun in the sky. Is the Sun in fact higher in the sky than it appears to you, or is it lower?

32.25 Holding a spoon in front of your face, convex side toward you, estimate the location of the image and its magnification.

32.26 A *solar furnace* uses a large parabolic mirror (such mirrors can be several stories high) to focus the light of the Sun to heat a target. A large solar furnace can melt metals. Is it possible to attain temperatures exceeding 6000 K (the temperature of the photosphere of the Sun) in a solar furnace? If so, how? If not, why not?

EXERCISES

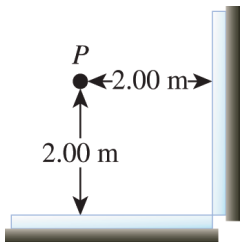
A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 32.2

32.27 A person sits 1.00 m in front of a plane mirror. What is the location of the image?

32.28 A periscope consists of two flat mirrors and is used for viewing objects when an obstacle impedes direct viewing. Suppose Curious George is looking through a periscope, in which the two flat mirrors are separated by a distance $L = 0.400$ m, at the Man in the Yellow Hat, whose hat is at $d_o = 3.00$ m from the upper mirror. What is the distance D of the final image of the yellow hat from the lower mirror?

32.29 A person stands at a point P relative to two plane mirrors oriented at 90.0°, as shown in the figure. How far away from each other do the person's images appear to be?

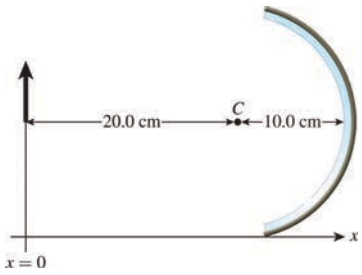


•32.30 Even the best mirrors absorb or transmit some of the light incident on them. The highest-quality mirrors might reflect 99.997% of the incident light. Suppose a cubical "room," 3.00 m on an edge, were constructed with such mirrors for the walls, floor, and ceiling. How slowly would such a room get dark? Estimate the time required for the intensity of light in such a room to fall to 1.00% of its initial value after the only light source in the room was switched off.

Section 32.3

32.31 The radius of curvature of a convex mirror is -25.0 cm. What is its focal length?

32.32 A concave spherical mirror is used to create an image of an object 5.00 cm tall that is located at position $x = 0$ cm, which is 20.0 cm from point *C,* the center of curvature of the mirror, as shown in the figure. The magnitude of the radius of curvature of the mirror is 10.00 cm Calculate the position x_i where the image is formed. Use the coordinate system given in the drawing. What is the height h_i of the image? Is the image upright (pointing up) or inverted (pointing down)? Is it real or virtual?



32.33 Convex mirrors are often used as sideview mirrors on cars. Many such mirrors display the warning "Objects in mirror are closer than they appear." Assume that a convex sideview mirror has a radius of curvature of 14.0 m and that a car is 11.0 m behind the mirror. For a flat mirror, the image distance would be 11.0 m, and the magnification would be 1. Find the image distance and the magnification for this convex mirror.

32.34 A 5.00-cm-tall object is placed 30.0 cm away from a convex mirror with a focal length of -10.0 cm. Determine the size, orientation, and position of the image.

32.35 The magnification of a convex mirror is $0.60\times$ for an object 2.0 m from the mirror. What is the focal length of this mirror?

•**32.36** An object is located at a distance of 100. cm from a concave mirror of focal length 20.0 m. Another concave mirror of focal length 5.00 cm is located 20.0 cm in front of the first concave mirror. The reflecting sides of the two mirrors face each other. What is the location of the final image formed by the two mirrors and the total magnification produced by them in combination?

••**32.37** The shape of an *elliptical* mirror is described by the curve $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$, with semimajor axis a and semiminor axis b. The foci of this ellipse are at the points (c,0) and (−c,0), with $c = \left(a^2 - b^2\right)^{1/2}$. Show that any light ray in the xy-plane that passes through one focus is reflected through the other. "Whispering galleries" make use of this phenomenon for reflecting sound waves.

Section 32.4

32.38 What is the speed of light in crown glass, whose index of refraction is 1.52?

32.39 An optical fiber with an index of refraction of 1.50 is used to transport light of wavelength 400. nm. What is the critical angle for transporting light through this fiber without loss? If the fiber is immersed in water? In oil?

32.40 A helium-neon laser produces light of wavelength $\lambda_{\text{vac}} = 632.8$ nm in vacuum. If this light passes into water, with index of refraction $n = 1.333$, what will each of the following characteristics be?

a) speed

b) frequency

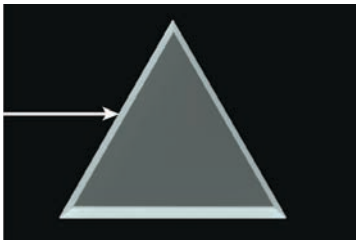
c) wavelength

d) color

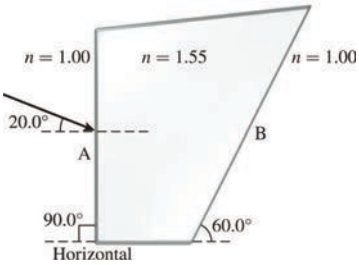
32.41 A light ray is incident from water, whose index of refraction is 1.33, on a plate of glass whose index of refraction is 1.73. What angle of incidence will result in fully polarized reflected light?

•**32.42** Suppose you are standing at the bottom of a swimming pool whose surface is perfectly calm. Looking up, you see a circular window to the "outer world." If your eyes are approximately 2.00 m beneath the surface, what is the diameter of this circular window?

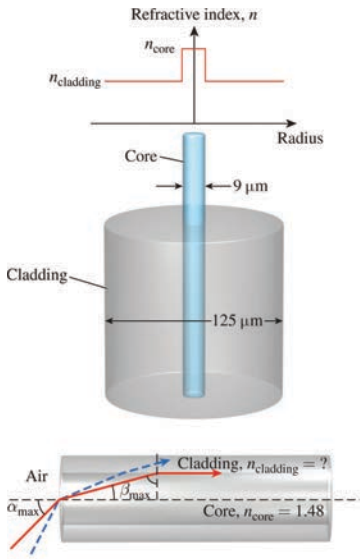
•**32.43** A ray of light of a particular wavelength is incident on an equilateral triangular prism whose index of refraction for light of this wavelength is 1.23. The ray is parallel to the base of the prism as it approaches and enters the prism at the midpoint of one of the sides, as shown in the figure. What is the direction of the ray when it emerges from the prism?



•**32.44** A collimated laser beam strikes the left side (A) of a glass block at an angle of 20.0° with respect to the horizontal, as shown in the figure. The block has an index of refraction of 1.55 and is surrounded by air, with an index of refraction of 1.00. The left side of the glass block is vertical (90.0° from horizontal) while the right side (B) is at an angle of 60.0° from the horizontal. Determine the angle θ_{BT} **with respect to the horizontal** at which the light exits surface B.



•**32.45** In a step index fiber, the index of refraction undergoes a discontinuity (jump) at the core-cladding boundary, as shown in the figure. Infrared light with wavelength 1550 nm propagates through such a fiber by total internal reflection at the core-cladding boundary. The index of refraction of the core for the infrared light is $n_{core} = 1.48$. If the maximum angle, α_{max}, at which light can enter the fiber with no light lost into the cladding is $\alpha_{max} = 14.033^\circ$, calculate the percent difference between the index of refraction of the core and the index of refraction of the cladding.



••**32.46** Refer to Figure 32.51 and prove that the arc of the primary rainbow represents the 42° angle from the direction of the sunlight.

•• **32.47** Use Fermat's Principle to derive the law of reflection.

••**32.48** Fermat's Principle, from which geometric optics can be derived, states that light travels by a path that minimizes the time of travel between points. Consider a light beam that travels a horizontal distance D and a vertical distance h, through two large flat slabs of material that have a vertical interface between them. One slab has a thickness $D/2$ and an index of refraction n_1, and the other has a thickness $D/2$ and an index of refraction n_2. Write the equation relating the indices of refraction and the angles from the horizontal that the light beam makes at the interface (θ_1 and θ_2) which minimize the time for this travel.

Additional Exercises

32.49 Suppose your height is 2.00 m and you are standing 50.0 cm in front of a plane mirror.

a) What is the image distance?

b) What is the image height?

c) Is the image inverted or upright?

d) Is the image real or virtual?

32.50 A light ray of wavelength 700. nm traveling in air ($n_1 = 1.00$) is incident on a boundary with a liquid ($n_2 = 1.63$).

a) What is the frequency of the refracted ray?

b) What is the speed of the refracted ray?

c) What is the wavelength of the refracted ray?

32.51 You have a spherical mirror with a radius of curvature of $+20.0$ cm (so it is concave facing you). You are looking at an object whose image size you want to double so you can see it better. At what locations could you put the object? Where will the images be for these object locations, and will they be real or virtual?

32.52 You are submerged in a swimming pool. What is the maximum angle at which you can see light coming from above the pool surface? That is, what is the angle for total internal reflection from water into air?

32.53 Light hits the surface of water at an incident angle of 30.0° with respect to the normal to the surface. What is the angle between the reflected ray and the refracted ray?

32.54 A spherical metallic Christmas tree ornament has a diameter of 8.00 cm. If Saint Nicholas is by the fireplace, 1.56 m away, where will he see his reflection in the ornament? Is the image real or virtual?

32.55 One of the factors that cause a diamond to sparkle is its relatively small critical angle. Compare the critical angle for diamond in air with that for diamond in water.

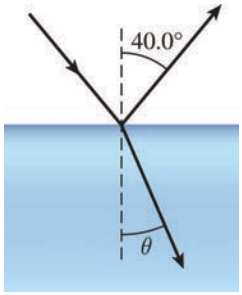
32.56 What kind of image, virtual or real, is formed by a converging mirror when the object is placed a distance away from the mirror that is

a) beyond the center of curvature of the mirror,

b) between the center of curvature and half of the distance to the center of curvature, and

c) closer than half of the distance to the center of curvature?

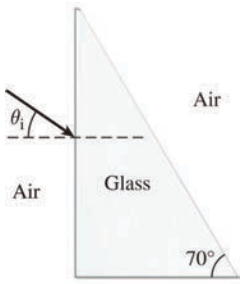
32.57 At what angle θ shown in the figure must a beam of light enter the water for the reflected beam to make an angle of 40.0° with respect to the normal of the water's surface?



•**32.58** A concave mirror forms a real image twice as large as the object. The object is then moved, and the new real image is three times the size of the object. If the image is 75 cm from its initial position, how far was the object moved and what is the focal length of the mirror?

•**32.59** How deep does a point in the middle of a 3.00-m-deep pool appear to be to a person standing beside the pool at a position 2.00 m horizontally from the point? Take the index of refraction for the liquid in the pool to be 1.30 and that for air to be 1.00.

•**32.60** What is the smallest incident angle θ_i at which the light beam shown in the figure will undergo total internal reflection in the prism, if the index of refraction of the prism for light of this wavelength is 1.500?



32.61 Reflection and refraction, like all classical features of light and other electromagnetic waves, are governed by the Maxwell equations. The Maxwell equations are *time-reversal invariant,* which means that any solution of the equations that is reversed in time is also a solution.

a) Suppose some configuration of electric charge density, ρ, current density, $\vec{j}$, electric field, $\vec{E}$, and magnetic field, $\vec{B}$, is a solution of the Maxwell equations. What is the corresponding time-reversed solution?

b) How, then, do one-way mirrors work?

••**32.62** Refer to Example 32.3 and use the numbers provided there. Further, assume that your eyes are at a height of 1.70 m above the water.

a) Calculate the time it takes for light to travel on the path from the fish to your eyes.

b) Calculate the time light would take on a straight-line path from the fish to your eyes.

c) Calculate the time light would take on a path from the fish vertically upward to the water surface and then straight to your eyes.

d) Calculate the time light would take on the straight-line path from the apparent location of the fish to your eyes.

e) What can you say about Fermat's Principle from the results of parts (a) through (d)?

32.63 If you want to construct a liquid mirror of focal length 2.50 m, with what angular velocity do you have to rotate your liquid?

••32.64 One proposal for a space-based telescope is to put a large rotating liquid mirror on the Moon. Suppose you want to use a liquid mirror that is 100.0 m in diameter and has a focal length of 347.5 m. The gravitational acceleration on the Moon is 1.62 m/s^2.

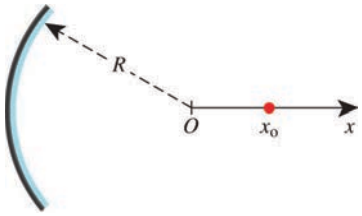
a) What angular velocity does your mirror have?

b) What is the linear speed of a point on the perimeter of the mirror?

c) How high above the center is the perimeter of the mirror?

MULTI-VERSION EXERCISES

32.65 The origin of a coordinate system is placed at the center of curvature of a spherical mirror with radius of curvature $R = 58.1$ cm (see the figure). An object is placed at $x_0 = 19.7$ cm. What is the *x*-coordinate of the image?

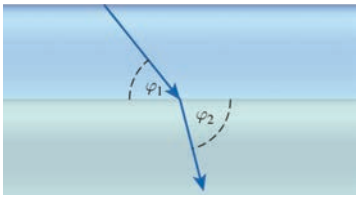


32.66 The origin of a coordinate system is placed at the center of curvature of a spherical mirror with radius of curvature $R = 59.3$ cm (see the figure). An object is placed at $x_0 = 39.5$ cm. What is the mirror's magnification?

32.67 The origin of a coordinate system is placed at the center of a spherical mirror with radius of curvature *R* (see the figure). An object is placed at $x_0 = 10.1$ cm. The image is formed at $x = -7.405$ cm. What is the value of *R*?

32.68 The origin of a coordinate system is placed at the center of curvature of a spherical mirror with radius of curvature *R* (see the figure). An object is placed at $x_0 = 10.3$ cm. The image is formed at $x = -7.548$ cm. What is the focal length of the mirror?

32.69 A layer of methyl alcohol, with index of refraction 1.329, rests on a block of ice, with index of refraction 1.310. A ray of light passes through the methyl alcohol at an angle of $\varphi_1 = 61.07^\circ$ relative to the alcohol-ice boundary. What is the angle φ_2 relative to the boundary at which the ray passes through the ice?



32.70 A layer of a transparent material rests on a block of fused quartz, whose index of refraction is 1.460. A ray of light passes through the unknown material at an angle of $\varphi_1 = 63.65^\circ$ relative to the boundary between the materials and is refracted at an angle of $\varphi_2 = 70.26^\circ$ relative to the boundary. What is the index of refraction of the unknown material?

32.71 A layer of carbon dioxide, with index of refraction 1.00045, rests on a block of ice, with index of refraction 1.310. A ray of light passes through the carbon dioxide at an angle of φ_1 relative to the boundary between the materials and then passes through the ice at an angle of $\varphi_2 = 72.06^\circ$ relative to the boundary. What is the value of φ_1?

32.72 A layer of water, with index of refraction 1.333, rests on a block of an unknown transparent material. A ray of light passes through the water at an angle of $\varphi_1 = 68.77^\circ$ relative to the boundary between the materials and then passes through the unknown material at an angle of $\varphi_2 = 72.98^\circ$ relative to the boundary. What is the speed of light in the unknown material?

The two images in Figure 33.1 are some of the largest and smallest objects we can optically observe with visible light. The image in Figure 33.1a is the Whirlpool Galaxy (M51), with a diameter of about 76,000 light-years $\left(7 \cdot 10^{20}\ \text{m}\right)$, and a distance from Earth of about 23 million light-years $\left(2 \cdot 10^{23}\ \text{m}\right)$. The image in Figure 33.1b shows assorted diatoms found living between crystals of annual sea ice in Antarctica. Diatoms are on the order of 20 microns $\left(2 \cdot 10^{-5}\ \text{m}\right)$ in length. Over the years, the ability to form images of these kinds of objects has completely changed our understanding of biology, astronomy, geology, engineering—in fact, just about every branch of science and technology.

All optical image-forming instruments work from a combination of lenses or mirrors. In a sense, the ideas in this chapter are simply applications of the principles discussed in Chapter 32. However, understanding how an image is formed is essential to interpreting the subject of the image. In this chapter we will examine a variety of image-forming instruments, including the human eye. The same principles of geometric optics govern image formation using other kinds of radiation; we will see some examples of this as well.

WHAT WE WILL LEARN

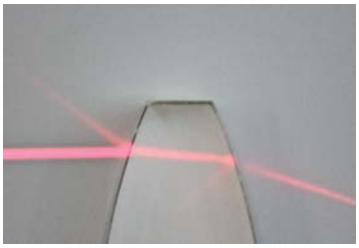
- Lenses can focus light and produce images governed by the Thin-Lens Equation, which states that the inverse of the object distance plus the inverse of the image distance equals the inverse of the focal length of the lens.
- Optical instruments are combinations of mirrors and lenses.
- A single converging lens can be used as a magnifier.
- Two-lens systems are often used in optical instruments.
- Placing a converging lens close to a diverging lens can produce a zoom lens.
- A camera is an optical instrument that records real images produced by a lens.
- The human eye is an optical instrument governed by the Thin-Lens Equation. Various types of lenses are used to correct defects in vision.
- Microscopes are systems of lenses designed to magnify the image of close but very small objects.
- Telescopes are systems of lenses or mirrors designed to magnify the image of distant but very large objects.

33.1 Lenses

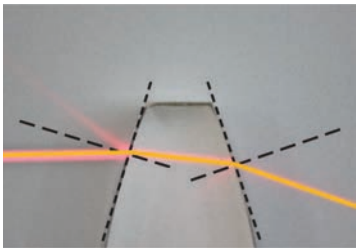
When light is refracted while crossing a curved boundary between two different media, the light rays obey the law of refraction at each point on the boundary. The angle at which the light rays cross the boundary (with respect to the local normal to the boundary) is different along the curve, so the refracted angle is different at different points along the curve. A spherical curved boundary between two optically transparent media forms a spherical surface. If light enters a medium through one spherical surface and then returns to the original medium through another spherical surface, the device that has the spherical surfaces is called a **lens.** Light rays that are initially parallel before they strike the lens are refracted in different directions, depending on the part of the lens they strike. Depending on the shape of the lens, the light rays can be focused or can diverge.

Converging Lenses

Figure 33.2a shows an example of a converging lens. A red light ray hits the left surface. Part of the ray gets reflected, and part of it enters the lens and gets refracted at the surface. It travels in a straight line through the lens until it hits the right surface, where part of it gets reflected and another part of it gets refracted as it leaves the lens. In Figure 33.2b we highlight the path of the twice-refracted ray in yellow. We also draw the two local tangent lines to the curved surfaces of the lens (short-dashed black lines) and the normal lines (long-dashed black lines). It is apparent that the law of reflection and Snell's Law of refraction, which we developed in the previous chapter, also hold here.



(a)



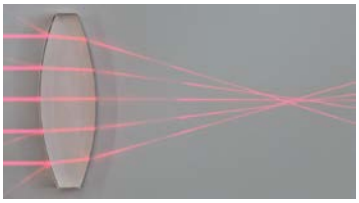
(b)

FIGURE 33.2 (a) A red light ray enters a converging lens from the right and gets refracted at both surfaces. (b) The local tangent lines (short-dashed black lines) and their normal lines (long-dashed) at the locations where the ray hits the surfaces are superimposed.

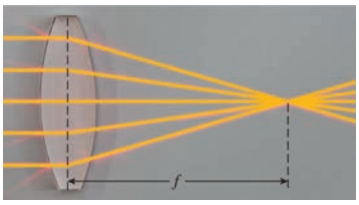
W. Bauer and G. D. Westfall

In Figure 33.3a we show a picture of five parallel light rays hitting the lens and being focused into the same point. In Figure 33.3b we represent the lens by a single dashed black line through its optical center and idealize the double refraction of the real rays with the single refraction of the yellow lines. This is called the *thin-lens approximation*. And from Figure 33.3b it is apparent that this

approximation is justified in this case. Notice also that the center ray in Figure 33.3 does not get refracted. This means that it forms the optic axis.



(a)



(b)

FIGURE 33.3 (a) Five parallel red light rays hit a converging lens from the left and focused at a single point. (b) Representation of the lens by a single dashed line through its center, and refraction of the idealized rays (yellow lines) through the same focal point.

W. Bauer and G. D. Westfall

Concept Check 33.1

If you shift all parallel rays in Figure 33.3 a bit up from their present location, the focal point will

a) move a bit down from its present location.

b) move a bit up from its present location.

c) remain unchanged.

d) move a bit right from its present location.

e) move a bit left from its present location.

Just like for the case of the curved mirrors in Chapter 32, the distance between the optical center and the focal point is called the focal length, f. It is easily verified experimentally that sending parallel rays into the lens from the right makes them converge at a focal point to the left of the lens, which is the same distance from the optic center f as the focal point on the right. The inverse of the focal length is called the **lens power**, P,

$$p = \frac{1}{f}. \qquad \textbf{(33.1)}$$

The power of the lens is measured in **diopters**, D, with $1\,\mathrm{D} = 1\,\mathrm{m}^{-1}$. Eyeglasses and contact lenses are typically characterized in terms of their diopter value.

Lenses can be used to form images, again following the same principles of ray tracing that we developed in the previous chapter. Figure 33.4 shows the geometric construction of the formation of an image using a converging lens. For convenience we use a simple arrow as our object and place its tail on the optic axis. This placement ensures that the tail of the arrow image is also on the optic axis, and we only have to worry about imaging the tip of the arrow. Our object has a height h_o and is located a distance d_o from the center of the lens.

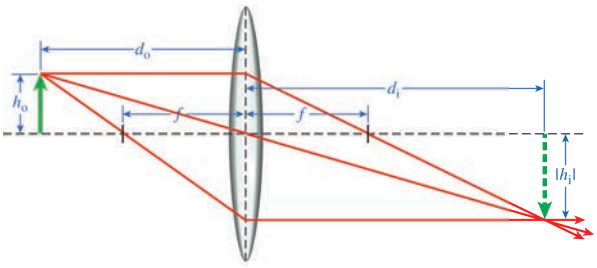


FIGURE 33.4 Real image produced by a converging lens for the case that the object distance is larger than the focal length.

Three special rays are useful for constructing images:

1. The first ray again is drawn from the tip of the arrow parallel to the optic axis and is refracted through the focal point on the opposite side of the lens.
2. A second ray is drawn from the tip of the arrow straight through the center of the lens.
3. A third ray is drawn from the tip of the arrow through the focal point on the same side of the lens and is then refracted parallel to the optic axis.

Concept Check 33.2

If you move the object in Figure 33.4 to the left of its present location, the image will

a) move to the left and become larger.

b) move to the left and become smaller.

c) remain unchanged.

d) move to the right and become larger.

e) move to the right and become smaller.

These three rays all intersect at the same point, which marks the tip of the arrow image. Obviously, if you have drawn any two of the

three rays and found their intersection, then you are done, but the third ray can provide a useful double-check. Perhaps equally obvious, but still worth mentioning is the fact that all rays emerging from the object and hitting the lens are focused in the same spot of the image. The only thing that makes the three rays highlighted by us special is that they are easy to construct.

Figure 33.4 shows the case in which $d_o > f$. In this case we find an image that is upside down (inverted). The image is formed on the opposite side of the lens from the object, and by convention it is called a real image. In Figure 33.5 we look at the case $d_o < f$. You can see that in this case the three rays have to be extended backwards to intersect. This means that the image is formed on the same side of the lens as the object, and by convention it is called a virtual image. You can see from Figure 33.5 that the image is upright.

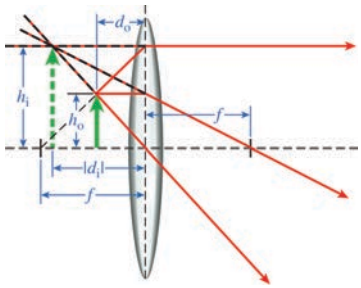

FIGURE 33.5
Imaginary image produced by a converging lens for the case that the object distance is smaller than the focal length.

Concept Check 33.3

If you cover the top half of the lens in Figure 33.4 with a material that does not allow light to pass through, then

a) the top half of the image will vanish.

b) the bottom half of the image will vanish.

c) the entire image will vanish.

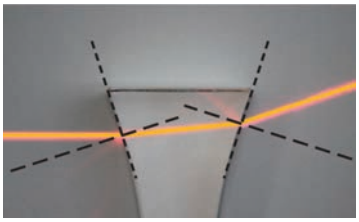
d) the entire image will still be visible, but will be fainter.

e) nothing will change.

Diverging Lenses

The discussion of diverging lenses follows very much the same ideas as those for converging lenses. In Figure 33.6 we show the path of a light ray through a diverging lens, in the same way that we have done it in Figure 33.2 for a converging lens.

(a)

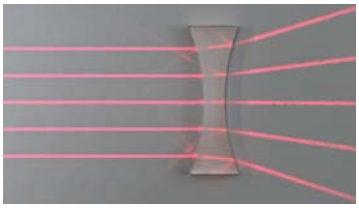


(b)

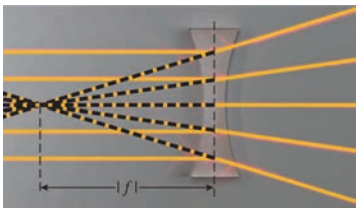
FIGURE 33.6 (a) A red light ray enters a diverging lens from the right and gets refracted at both surfaces. (b) The local tangent lines (short-dashed black lines) and their normal lines (long-dashed) at the locations where the ray hits the surfaces are superimposed.

W. Bauer and G. D. Westfall

It is clear from Figure 33.6 that the ray is refracted away from the optic axis, whereas in the case of the converging lens the ray is refracted toward the optic axis. This becomes even more apparent in Figure 33.7, where we examine five parallel rays entering the diverging lens. As the name suggests, the rays diverge from each other. However, as you can see in Figure 33.7b, if one extends the refracted rays (yellow-black dashed lines) on the opposite side of the lens, then they also intersect at one point on the optic axis, the focal point.



(a)



(b)

FIGURE 33.7 (a) Five parallel red light rays hit a converging lens from the left and focused at a single point. (b) Representation of the lens by a single dashed line through its center, and refraction of the idealized rays (yellow lines) through the same focal point.

W. Bauer and G. D. Westfall

Self-Test Opportunity 33.1

The images in Figures 33.4 and 33.5 are both enlarged. Is this always the case for a converging lens? Why, or why not?

Diverging lenses can also be used to form images. Figure 33.8 shows the geometric construction for the formation of an image using a diverging lens. As you can see, the same three special rays used for converging lenses can also be used for diverging lenses, but you have to be aware that you need to extrapolate the refracted rays on the other side of the lens.

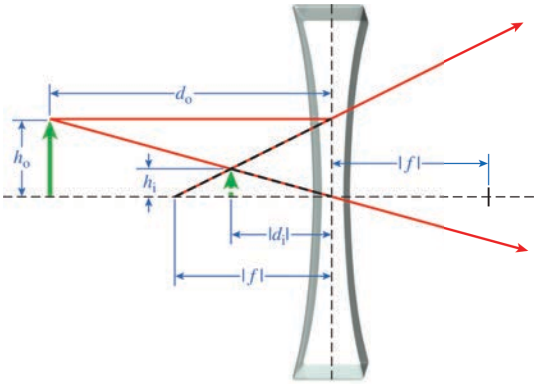


FIGURE 33.8 Image produced by a diverging lens of object placed a distance from the lens larger than the focal length of the lens.

Lens Equations

For curved mirrors we went from ray tracing and image construction to quantitative calculation of image distances and heights by deriving the mirror equation, which provides a relationship between focal length f, object distance d_o, and image distance d_i. It turns out that the same formal relationship between these physical quantities,

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}, \tag{33.2}$$

also holds for lenses and is called the **Thin-Lens Equation.** However, in order for this relationship to work, certain sign conventions have to be followed, which are summarized in Table 33.1.

Table 31.1 **Sign Conventions for Image Construction with a Single Lens**

	Converging Lens	Diverging Lens
Object distance	$d_o > 0$	$d_o > 0$
Focal length	$f_{\text{conv.}} > 0$	$f_{\text{div.}} < 0$
Image distance	Same side as object: $d_i < 0$ Opposite side: $d_i > 0$	Same side as object: $d_i < 0$ Opposite side: $d_i > 0$

The magnification is again defined as the ratio of image size to object size, and just like for mirrors, it is

$$m = \frac{h_{\mathrm{i}}}{h_{\mathrm{o}}} = -\frac{d_{\mathrm{i}}}{d_{\mathrm{o}}}. \qquad \textbf{(33.3)}$$

The derivation of equations 33.2 and 33.3 is in complete analogy to the derivation 32.1 in the previous chapter for the spherical-mirror equation.

For curved mirrors we had seen that the focal length was simply half of the radius of curvature. For lenses, we can have a different curvature on opposite sides of the lens. In addition, we also expect the index of refraction of the lens to play a role. What we find is the **Lens-Maker's Formula,**

$$\frac{1}{f} = \frac{n_{\mathrm{lens}} - n_{\mathrm{medium}}}{n_{\mathrm{medium}}} \left(\frac{1}{R_1} - \frac{1}{R_2} \right), \qquad \textbf{(33.4)}$$

where n_{lens} and n_{medium} are the indices of refraction of the lens and the medium surrounding it, respectively, and R_1 and R_2 are the radii of curvature of the two lens surfaces. The radii of curvature can have positive and negative signs, and the sign convention is that the radius of curvature is positive if the ray is hitting the circle segment from the outside, and it is negative if the ray is hitting the circle segment from the inside (see Figure 33.9).

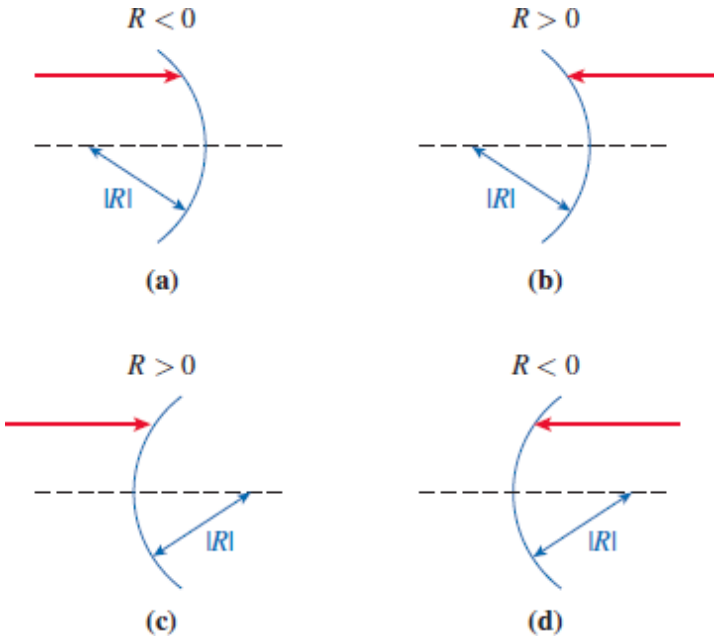

FIGURE 33.9 Sign convention for the radius of curvature of a lens surface (blue curve).

Concept Check 33.4

If you move the object in Figure 33.8 to the left of its present location, the image will

a) move to the left and become larger.

b) move to the left and become smaller.

c) remain unchanged.

d) move to the right and become larger.

e) move to the right and become smaller.

Note the role of the medium surrounding the lens in equation 33.4: if the index of refraction of the medium is smaller than that of the lens, a converging lens might look like the one shown in Figure 33.3; however, if the same lens is put into a medium with $n_{\text{medium}} > n_{\text{lens}}$, the same lens acts as a diverging lens! In most cases the medium surrounding the lens is air, with an index of refraction of 1, in which case equation 33.4 simplifies to

$$\frac{1}{f} = (n_{\text{lens}} - 1)\left(\frac{1}{R_1} - \frac{1}{R_2}\right). \qquad \textbf{(33.5)}$$

Even though equation 33.5 is only a special case of equation 33.4, it is far more useful in practical applications, because most lenses in optical instruments are surrounded by air as the optical medium.

DERIVATION 33.1 Lens-Maker's Formula

We start the derivation of the Lens-Maker's Formula by assuming that we have light traveling in a medium with index of refraction n_{medium} incident on a spherical surface of an optical medium with index of refraction n_{lens} and radius of curvature R (Figure 33.10). We draw the optic axis as a line perpendicular to the spherical face of the optical medium, through the center C of the spherical face. We assume a light ray originating from a point source at a distance d_o from the lens at an angle α with respect to the optic axis. This ray makes an angle θ_1 with respect to a normal to the surface of the optical medium and then gets refracted according to Snell's Law of refraction (see Chapter 32), $n_{\text{medium}} \sin\theta_1 = n_{\text{lens}} \sin\theta_2$, where θ_2 is the angle the refracted light ray makes with respect to the normal to the surface. If α is a small angle, then the angles θ_1 and θ_2 will be small as well, and we can write $n_{\text{medium}}\ \theta_1 = n_{\text{lens}}\theta_2$.

Page 1016

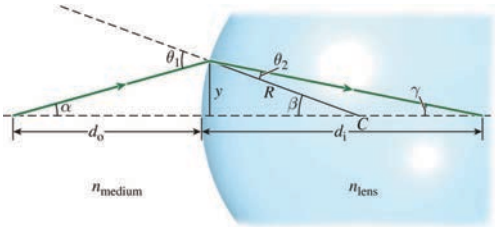

FIGURE 33.10 Light traveling in a medium incident on a spherical surface of a lens.

Looking at Figure 33.10, we can see the relationship between the angles $\theta_1 = \alpha + \beta$ and $\theta_2 = \beta - \gamma$. Inserting these into our small-angle approximation of Snell's Law results in

$$n_{\text{medium}}(\alpha + \beta) = n_{\text{lens}}(\beta - \gamma).$$

From Figure 33.3 and again using the small-angle approximation, we can see

$$\alpha \approx \tan\alpha \approx \frac{y}{d_{\text{o}}}, \quad \beta \approx \tan\beta \approx \frac{y}{R}, \quad \gamma \approx \tan\gamma \approx \frac{y}{d_{\text{i}}}.$$

Inserting these relationships for the three angles into the previous equation yields

$$n_{\text{medium}}\left(\frac{y}{d_{\text{o}}} + \frac{y}{R}\right) = n_{\text{lens}}\left(\frac{y}{R} - \frac{y}{d_{\text{i}}}\right).$$

Finally, we cancel out the factor y on both sides of this equation and rearrange, and find

$$\frac{n_{\text{medium}}}{d_{\text{o}}} + \frac{n_{\text{lens}}}{d_{\text{i}}} = \frac{n_{\text{lens}} - n_{\text{medium}}}{R}.$$

The quantity $p_{\text{s}} \equiv (n_{\text{lens}} - n_{\text{medium}})/R$ is called the surface power of the lens surface. What have we accomplished so far? We have derived an equation for the image distance for a given object distance and for a given radius of curvature of the lens, for refraction of light from one surface of the lens. But our lens has a front and a back surface (see Figure 33.11). Therefore our equation is applicable for both surfaces. Adding indices “1” and “2” we then have two equations,

$$\frac{n_{\text{medium}}}{d_{\text{o},1}} + \frac{n_{\text{lens}}}{d_{\text{i},1}} = \frac{n_{\text{lens}} - n_{\text{medium}}}{R_1} \quad \text{and} \quad \frac{n_{\text{lens}}}{d_{\text{o},2}} + \frac{n_{\text{mec}}}{d_{\text{i},}}$$

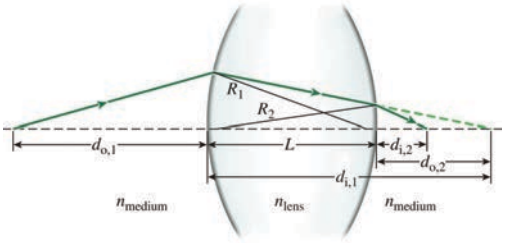

FIGURE 33.11 A lens of thickness L. The left face of the lens has radius R_1 and the right face of the lens has radius R_2.

If the rays come into the lens from the right, as indicated in Figure 33.11, they are refracted on surface 1 and form an image at $d_{i,1}$ Since the image is real, according to our sign convention in Table 33.1, $d_{i,1} > 0$. That image acts as the object for the refraction of rays on surface 2. You can see from Figure 33.11 that we measure the distance for refraction off surface 2 relative to that surface, and that $|d_{i,1}| = L + |d_{o,2}|$, where L is the lens thickness.

We now make the additional assumption that our lens is thin enough that we can neglect its thickness L relative to the image and object distances in the problem. In this approximation we then have $|d_{i,1}| \approx |d_{o,2}|$. Our rays travel from left to right, and positive object distances imply that the object is to the left of the lens. However, as you can see from Figure 33.11, the object for the refraction off the second surface is to the right of the lens, which means a negative object distance. Therefore $d_{o,2} = -d_{i,1}$.

With this result we can combine the two equations for the surface powers of the two lenses and obtain

$$\frac{n_{\text{medium}}}{d_{o,1}} + \frac{n_{\text{lens}}}{d_{i,1}} = \frac{n_{\text{lens}} - n_{\text{medium}}}{R_1} \Rightarrow \frac{n_{\text{lens}}}{d_{i,1}} = \frac{n_{\text{lens}} - 1}{R}$$

$$\frac{n_{\text{lens}}}{d_{o,2}} + \frac{n_{\text{medium}}}{d_{i,2}} = \frac{n_{\text{medium}} - n_{\text{lens}}}{R_2} \Rightarrow \frac{n_{\text{lens}}}{d_{o,2}} = \frac{n_{\text{medium}}}{R}$$

$$\frac{n_{\text{lens}} - n_{\text{medium}}}{R_1} - \frac{n_{\text{medium}}}{d_{o,1}} = -\frac{n_{\text{medium}}}{R_2}$$

Rearranging now results in

$$\frac{n_{\text{medium}}}{d_{\text{o},1}} + \frac{n_{\text{medium}}}{d_{\text{i},2}} = \frac{n_{\text{lens}} - n_{\text{medium}}}{R_1} - \frac{n_{\text{medium}} - n_{\text{lens}}}{R_2}$$

$$\frac{1}{d_{\text{o},1}} + \frac{1}{d_{\text{i},2}} = \frac{n_{\text{lens}} - n_{\text{medium}}}{n_{\text{medium}}}\left(\frac{1}{R_1} - \frac{1}{R_2}\right).$$

Page 1017

The combination of the two refracting surfaces thus maps an object located at $d_{\text{o},1}$ into the image located at $d_{\text{i},2}$. Using the Thin-Lens Equation 33.2, we see that the left side of our result is simply $1/f$, and we arrive at our desired result for the Lens-Maker's Formula

$$\frac{1}{f} = \frac{n_{\text{lens}} - n_{\text{medium}}}{n_{\text{medium}}}\left(\frac{1}{R_1} - \frac{1}{R_2}\right).$$

Concept Check 33.5

If you have a converging lens with a focal length of 15.0 cm in air and then put this lens in water, its focal length will be

a) smaller than 15.0 cm.

b) still the same 15.0 cm.

c) larger than 15.0 cm.

d) either smaller or larger than 15.0 cm, depending on the index of refraction of the lens.

Lenses do not necessarily have the same curvature on the entrance and exit surfaces. Lenses can be formed in several different ways, as illustrated in Figure 33.12 for several different lenses in air. For example, light incident from the left on the converging meniscus lens shown in Figure 33.12 would first encounter a convex surface $(R_2 > 0)$ and then a second convex surface $(R_1 > 0)$. For the converging meniscus lens, $R_1 < R_2$, therefore $1/R_1 > 1/R_2$, so the focal length of the lens given by the Lens-Maker's Formula in air (equation 33.5) is positive, producing a converging lens. For the diverging meniscus lens shown in Figure 33.12, the first surface is convex $(R_1 > 0)$. and the second surface is also convex $(R_2 > 0)$ However, for the diverging meniscus lens, $R_1 > R_2$ and $1/R_1 < 1/R_2$, so the focal length is negative, producing a diverging lens. Meniscus lenses are commonly used in corrective eyeglasses.

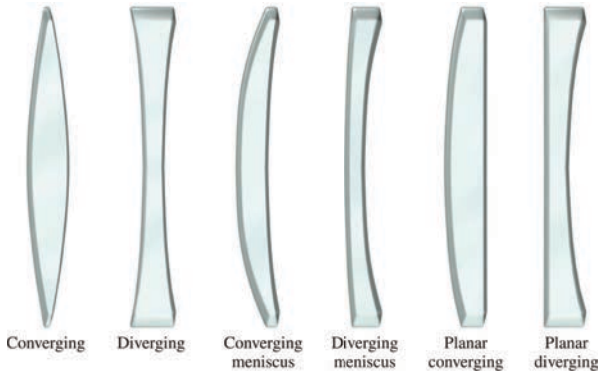

FIGURE 33.12 Different types of lenses created by different radii of curvature on the entrance and exit surfaces.

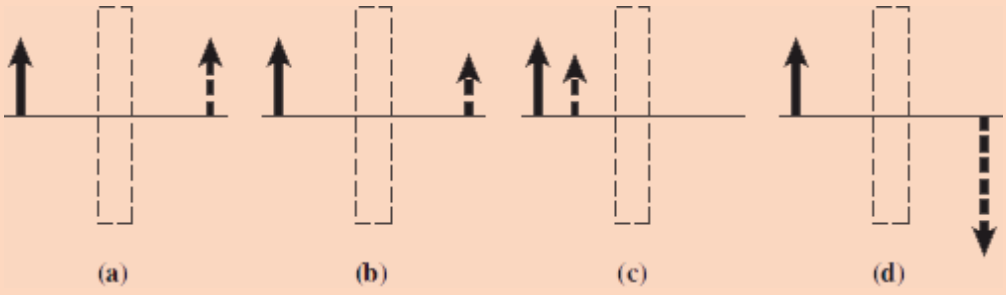
For a converging lens, we find that for $d_o > f$ we always get a real, inverted image, i.e., an upside-down image formed on the opposite side of the lens. If $d_o = f$, then $1/d_i = 0$, and the image is located at infinity. For a converging lens and $d_o < f$, then we always get a virtual, upright, and enlarged image on the same side of the lens as the object. The results for all values of the object distance are summarized in Table 33.2 for quick reference. Diverging lenses always produce an image that is virtual, upright, and reduced in size.

Table 33.2 Image Characteristics for Converging Lenses

Case	Image Type	Image Orientation	Magnification
$f < d_o < 2f$	Real	Inverted	Enlarged
$d_o = 2f$	Real	Inverted	Same size
$d_o > 2f$	Real	Inverted	Reduced
$d_o = f$			Infinity
$d_o > f$	Virtual	Upright	Enlarged

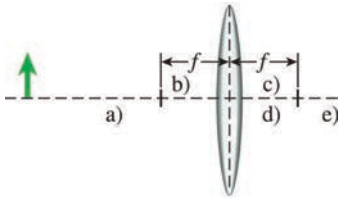
Self-Test Opportunity 33.2

In the four diagrams shown in the figure below, the solid arrow represents the object and the dashed arrow represents the image. The dashed rectangle represents a single optical element. The possible optical elements include a plane mirror, a converging mirror, a diverging mirror, a diverging lens, and a converging lens. Match each diagram with the corresponding optical element.



Concept Check 33.6

An object is placed as shown in the figure. Which letter is closest to the location where the image is formed?



EXAMPLE 33.1 Image Formed by a Thin Lens

We place an object with height $h_o = 5.00\,\text{cm}$ at a distance $d_o = 16.0\,\text{cm}$ from a thin converging lens with focal length $f = 4.00\,\text{cm}$ (Figure 33.13).

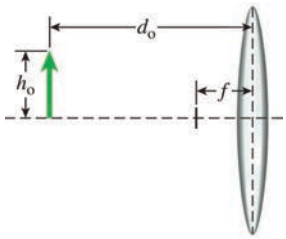


FIGURE 33.13
An object placed in front of a thin converging lens.

PROBLEM

What is the image distance? What is the linear magnification of the image? What is the image height?

SOLUTION

The image distance can be calculated using the Thin-Lens Equation (equation 33.2),

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}.$$

Solving for the image distance, we get

$$d_i = \frac{d_o f}{d_o - f} = \frac{(16.0\,\text{cm})(4.00\,\text{cm})}{16.0\,\text{cm} - 4.00\,\text{cm}} = 5.33\,\text{cm}.$$

The image distance is positive. Therefore, the image is real and appears on the opposite side of the lens from the object. The magnification formula for lenses is given by

$$m = \frac{h_\mathrm{i}}{h_\mathrm{o}} = -\frac{d_\mathrm{i}}{d_\mathrm{o}}.$$

Thus, we can calculate the magnification using the given object distance and the calculated image distance:

$$m = -\frac{d_\mathrm{i}}{d_\mathrm{o}} = -\frac{5.33\ \mathrm{cm}}{16.0\ \mathrm{cm}} = -0.333.$$

The magnification is negative, so the image is inverted. The magnitude of the magnification is less than one, so the image is reduced. We can now calculate the image height:

$$h_\mathrm{i} = mh_\mathrm{o} = (-0.333)(5.00\ \mathrm{cm}) = -1.67\ \mathrm{cm}.$$

The image height is negative, so the image is inverted, as we expected from the negative magnification.

The resulting image is illustrated in Figure 33.14.

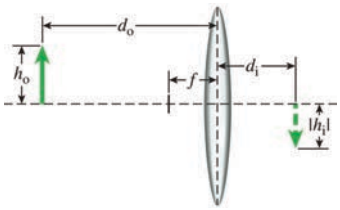

FIGURE 33.14
Image formed by a converging thin lens.

SOLVED PROBLEM 33.1 Image of the Moon

PROBLEM

An image of the Moon is focused onto a screen, using a converging lens of focal length $f = 50.0\,\text{cm}$. The radius of the Moon is $R = 1.737 \cdot 10^6\text{m}$, and the mean distance between Earth and the Moon is $d = 3.844 \cdot 10^8\text{m}$. What is the radius of the Moon in the image on the screen?

SOLUTION

THINK

The linear magnification of the image produced by the lens can be expressed in terms of the ratio of the image size to the object size and in terms of the ratio of image distance to the object distance.

SKETCH

Figure 33.15 shows a sketch of the image of the Moon produced by a converging lens. A blue arrow represents the image of the Moon.

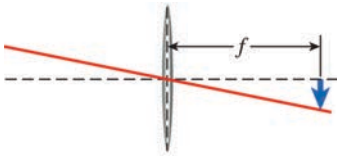

FIGURE 33.15
Image of the Moon produced by a converging lens.

RESEARCH

The relationship between the object distance d_o and the image distance d_i for a lens with focal length f is given by the Thin-Lens Equation,

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}.$$

We can solve this equation for the image distance,

$$d_i = \frac{d_o f}{d_o - f}.$$

In this case, the object distance is the distance from Earth to the Moon. Because the object distance is much greater than the focal length of the lens, we can write

$$d_i \approx \frac{d_o f}{d_o} = f.$$

The linear magnitude of the magnification m for a lens can be written as

$$m = -\frac{d_i}{d_o} = \frac{h_i}{h_o}$$

where h_i is the height (radius) of the image and h_o is the height of the object, which in this case is the radius of the Moon.

SIMPLIFY

We can solve the previous equation for the image height,

$$h_i = -h_o \frac{d_i}{d_o}.$$

Taking the object height to be the radius of the Moon *R,* the object distance to be the distance from Earth to the Moon *d,* and the image distance to be the focal length of the lens *f,* we can write

$$h_{\mathrm{i}} = -R\frac{f}{d}.$$

CALCULATE

Putting in the numerical values, we have

$$h_{\mathrm{i}} = -R\frac{f}{d} = \left(1.737 \cdot 10^{6}\mathrm{m}\right)\frac{0.500\ \mathrm{m}}{3.844 \cdot 10^{8}\ \mathrm{m}} = -0.002259$$

ROUND

We report our result for the radius of the image of the Moon on the screen to three significant figures,

$$h_{\mathrm{i}} = -2.26 \cdot 10^{-3}\mathrm{m} = -2.26\ \mathrm{mm}.$$

DOUBLE-CHECK

The Moon is relatively close to Earth and we can see the Moon as a disk easily with the naked eye. Thus, it seems reasonable that we could produce an image of the Moon with radius 2.26 mm on a screen with a lens of focal length 50.0 cm. The negative sign for the image height means that our image of the Moon is inverted.

SOLVED PROBLEM 33.2 Two Positions of a Converging Lens

A light bulb is at a distance $d = 1.45$ m away from a screen. A converging lens with focal length $f = 15.3$ cm forms an image of the light bulb on the screen for two lens positions.

PROBLEM

What is the distance between these two positions?

SOLUTION

THINK

The sum of the object distance of the lens plus the image distance of the lens is equal to the distance of the light bulb from the screen. Using the lens equation, we can solve for the possible image distances using the quadratic equation. The distance between the two image distances is the distance between the two lens positions.

SKETCH

Figure 33.16 shows a sketch of the lens placed between the light bulb and the screen.

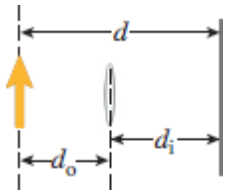

FIGURE 33.16 A lens is placed between a light bulb and a screen.

RESEARCH

The Thin-Lens Equation is

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}, \qquad \text{(i)}$$

where d_o is the object distance, d_i is the image distance, and f is the focal length. We can express the object distance in terms of the image distance and the distance of the light bulb from the screen d,

$$d_o = d - d_i. \qquad \text{(ii)}$$

Substituting equation (ii) into equation (i) gives us

$$\frac{1}{d - d_i} + \frac{1}{d_i} = \frac{1}{f}.$$

We can rearrange this equation to get

$$d_i + (d - d_i) = \frac{d_i(d - d_i)}{f}.$$

Collecting terms and multiplying by f gives us

$$df = d_i d - d_i^2. \qquad \text{(iii)}$$

SIMPLIFY

We can rewrite equation (iii) so that we can recognize it as a quadratic equation, for which we can find the solutions:

$$d_i^2 - d_i d + df = 0.$$

The solutions of this equation are

$$d_{\mathrm{i}} = \frac{d \pm \sqrt{d^2 - 4df}}{2},$$

where one solution corresponds to the + sign and the other solution corresponds to the – sign.

CALCULATE

The solution corresponding to the + sign is

$$d_{\mathrm{i}+} = \frac{(1.45\ \mathrm{m}) = \sqrt{(1.45\ \mathrm{m})^2 - 4(1.45\ \mathrm{m})(0.153\ \mathrm{m})}}{2} =$$

The solution corresponding to the – sign is

$$d_{\mathrm{i}-} = \frac{(1.45\ \mathrm{m}) - \sqrt{(1.45\ \mathrm{m})^2 - 4(1.45\ \mathrm{m})(0.153\ \mathrm{m})}}{2} = ($$

The difference between the two positions is $\Delta d_{\mathrm{i}} = 1.10232\ \mathrm{m}$.

ROUND

We report our result to three significant figures,

$$\Delta d_{\mathrm{i}} = 1.10\ \mathrm{m}.$$

(*Note*: Even though we have found two positions for the lens that allow an image to be formed, it is not correct to assume that the image has the same size in both cases.)

DOUBLE-CHECK

To double-check our answer, we substitute our solutions for the image distance into the Thin-Lens Equation and show that they work. For the first solution, $d_{\mathrm{i}} = 1.276\ \mathrm{m}$, so the corresponding object distance is $d_{\mathrm{o}} = d - d_{\mathrm{i}} = 0.174\ \mathrm{m}$. The lens equation then tells us

$$\frac{1}{0.174} + \frac{1}{1.276} = \frac{1}{0.153\,\mathrm{m}},$$

which agrees within round-off errors. For the second solution, we simply reverse the role of the image distance and object distance in the Thin-Lens Equation, and we get the same answer. Thus, our result seems reasonable.

33.2 Magnifier

One way to make an object appear larger is to bring it closer. However, if the object is brought too close to the eye, the object will appear fuzzy. The position closest to the eye that an object can be placed at and remain in focus is called the "near point," as discussed in detail below. Another way to make an object appear larger is to use a **magnifier** or magnifying glass (Figure 33.17).

FIGURE 33.17 A typical magnifying glass.

Wolfgang Bauer/McGraw Hill

A magnifier is nothing more than a converging lens that produces an enlarged virtual image of an object. This image appears at a distance that is at or beyond the near point of the eye, so an observer can clearly see the image. The **angular magnification** m_θ of the magnifier is defined as the ratio of the apparent angle subtended by the image to the angle subtended by the object when located at the near point.

Figure 33.18 shows the geometry of a magnifier. Assume an object with height h_o. Without a magnifier, the largest angle θ_1 that you can attain and still see the object clearly occurs when you place the object at the near point d_{near} (Figure 33.18a). You can get a

magnified image of the object by placing the object just inside the focal length of a converging lens (Figure 33.18b). You then look through the lens at the image, which is intentionally located at least as far away as the near point. Therefore you can see the enlarged, upright, virtual image. The angle subtended by the image is θ_2.

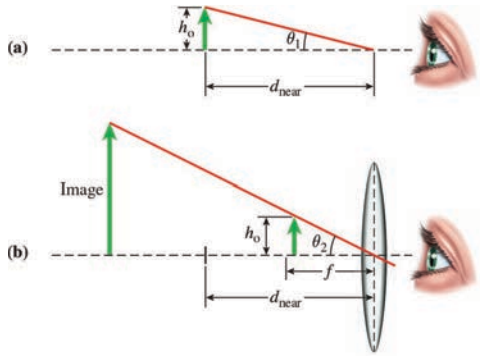

FIGURE 33.18 The geometry of a magnifier. (a) Viewing an object at the near point. (b) Viewing a magnified image of the object.

The angular magnification of the magnifier is defined as

$$m_\theta = \frac{\theta_2}{\theta_1}. \tag{33.6}$$

Figure 33.18a shows that the angle subtended by the object without the magnifier is given by

$$\tan\theta_1 = \frac{h_o}{d_{near}}.$$

Figure 33.18b shows that the angle subtended by the image of the object is given by

$$\tan\theta_2 = \frac{h_o}{f},$$

where f is the focal length of the lens. We assume that the object is placed at the focal length of the lens, so the image is at minus infinity. (Recall from Section 33.1 that a ray through the center of the lens is not bent. It is this ray that forms the hypotenuse of the right triangle used for this equation.) We then make a small-angle approximation to get $\tan\theta_1 \approx \theta_1$ and $\tan\theta_2 \approx \theta_2$. Thus, the angular magnification of a magnifier can be written as

$$m_\theta = \frac{\theta_2}{\theta_1} \approx \frac{h_o/f}{h_o/d_{\text{near}}} = \frac{d_{\text{near}}}{f}.$$

Assuming a typical value for the near point of 25 cm (which is the value for a middle-aged person; for a 20-year-old the near point may be closer to 10 cm), the angular magnification can be written as

$$m_\theta \approx \frac{d_{\text{near}}}{f} \approx \frac{0.25\ \text{m}}{f}. \qquad \textbf{(33.7)}$$

Concept Check 33.7

What is the focal length (in meters) of a magnifying glass that gives an angular magnification of 6?

a) 0.010 m

b) 0.021 m

c) 0.035 m

d) 0.042 m

e) 0.055 m

The magnification obtained in equation 33.7 is not the maximum magnification that is achievable with a magnifier. That maximum can be reached if the final image can be placed at the near point.

Using the lens equation with $d_{\mathrm{i}} = -d_{\mathrm{near}}$ to find d_{o} and then using $\theta_2 = h_{\mathrm{o}}/d_{\mathrm{o}}$, we find $m_\theta = (0.25\ \mathrm{m}/f) + 1$, if $d_{\mathrm{near}} = 0.25\ \mathrm{m}$. However, it can be quite delicate to obtain a sharp image of the object in this configuration; this is why most people prefer to use the magnifying glass as we described above. Henceforth, unless otherwise stated, we will assume that the image is at infinity and will use equation 33.7.

33.3 Systems of Two or More Optical Elements

We have seen that a lens or mirror can produce an image of an object. This image can then, in turn, be used as the object for a second lens or mirror. The recurring theme for all two-lens systems is that the image of the first lens becomes the object of the second lens. Let's start our study of multi-lens systems by considering a two-lens system consisting of two converging lenses, placed as shown in Figure 33.19.

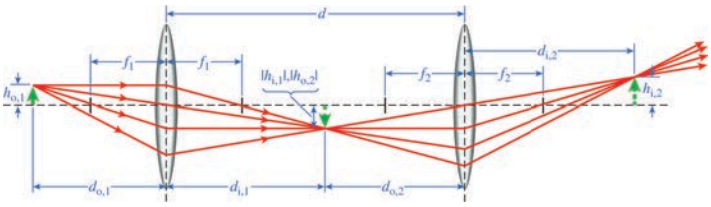

FIGURE 33.19 A system of two converging lenses.

An object with height $h_{o,1}$ is placed a distance $d_{o,1}$ from the first lens, which has a focal length f_1. An image is produced at a distance $d_{i,1}$ given by the Thin-Lens Equation (33.2),

$$\frac{1}{d_{o,1}} + \frac{1}{d_{i,1}} = \frac{1}{f_1}.$$

Given the value of $d_{o,1}$ that we have chosen, this image is real and inverted. This image then becomes the object for the second lens. The height of this object is the same as the height of the image produced by the first lens. The object is located a distance $d_{o,2}$ from the second lens, which has a focal length f_2. An image is formed at a distance $d_{i,2}$ again governed by the Thin-Lens Equation,

$$\frac{1}{d_{o,2}} + \frac{1}{d_{i,2}} = \frac{1}{f_2}.$$

For the parameters of the system depicted in Figure 33.19, the final image of the second lens is real and inverted, compared to the second object (first image). The linear magnification of the first lens is given by $m_1 = h_{i,1}/h_{o,1}$ and the linear magnification of the second lens is given by $m_2 = h_{i,2}/h_{o,2}$. The product of the linear magnifications of the two lenses gives the linear magnification of the two-lens system:

$$m_{12} = m_1 m_2 = \left(\frac{h_{i,1}}{h_{o,1}}\right)\left(\frac{h_{i,2}}{h_{o,2}}\right) = \frac{h_{i,2}}{h_{o,1}}. \quad \textbf{(33.8)}$$

From equation 33.8 we can see that the image produced by this two-lens system is real and upright. Thus, this system of lenses can be used to produce real images that are not inverted. This kind of image formation cannot be done with a single converging lens.

Now let's consider a two-lens system with one converging lens and one diverging lens (Figure 33.20). An object with height $h_{o,1}$ is placed a distance $d_{o,1}$ from the first lens, which has a focal length f_1. Again, an image is produced at a distance $d_{i,1}$ given by the Thin-Lens Equation (equation 33.2). This particular image is real, inverted, and enlarged. Just like in the previous case, this image generated by the first lens then becomes the object for the second lens. This second image is virtual, upright with respect to the first image, and reduced. The combined linear magnification of the two lenses is again the product of the linear magnifications of the individual lenses and also given by $m_{12} = m_1 m_2 = h_{i,2}/h_{o,1}$, just like in the case discussed previously. Figure 33.20 shows that the final image produced by this two-lens system is virtual and inverted with respect to the original object.

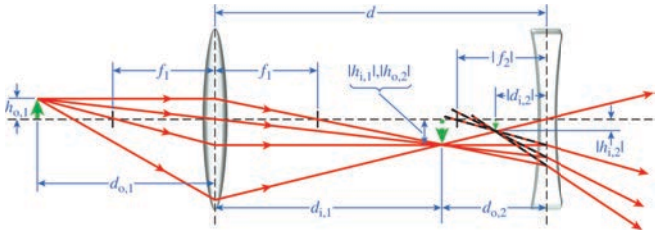

FIGURE 33.20 A two-lens system consisting of a converging lens and a diverging lens.

Now let's take this same two-lens system of a converging lens followed by a diverging lens and put the two lenses close together so that their separation x is less than their individual focal lengths (Figure 33.21). This two-lens system acts as a converging lens. By varying the distance x we can vary the effective focal length of the converging lens system. This arrangement is called a **zoom lens.**

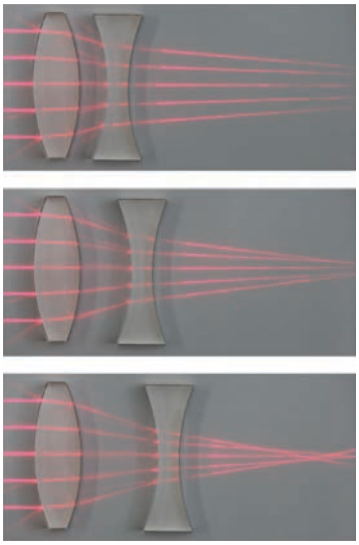

FIGURE 33.21 A zoom lens system consisting of a converging lens followed by a diverging lens. Three different distances between the two lenses are shown.

W. Bauer and G. D. Westfall

The effective focal length of this two-lens system is defined as the distance from the center of the first lens to the position of the final image for an object originally located at infinity. The first lens has a focal length f_1, which means that objects placed at a large distance will produce an image at an image distance of $d_{\mathrm{i},1} = f_1$. We can understand this result using the Thin-Lens Equation,

$$\frac{1}{d_{\mathrm{o},1}} + \frac{1}{d_{\mathrm{i},1}} = \frac{1}{\infty} + \frac{1}{d_{\mathrm{i},1}} = 0 + \frac{1}{d_{\mathrm{i},1}} = \frac{1}{d_{\mathrm{i},1}} = \frac{1}{f_1}.$$

Assuming $f_1 > x$, the image produced by the first lens is generated on the right side of the second lens. This means that the object distance for the second lens must be negative in this case, because

we have defined positive object distances to be to the left of a lens. The object distance for the second lens is

$$d_{o,2} = -(d_{i,1} - x) = x - d_{i,1} = x - f_1.$$

Using this image as the object for the second lens, we get

$$\frac{1}{d_{o,2}} + \frac{1}{d_{i,2}} = \frac{1}{x - f_1} + \frac{1}{d_{i,2}} = \frac{1}{f_2}.$$

This equation can be solved for $d_{i,2}$ to get the effective focal length of the zoom lens system,

$$f_{\text{eff}} = x + d_{i,2} = x + \frac{f_2(x - f_1)}{x - (f_2 + f_1)}. \qquad \textbf{(33.9)}$$

Equation 33.9 and Figure 33.21 show that when the lenses are close together, the effective focal length is longer; when the lenses are farther apart, the effective focal length is shorter. Thus, by adjusting the distance between the converging lens and the diverging lens, we can produce an effective lens with varying focal length, as is done in zoom lenses of cameras. Note that for cameras, this result is useful only for $f_{\text{eff}} > x$ because objects at infinity must produce a real image on the digital image recorder (for a digital camera) or on the film (for an old-fashioned conventional camera).

Self-Test Opportunity 33.3

Use equation 33.9 to show that the effective focal length f_{eff} of two thin lenses with focal lengths f_1 and f_2 close together is given by

$$\frac{1}{f_{\text{eff}}} = \frac{1}{f_1} + \frac{1}{f_2}.$$

Concept Check 33.8

In Figure 33.21 the lenses are arranged so that the light first hits the converging lens and then the diverging one. What happens if you switch the two lenses so the light first hits the diverging one?

a) You still have a zoom lens with the approximately same effective focal length.

b) You have a diverging zoom lens.

c) You cannot form an image.

d) You still have a zoom lens, but with a much longer effective focal length.

Self-Test Opportunity 33.4

A normal 35-mm camera has a lens with a focal length of 50 mm. Suppose you replace the normal lens with a zoom lens whose focal length can be varied from 50 mm to 200 mm and use the camera to photograph an object at a very large distance. Compared to a 50-mm lens, what magnification of the image would be achieved using the 200-mm focal length?

SOLVED PROBLEM 33.3 Image Produced by Two Lenses

Consider a system of two lenses. The first lens is a converging lens with a focal length $f_1 = 21.4\,\text{cm}$. The second lens is a diverging lens with focal length $f_2 = -34.4\,\text{cm}$. The center of the second lens is $d = 80.0\,\text{cm}$ to the right of the center of the first lens. An object is placed a distance $d_{o,1} = 63.5\,\text{cm}$ to the left of the first lens. These lenses produce an image of the object.

PROBLEM

Where is the image produced by the second lens located with respect to the center of the second lens? What are the characteristics of the image? What is the linear magnification of the final image with respect to the original object?

SOLUTION

THINK

The Thin-Lens Equation (which we will here call simply the lens equation) tells us where the first lens produces an image of the object placed to the left of the first lens. The image produced by the first lens becomes the object for the second lens. We again use the lens equation to locate the image produced by the second lens.

SKETCH

Figure 33.22 shows a sketch of the object, the first lens, and the second lens.

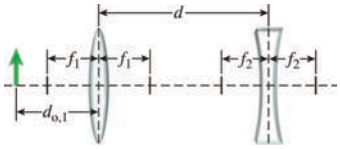

FIGURE 33.22 A system of two lenses with focal lengths and object distance marked.

RESEARCH

The lens equation applied to the first lens gives

$$\frac{1}{d_{o,1}} + \frac{1}{d_{i,1}} = \frac{1}{f_1},$$

where $d_{i,1}$ is the image distance for the first lens. Solving for the image distance of the first lens gives

$$d_{i,1} = \frac{d_{o,1} f_1}{d_{o,1} - f_1}. \qquad \text{(i)}$$

The lens equation applied to the second lens gives

$$\frac{1}{d_{o,2}} + \frac{1}{d_{i,2}} = \frac{1}{f_2},$$

where $d_{o,2}$ is the object distance for the second lens and $d_{i,2}$ is the image distance for the second lens. We can solve for the image distance for the second lens,

$$d_{i,2} = \frac{d_{o,2} f_2}{d_{o,2} - f_2}. \qquad \text{(ii)}$$

The object for the second lens is the image produced by the first lens. Thus, we can relate the object distance for the second lens to the image distance of the first lens and the distance between the two lenses:

$$d_{\mathrm{o},2} = d - d_{\mathrm{i},1}. \tag{iii}$$

SIMPLIFY

We can substitute equation (iii) into equation (ii) to obtain

$$d_{\mathrm{i},2} = \frac{(d - d_{\mathrm{i},1})f_2}{(d - d_{\mathrm{i},1}) - f_2}. \tag{vi}$$

We can then substitute equation (i) into equation (iv) to obtain an expression for the image distance of the second lens in terms of the quantities given in the problem:

$$d_{\mathrm{i},2} = \frac{\left(d - \left(\frac{d_{\mathrm{o},1}f_1}{d_{\mathrm{o},1} - f_1}\right)\right)f_2}{\left(d - \left(\frac{d_{\mathrm{o},1}f_1}{d_{\mathrm{o},1} - f_1}\right)\right) - f_2}.$$

CALCULATE

Putting in the numerical values gives us

$$d_{\mathrm{i},2} = \frac{\left((80.0\ \mathrm{cm}) - \left(\frac{(63.5\ \mathrm{cm})(21.4\ \mathrm{cm})}{(63.5\ \mathrm{cm}) - (21.4\ \mathrm{cm})}\right)\right)(-34.}{\left((80.0\ \mathrm{cm}) - \left(\frac{(63.5\ \mathrm{cm})(21.4\ \mathrm{cm})}{(63.5\ \mathrm{cm}) - (21.4\ \mathrm{cm})}\right)\right) - (-3}$$

ROUND

We report our result for the location of the image to three significant figures,

$$d_{i,2} = -20.0 \text{ cm}.$$

DOUBLE-CHECK

To double-check our result and calculate the quantities needed to answer the remaining parts of the problem, we calculate the position of the image produced by the first lens:

$$d_{i,1} = \frac{d_{o,1} f_1}{d_{o,1} - f_1} = \left(\frac{(63.5 \text{ cm})(21.4 \text{ cm})}{(63.5 \text{ cm}) - (21.4 \text{ cm})} \right) = 32.3 \text{ cm}$$

The image distance for the first lens is positive, so the image is real and formed 32.3 cm to the right of the first lens. The object distance for the second lens is then

$$d_{o,2} = d - d_{i,1} = 47.7 \text{ cm}.$$

The image formed by the first lens is 47.7 cm to the left of the second lens, which seems reasonable. We can then calculate the image distance for the second lens:

$$d_{i,2} = \frac{d_{o,2} f_2}{d_{o,2} - f_2} = \left(\frac{(47.7 \text{ cm})(-34.4 \text{ cm})}{(47.7 \text{ cm}) - (-34.4 \text{ cm})} \right) = -20.0$$

which agrees with our result. Thus, our answer for the distance of the image from the center of lens 2 seems reasonable.

The final image is virtual because it is on the same side of lens 2 as the object for lens 2, which we know because the image distance for lens 2 is negative. The linear magnification for the final image compared with the original object is

$$m = m_1 m_2 = \left(-\frac{d_{\mathrm{i},1}}{d_{\mathrm{o},1}}\right)\left(-\frac{d_{\mathrm{i},2}}{d_{\mathrm{o},2}}\right) = \left(-\frac{32.3\,\mathrm{cm}}{63.5\,\mathrm{cm}}\right)\left(-\frac{\text{-}}{\text{-}}\right.$$

The image is reduced because $|m| < 1$. The image is inverted because $m < 0$.

SOLVED PROBLEM 33.4 Image Produced by a Lens and a Mirror

An object is placed a distance $d_{o,1} = 25.6\,\text{cm}$ to the left of a converging lens with focal length $f_1 = 20.6\,\text{cm}$. A converging mirror with focal length $f_2 = 10.3\,\text{cm}$ is placed a distance $d = 120.77\,\text{cm}$ to the right of the lens.

PROBLEM

What is the magnification of the image produced by the lens-and-mirror combination?

SOLUTION

THINK

The lens will produce a real, inverted image of the object. This image becomes the object for the converging mirror. The object distance for the mirror is the distance between the lens and the mirror minus the image distance of the lens. The overall magnification is the magnification of the lens times the magnification of the mirror.

SKETCH

Figure 33.23 shows a sketch of the object, the lens, and the mirror.

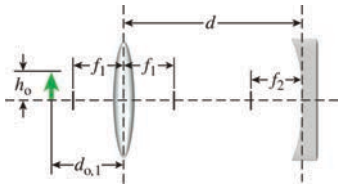

FIGURE 33.23 An object being imaged by a lens-and-mirror combination.

RESEARCH

The Thin-Lens Equation tells us that the image distance $d_{\mathrm{i},1}$ for the lens is given by

$$d_{\mathrm{i},1} = \frac{d_{\mathrm{o},1} f_1}{d_{\mathrm{o},1} - f_1}. \qquad \text{(i)}$$

The mirror equation tells us that the image distance for the mirror is

$$d_{\mathrm{i},2} = \frac{d_{\mathrm{o},2} f_2}{d_{\mathrm{o},2} - f_2}, \qquad \text{(ii)}$$

where the object distance for the mirror is

$$d_{\mathrm{o},2} = d - d_{\mathrm{i},1}. \qquad \text{(iii)}$$

The magnification m of the lens-and-mirror system is given by

$$m = m_1 m_2, \qquad \text{(iv)}$$

where m_1 is the magnification of the lens and m_2 is the magnification of the mirror.

SIMPLIFY

The magnification of the lens using equation (i) is

$$m_1 = -\frac{d_{\mathrm{i},1}}{d_{\mathrm{o},1}} = -\frac{\left(\frac{d_{\mathrm{o},1} f_1}{d_{\mathrm{o},1} - f_1}\right)}{d_{\mathrm{o},1}} = -\frac{f_1}{d_{\mathrm{o},1} - f_1} = \frac{}{f_1}$$

Similarly, the magnification of the mirror using equation (ii) is

$$m_2 = -\frac{d_{i,2}}{d_{o,2}} = -\frac{\left(\frac{d_{o,2}f_2}{d_{o,2}-f_2}\right)}{d_{o,2}} = -\frac{f_2}{d_{o,2}-f_2} = \frac{}{f_2}$$

We can then write for the overall magnification, using equations (iii), (v), and (vi) in equation (iv)

$$m = \left(\frac{f_1}{f_1 - d_{o,1}}\right)\left(\frac{f_2}{f_2 - d_{o,2}}\right) = \left(\frac{f_1}{f_1 - d_{o,1}}\right)\left(\frac{}{f_2 - (}\right.$$

Finally, substituting from equation (i) for the image distance for the lens gives us

$$m = \left(\frac{f_1}{f_1 - d_{o,1}}\right)\frac{f_2}{f_2 - \left(d - \frac{d_{o,1}f_1}{d_{o,1} - f_1}\right)}.$$

CALCULATE

Putting in the numerical values gives us

$$m = \left(\frac{(20.6\text{ cm})}{(20.6\text{ cm}) - (25.6\text{ cm})}\right)\frac{(1}{(10.3\text{ cm}) - \left((120.77\text{ cn}\right.}$$

$$m = 8.490596.$$

ROUND

We report our result to three significant figures,

$$m = 8.49.$$

DOUBLE-CHECK

To double-check our result, we first calculate the image distance for the lens,

$$d_{\mathrm{i},1} = \frac{d_{\mathrm{o},1} f_1}{d_{\mathrm{o},1} - f_1} = \frac{(25.6\ \mathrm{cm})(20.6\ \mathrm{cm})}{(25.6\ \mathrm{cm}) - (20.6\ \mathrm{cm})} = 105.47\ \mathrm{cm}.$$

The object distance for the mirror is then

$$d_{\mathrm{o},2} = d - d_{\mathrm{i},1} = 120.77\ \mathrm{cm} - 105.47\ \mathrm{cm} = 15.3\ \mathrm{cm}.$$

The image distance for the mirror is then

$$d_{\mathrm{i},2} = \frac{d_{\mathrm{o},2} f_2}{d_{\mathrm{o},2} - f_2} = \frac{(15.3\ \mathrm{cm})(10.3\ \mathrm{cm})}{(15.3\ \mathrm{cm}) - (10.3\ \mathrm{cm})} = 31.52\ \mathrm{cm}.$$

The magnification of the image is then

$$m = \frac{d_{\mathrm{i},1}}{d_{\mathrm{o},1}} \frac{d_{\mathrm{i},2}}{d_{\mathrm{o},2}} = \frac{105.5\ \mathrm{cm}}{25.6\ \mathrm{cm}} \frac{31.52\ \mathrm{cm}}{15.3\ \mathrm{cm}} = 8.49,$$

which agrees with our result.

In general it is always a good idea to keep with our seven-step method for problem solving and only insert numerical values at the very end. However, for problems involving two or more optical elements, it may be reasonable to make an exception to this general procedure. You can see from the preceding two solved problems that the formulas can get quite cumbersome. Many students find it simpler to compute intermediate image distances and heights numerically first and then use these values to continue further. Arguably, this leads to fewer errors in calculations, in particular

under exam pressure. In the last two solved problems we have used this approach as our double-checks. Feel free to employ either technique in solving multi-element optics problems.

33.4 Human Eye

The human eye can be considered an optical instrument. The eye is nearly spherical in shape, about 2.5 cm in diameter (Figure 33.24). The front part of the eye is more sharply curved than the rest of the eye and is covered with the *cornea*. Behind the cornea is a fluid called the *aqueous humor*. Behind that is the *lens,* composed of a fibrous jelly. The lens is held in place by ligaments that connect it to the *ciliary muscles,* which allow the lens to change shape and thus change its focus. Behind the lens is the *vitreous humor*.

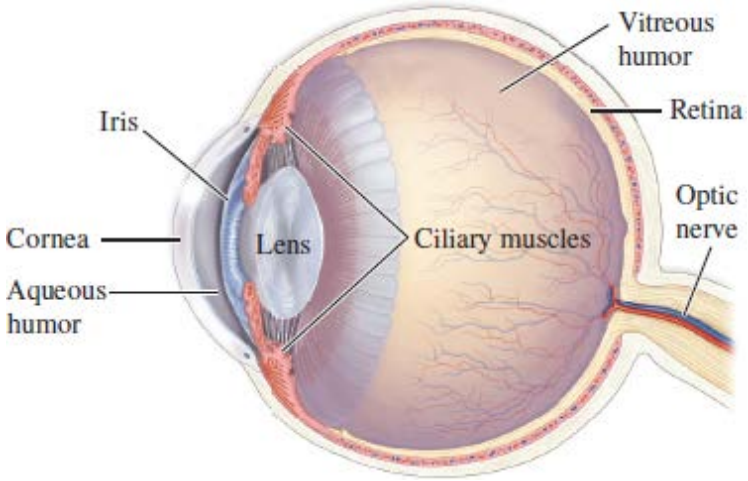

FIGURE 33.24 Drawing of the human eye, showing its major features.

Scott Bodell/Getty Images

The index of refraction of the two fluids in the eye is 1.34, close to that of water (1.33). The index of refraction of the material making up the lens is about 1.40. Thus, most refraction of light rays occurs at the air/cornea boundary, which has the largest difference in indices of refraction.

Refraction at the cornea and lens surfaces produces a real, inverted image on the *retina* of the eye. Cells in the retina called rods and cones convert the image from light to electrical impulses. These impulses are then sent to the brain through the *optic nerve*. The brain interprets the inverted image so that we see it upright. In front of the lens is the *iris,* the colored part of the eye, which partially opens or closes to regulate the amount of light incident on the retina.

For an object to be seen clearly, the image must be formed at the location of the retina (Figure 33.25a). The shape of the eye cannot be changed; so changing the shape of the lens must control the distance of the image. For a distant object, relaxing the lens focuses the image at the retina. For close objects, the ciliary muscle increases the curvature of the lens to again focus the image on the retina. This process is called **accommodation.**

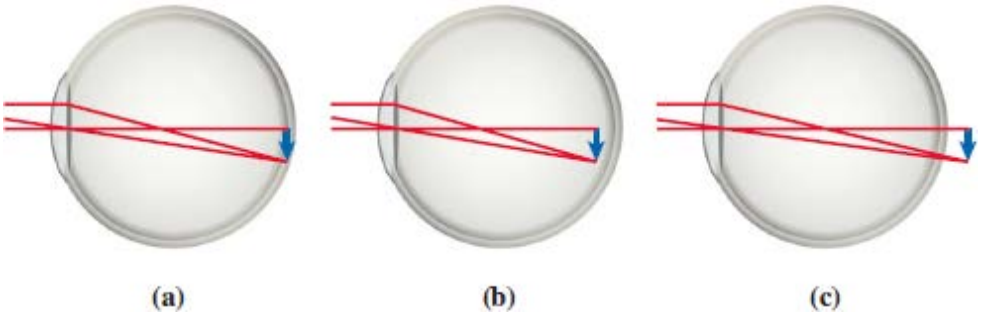

FIGURE 33.25 (a) Image produced by the lens of a normal-sighted person; (b) image produced by the lens of a nearsighted person; (c) image produced by a the lens of farsighted person.

The extremes over which distinct vision is possible are called the far point and near point. The **far point** of a normal eye is infinity. The **near point** of a normal eye depends on the ability of the eye to focus. This ability changes with age. A young child can focus on objects as near as 7 cm. As a person ages, the near point increases. Typically, a 50-year-old person has a near point of 40 cm.

Several common vision defects result from incorrect focal distances. In the case of **myopia** (nearsightedness), the image is produced in front of the retina (Figure 33.25b). In the case of **hyperopia** (farsightedness), the image would be produced behind the retina (Figure 33.25c) if it could, but the retina absorbs the light before an image can be formed. Myopia can be corrected using diverging lenses, while hyperopia can be corrected using converging lenses.

EXAMPLE 33.2 Corrective Lenses

PROBLEM 1

Optometrists often quote the power, P, of a corrective lens rather than its focal length, f (see equation 33.1). What is the power of the corrective lens for a myopic (nearsighted) person whose uncorrected far point is 15 cm?

SOLUTION 1

The corrective lens must form a virtual, upright image of an object located at infinity, with the image located 15 cm in front of the lens (Figure 33.26).

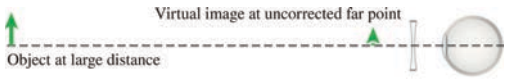

FIGURE 33.26 Geometry of a corrective lens for nearsightedness.

Thus, the object distance d_o is ∞ and the image distance d_i is -15 cm. From the lens equation

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f},$$

Page 1028

we have

$$\frac{1}{\infty} + \frac{1}{-0.15\ \text{m}} = \frac{1}{f} = -6.7\ \text{diopter}.$$

The required lens is a diverging lens with a power of -6.7 diopter and a focal length of -0.15 m.

PROBLEM 2

A hyperopic (farsighted) person whose uncorrected near point is 75 cm wishes to read a newspaper at a distance of 25 cm. What is the power of the corrective lens needed for this person to read the paper?

SOLUTION 2

The corrective lens must produce a virtual, upright image of the newspaper at the uncorrected near point of the person's vision (Figure 33.27).

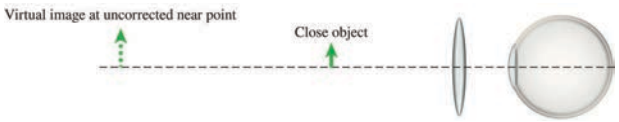

FIGURE 33.27 Geometry of a corrective lens for farsightedness.

The object and image are on the same side of the lens, so the image distance is negative. Thus, the object distance is 25 cm and the image distance is -75 cm:

$$\frac{1}{0.25\ \text{m}} + \frac{1}{-0.75\ \text{m}} = \frac{1}{f} = +2.7\ \text{diopter}.$$

The required lens is a converging lens with a power of $+2.7$ cm diopter, corresponding to a focal length of $+0.37$ m.

Concept Check 33.9

A hyperopic (farsighted) person can read a newspaper at a distance of $d = 125\,\text{cm}$, but no closer. What power lens should this person use for reading if they wish to hold the newspaper at a distance of 25 cm from their eyes?

a) -3.5 diopter

b) -1.25 diopter

c) $+0.50$ diopter

d) $+2.5$ diopter

e) $+3.2$ diopter

Contact Lenses

The corrective lenses described in Example 33.2 consist of converging and diverging lenses. The converging lenses are convex on both surfaces and the diverging lenses are concave on both surfaces. These lenses correct vision well, but can be inconvenient.

A more convenient type of corrective lens is the **contact lens.** A contact lens is placed directly on the cornea of the eye, relieving the person from having to wear external glasses. These lenses are convex on the entrance surface and concave on the exit surface, similar to the meniscus lenses discussed in Section 33.1 (Figure 33.12). The concave exit surface is placed directly on the eye, and of course its curvature is determined by the curvature of the eyeball. It is possible to produce contact lenses that are converging or diverging (Figure 33.28) by varying the curvature of the entrance surface.

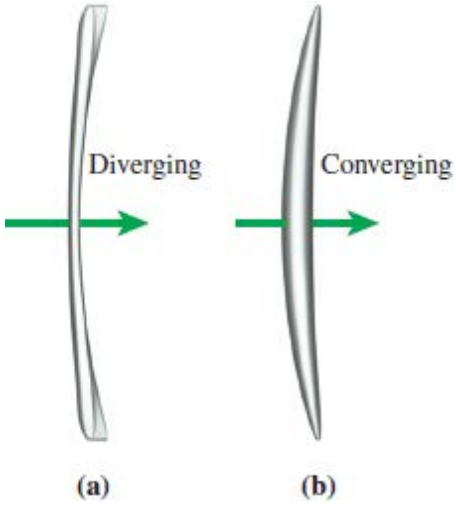

FIGURE 33.28 (a) A diverging contact lens. (b) A converging contact lens. The green arrows represent the direction of the light traveling through the lenses.

The contact lens shown in Figure 33.28a has $R_1 > R_2$ and thus has a negative focal length, corresponding to a diverging lens. The contact lens shown in Figure 33.28b has $R_1 < R_2$, which gives a positive focal length and a converging lens. Note, however, that the index of refraction of typical materials used for contact lenses is in the range between 1.4 and 1.8 and thus higher than the index of refraction of the cornea, which is slightly less than 1.4. In order to find the power of the contact lens, we cannot simply use the Lens-Maker's Formula 33.4, because the index of refraction of the medium next to the entrance and exit surfaces is different. Instead, we have to examine the change in the surface power of the cornea due to the presence of the contact lens and compare it to the sum of the surface powers of the entrance and exit surfaces of the lens.

LASIK Surgery

An alternative to corrective lenses has been developed in which the cornea is altered to produce the desired optical response of the human eye. One such method, laser-assisted in situ keratomileusis **(LASIK) surgery,** uses a laser to modify the curvature of the cornea.

An example of LASIK surgery used to correct myopia is shown in Figure 33.29. Part (a) shows a myopic human eye, with the image produced in front of the retina. The effective focal length of this eye is too short. The LASIK procedure begins with the cutting of a flap off the surface of the cornea and folding it back (Figure 33.29b), exposing the inner part of the cornea, called the stroma. An ultraviolet (UV) laser (wavelength 193 nm) is used to remove material in the stroma with very short laser pulses of duration on the order of 10 ns and energy of the order of 1 mJ, producing a flatter surface. This flatter surface corresponds to a larger radius of curvature for the cornea. (The laser operates with ultraviolet light that breaks down the molecular structure of the cornea without heating the surface.) The flap is then folded back and the cornea heals. The Lens-Maker's Formula (equation 33.4) tells us that increasing the front radius R_1 will increase the effective focal length f of the eye. Thus, the surgery allows the image to be produced on the retina (Figure 33.29c).

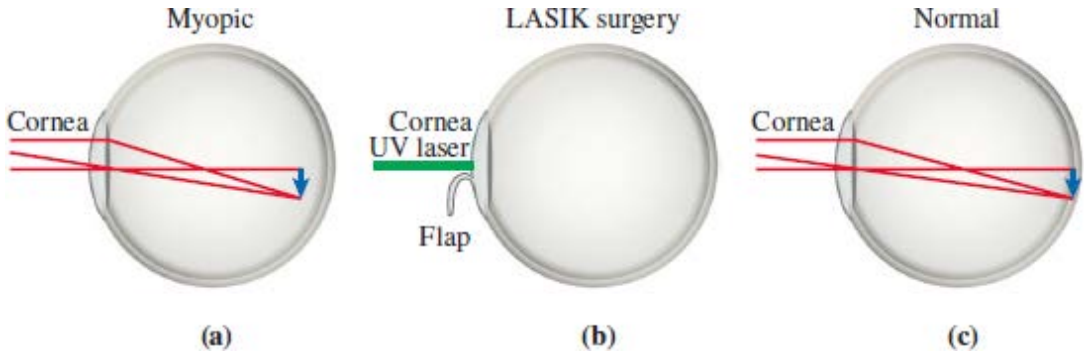

FIGURE 33.29 (a) A myopic (nearsighted) human eye, where the image is formed in front of the retina. (b) In LASIK surgery, a flap is cut from the surface of the cornea and part of the stroma is removed using a UV laser. The flap is then folded back and the cornea heals. (c) Normal vision is produced by focusing the image on the retina.

The technique described here is specific for myopic patients. The LASIK procedure does not work as well for hyperopic patients or for patients with astigmatism (irregular curvature of the cornea). To treat hyperopic patients, the laser must remove material in the stroma around the center of the cornea to increase the curvature of the surface.

33.5 Camera

The **camera** is an optical instrument consisting of a body that excludes light and contains a system of lenses that focuses an image of an object on a recording medium such as photographic film or a digital sensor. A camera with a digital sensor is often called a digital camera, which is our main interest in the present section. A drawing of a digital camera is shown in Figure 33.30.

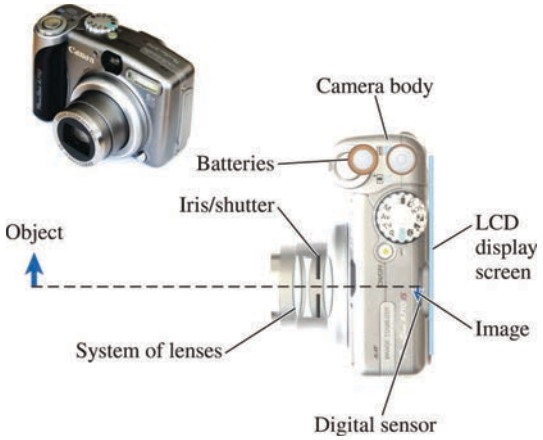

FIGURE 33.30 A typical digital camera produces an image on a digital sensor.

W. Bauer and G. D. Westfall

Normally we refer to the system of lenses in the camera as just the lens of the camera, neglecting the sophisticated multiple elements required to produce a high-quality image. The lens of the camera produces a real, inverted image of an object on the digital sensor. The camera lens is designed so that it can be moved to produce a sharp, focused image on the digital image recorder, depending on the image distance and the focal length of the lens. Many digital cameras have lenses that can be adjusted to have different focal lengths. A small digital camera, such as the one in Figure 33.30, with a 6× zoom lens can vary the focal length of the lens from 5.8 mm to 34.8 mm.

The lens has an opening area. An iris can be used to limit this opening area. The opening area is termed the **aperture** of the lens.

The aperture is important because the amount of light that the camera can collect is proportional to the aperture. Because the aperture is usually a circle, we usually characterize the aperture by its diameter.

The size of the lens is often referred to as the ***f*-number** of the lens. The *f*-number of a lens is defined as the focal length of the lens divided by the diameter of the aperture of the lens:

$$f\text{-number} = \frac{\text{focal length}}{\text{aperture diameter}} = \frac{f}{D}. \qquad \textbf{(33.10)}$$

A lens with a small *f*-number is called a fast lens, and a lens with a large *f*-number is called a slow lens. A small *f*-number implies a large aperture, which means that the lens can collect a large amount of light. A large *f*-number implies a small aperture, which means that the lens cannot collect a large amount of light. By convention, the *f*-number of a lens is usually written as $f/\#$, where $\#$ represents the ratio of the focal length of the lens divided by the aperture diameter. For example, the small digital camera in Figure 33.30 has a lens with *f*-number ranging from $f/2.8$ to $f/4.8$.

The aperture of the camera can be controlled by a variable iris, which limits the amount of light incident on the digital sensor. Conventionally, the *f*-number of a lens was set by twisting a ring on the lens. The ring had multiple indents placed at stops to help the photographer select the required amount of light. These ***f*-stops** were placed at intervals that changed the amount of light accepted by a factor of two. Because the aperture depends on the square of the diameter, the *f*-stops were spaced a factor of $\sqrt{2}$ apart. Some of the standard *f*-stops are $f/2$, $f/2.8$, $f/4$, $f/5.6$, $f/8$, $f/11$, and $f/16$. Modern digital cameras usually set the required *f*-number automatically.

The digital image sensor requires a specific amount of light to form a good image. The iris can function as a shutter to control the

amount of time the sensor sees and the total amount of light that is incident on the sensor. Unlike a film camera, the shutter of a digital camera is usually open to allow the photographer to see exactly what the camera sees on the LCD screen on the back of the camera. The total amount of light energy is the product of the time the light is incident on the digital sensor times the aperture times the light intensity. A digital sensor can also be programmed to accept light only over a given time interval without the use of a mechanical shutter. A typical time interval for an exposure varies from $1/60^{\text{th}}$ of a second to $1/1000^{\text{th}}$ of a second. Short exposure times allow the camera to capture a moving image without blurring. To prevent unwanted light interfering with a recorded image, the shutter closes while the image is being read out.

In addition to controlling the amount of light incident on the digital sensor, the iris can also affect the image by changing the **depth of field** of the image, which is the range in object distance where the image is in focus. If the iris is small (larger *f*-number), the range of angles of incident light is restricted, and a wider range of object distances will still produce a focused image on the digital sensor. If the iris is wide open (smaller *f*-number), a larger range of angles are admitted into the camera, meaning that only a narrow range of object distances will produce a focused image on the digital sensor. Thus, the photographer can increase the depth of field of an image by closing down the aperture and increasing the exposure time, or decrease the depth of field by opening the aperture and decreasing the exposure time.

The standard photographic film used for many years was 36 mm wide and 24 mm tall and was usually called 35-mm film. Most digital sensors are much smaller than 35-mm film. A typical small digital camera has a digital sensor that is 5.76 mm wide and 4.29 mm tall. This small size affects the magnification of the image produced by the camera, depending on the focal length of the lens. The **angle of view** of the camera, α, is more relevant to photography than the magnification. The angle of view can be defined in terms of the horizontal angle, the vertical angle, or the diagonal angle, where horizontal and vertical refer to the geometry of the film or digital sensor. We will consider the horizontal angle

of view here, but the other two versions can be easily calculated from our results for the horizontal angle of view.

We can derive an expression for the horizontal angle of view, α, starting with our definition of linear magnification, m,

$$m = \frac{h_\mathrm{i}}{h_\mathrm{o}} = -\frac{d_\mathrm{i}}{d_\mathrm{o}},$$

where h_i is the image height, h_o is the object height, d_i is the image distance, and d_o is the object distance. Because photographers are not concerned about whether the image is upright or inverted, we will use the absolute value of the heights and distances in this calculation. In Figure 33.31 we show a schematic drawing containing an object, its corresponding image on film or a digital sensor, and the lens.

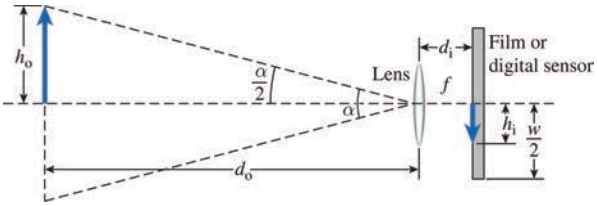

FIGURE 33.31 Schematic drawing of a camera showing the angle of view.

The horizontal width of the sensor is w. The object as shown in Figure 33.31 subtends an angle of $\alpha/2$ and the horizontal angle of view is α. The maximum image size that the film or digital sensor can detect occurs when the image height is equal to half the width of the film or digital sensor, $h_\mathrm{i} = w/2$. If the object is not too close to the camera, the image distance is approximately equal to the focal length f of the lens, so we can use the definition of the linear magnification to write

$$\frac{w/2}{h_\mathrm{o}} = \frac{d_\mathrm{i}}{d_\mathrm{o}} \approx \frac{f}{d_\mathrm{o}} \Rightarrow \frac{h_\mathrm{o}}{d_\mathrm{o}} \approx \frac{w}{2f}.$$

From Figure 33.31, we can see that the horizontal angle of view can be related to the object height and object distance as

$$\frac{h_\text{o}}{d_\text{o}} = \tan(\alpha/2).$$

Combining these two equations for the ratio h_o/d_o gives us

$$\frac{h_\text{o}}{d_\text{o}} = \frac{w}{2f} = \tan(\alpha/2).$$

Thus, the horizontal angle of view is

$$\alpha = 2\tan^{-1}\left(\frac{w}{2f}\right). \qquad \textbf{(33.11)}$$

As an example of the effect of changing the focal length on a picture taken with a camera, we show three photos of a statue taken with different zoom settings in Figure 33.32.

FIGURE 33.32 Photos of a statue using three different zooms: (a) $1\times$ zoom; (b) $3\times$ zoom; (c) $6\times$ zoom.

W. Bauer and G. D. Westfall

The $1\times$ zoom setting corresponds to a focal length of 5.8 mm, the $3\times$ setting corresponds to a focal length of 17.4 mm, and the $6\times$ setting corresponds to a focal length of 34.8 mm. The horizontal angle of view is shown for each of the three zoom settings in Figure 33.33.

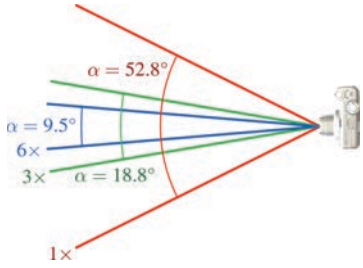

FIGURE 33.33 The horizontal angle of view for a small digital camera with $1\times$, $3\times$, and $6\times$ zooms.

W. Bauer and G. D. Westfall

The horizontal angle of view for the $1\times$ zoom setting of $\alpha = 52.8^\circ$ is close to the horizontal angle of view of normal human vision of α~$50^\circ - 60^\circ$. (Our peripheral vision extends to approximately 180°, but the inner $50^\circ - 60^\circ$ dominate our perception.) The $6\times$ zoom setting has a narrow horizontal angle of view of $\alpha = 9.5^\circ$, providing a magnified image of the statue. For the camera to have a wider horizontal angle of view (wide-angle view), it would need a lens with a focal length less than 5.8 mm.

The digital sensor is composed of millions of electronic picture elements (pixels). For example, the small digital camera in Figure 33.30 uses a charge-coupled device (CCD) digital sensor with an array of pixels 3072 pixels wide and 2304 pixels tall for a total of 7,077,888 pixels (7.1 megapixels). Each pixel responds to light by liberating electrons. An analog-to-digital converter (ADC) reads out the pixels by digitizing the number of liberated electrons. The pixels in each row are digitized in order. Then the next row is shifted down and digitized until all the pixels are digitized. The question now remains: How does the CCD produce a color picture? The CCD responds only to the intensity of light, not the wavelength. The answer is that light from the image focused on the CCD first passes through a Bayer filter as illustrated in Figure 33.34.

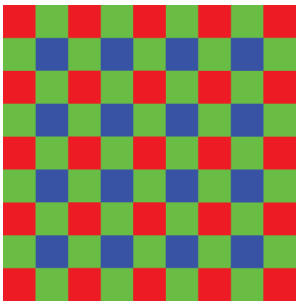

FIGURE 33.34 A portion of a Bayer filter used to produce color images with digital sensors.

The Bayer filter consists of rows of alternating pixels of red and green, followed by a row of alternating pixels of blue and green. There are more green pixels than red or blue pixels because the eye responds better to green than to red or blue. A small microprocessor in the camera calculates the best color for each pixel, based on the intensity of the red, green, and blue light passed by the Bayer filter.

A computer projector works much like a digital camera, except that the object is at the focus of the lens, which projects an image on a distant screen. The object for the projector can be a small light-transmitting LCD (liquid crystal display, see Chapter 31) screen that displays the image to be projected. A bright light shines through the LCD to produce the object for the lens. Another type of projector is the DLP (digital light processor), which uses small mirrors etched on a computer chip to produce the image. Each mirror represents a pixel. Colors are produced by alternately bathing the chip in red, green, and blue light. The image produced by the mirrors becomes the object for a lens, which projects the image on a screen. Movie theaters commonly use digital projectors based on DLP.

EXAMPLE 33.3 Focal Length of a Simple Point-and-Shoot Camera

For certain occasions, a simple point-and-shoot camera is sufficient. For example, you might want to take pictures in a situation in which you might lose or damage your smartphone. One solution is an inexpensive disposable camera that uses 35-mm film (36 mm wide and 24 mm tall) like the one shown in Figure 33.35. You could also envision another version that uses a digital sensor that is 4.0 mm wide and 3.0 mm tall.

FIGURE 33.35 A simple point-and-shoot camera with fixed focal length.

W. Bauer and G. D. Westfall

PROBLEM

What are the required focal lengths of the lenses for these cameras if they are to have a horizontal angle of view of $\alpha = 46^\circ$?

SOLUTION

The expression for the horizontal angle of view is given by equation 33.11:

$$\alpha = 2 \tan^{-1}\left(\frac{w}{2f}\right).$$

We can rearrange this equation to obtain the focal length

$$f = \frac{w}{2\,\tan(\alpha/2)}.$$

The focal length for the 35-mm film version is

$$f = \frac{w}{2\,\tan(\alpha/2)} = \frac{36\,\text{mm}}{2\tan(46^\circ/2)} = 42\,\text{mm}.$$

The focal length for the digital sensor version is

$$f = \frac{w}{2\,\tan(\alpha/2)} = \frac{4.0\,\text{mm}}{2\,\tan(46^\circ/2)} = 4.7\,\text{mm}.$$

The digital sensor version would be considerably smaller than the 35-mm film version.

33.6 Microscope

The simplest **microscope** is a system of two lenses. For example, Figure 33.36 shows a microscope constructed of two thin lenses. The first lens is a converging lens of short focal length, f_o, called the **objective lens.** The second lens is another converging lens of greater focal length, f_e, called the **eyepiece.**

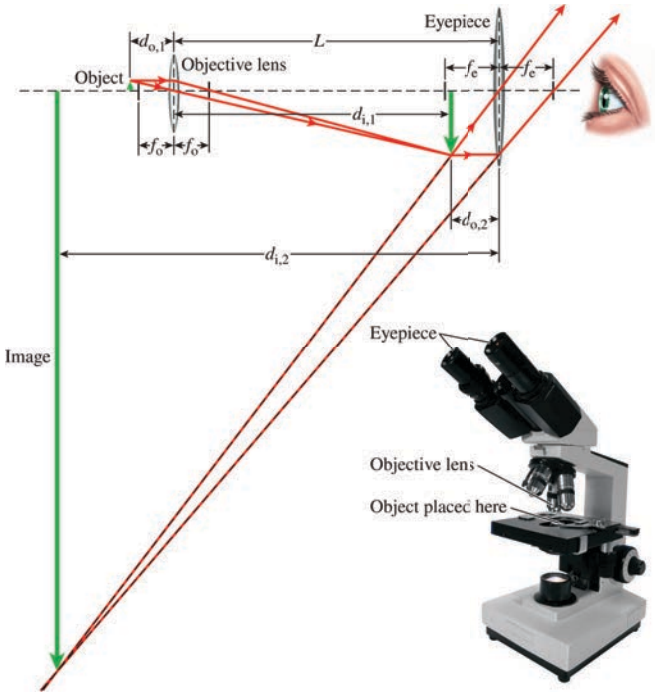

FIGURE 33.36 Geometry of the image formed by a microscope. The objective lens, eyepiece, and object for a real microscope are also shown.

Microscope: Comstock/Getty Images

The object to be observed is placed just outside the focal length f_o of the objective lens, so that $d_{o,1} \approx f_o$. This arrangement allows the objective lens to form a real, inverted, and enlarged image of the object some distance from the objective lens. This image then

becomes the object for the eyepiece lens. This intermediate image is placed just inside the focal length f_{e} of the eyepiece lens, so that the eyepiece lens produces a virtual, upright, and enlarged image of the intermediate image and $d_{\mathrm{o},2} \approx f_{\mathrm{e}}$. The resulting magnification of the microscope is the product of the magnification from each lens.

Let L be the distance between the two lenses, and assume $L \gg f_{\mathrm{o}}, f_{\mathrm{e}}$. Using the notation of Section 33.3, this means that $d_{\mathrm{i},1} \approx L$. Thus, the linear magnification of the microscope is

$$m = \frac{d_{\mathrm{i},1} d_{\mathrm{i},2}}{d_{\mathrm{o},1} d_{\mathrm{o},2}} = -\frac{(0.25\ \mathrm{m}) L}{f_{\mathrm{o}} f_{\mathrm{e}}}, \qquad \textbf{(33.12)}$$

where we have used $d_{\mathrm{i},2} = -0.25\ \mathrm{m}$ because we assume that the final image is produced at a comfortable viewing distance of 0.25 m.

EXAMPLE 33.4 Magnification of a Microscope

Consider a microscope that consists of an objective lens and an eyepiece lens separated by 15 cm. The focal length of the objective lens is 2 mm, and the focal length of the eyepiece lens is 20 mm. Assume the final image is produced at a distance of 25 cm.

PROBLEM

What is the magnitude of the linear magnification of this microscope?

SOLUTION

Taking our expression for the linear magnification of a microscope (equation 33.12), we have

$$|m| = \frac{(0.25\text{ m})L}{f_\text{o} f_\text{e}} = \frac{(0.25\text{ m})(0.15\text{ m})}{(0.002\text{ m})(0.020\text{ m})} = 940.$$

Concept Check 33.10

A microscope is intended to have a linear magnification whose magnitude is 330. If the objective lens has a power of 350 diopter and the eyepiece lens has a power of 10.0 diopter, how long must the microscope be? Assuming final image is produced at a distance of 25 cm.

a) 37.7 cm

b) 40.0 cm

c) 51.3 cm

d) 65.0 cm

e) 75.0 cm

33.7 Telescope

Telescopes come in many forms, including **refracting telescopes** and **reflecting telescopes.** In this chapter we study the magnification of the telescope, which is a measure of the telescope's ability to help us see large but distant objects. The resolution of a telescope, which is the capability to distinguish two nearby objects, is equally important and will be covered in Chapter 34.

Refracting Telescope

The refracting telescope consists of two converging lenses—the objective and the eyepiece. A modern commercial refracting telescope used by amateur astronomers is shown in Figure 33.37. In the following examples, we represent a telescope using two thin lenses. However, an actual refracting telescope uses more sophisticated lenses.

FIGURE 33.37 A modern telescope used by amateur astronomers. This telescope has an 80-mm diameter objective lens with a 400-mm focal length.

Meade Instruments

Because the object to be viewed is at a large distance, the incoming light rays can be considered to be parallel. Thus, the objective lens forms a real image of the distant object at distance f_o (Figure 33.38). The eyepiece is placed so that the image formed by the objective is a distance f_e from the eyepiece. Thus, the eyepiece forms a virtual, magnified image at infinity of the image formed by

the objective, again producing parallel rays. In Figure 33.38, the parallel light rays from the distant object are shown incident on the objective lens. Red-and-black dashed lines depict the parallel light rays forming the virtual image.

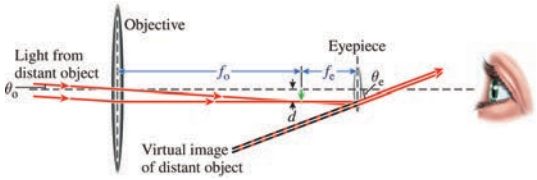

FIGURE 33.38 Geometry of an image formed by a refracting telescope.

Because the telescope deals with objects at large distances, it is not helpful to determine the magnification of the telescope using the formula for linear magnification which involves distances found from the lens equation. Therefore, we define the angular magnification of the telescope as -1 times the angle observed in the eyepiece θ_e divided by the angle subtended by the object being viewed θ_o (Figure 33.38),

$$m_\theta = -\frac{\theta_e}{\theta_o} = -\frac{f_o}{f_e}. \qquad \textbf{(33.13)}$$

DERIVATION 33.2 Angular Magnification

The angle θ_o is the angle subtended by a distant object. The height of the image produced by the objective lens is d (Figure 33.38). This image is produced at the focal length of the objective lens, f_o. Because the focal length of the objective lens is large compared with the image size,

$$\theta_o \approx \tan\theta_o = \frac{d}{f_o}.$$

The image is placed at the focal point of the eyepiece lens. The apparent angle in the eyepiece, θ_e, can be written as

$$\theta_e \approx \tan\theta_e = \frac{d}{f_e},$$

again assuming that the image size is small compared with the focal length of the eyepiece. The ratio of the apparent eyepiece angle to the objective angle gives the angular magnification:

$$\frac{\theta_e}{\theta_o} = \frac{d/f_e}{d/f_o} = \frac{f_o}{f_e}.$$

Page 1035

Thus, the angular magnification of a refracting telescope is

$$m_\theta = -\frac{f_o}{f_e},$$

where the minus sign means that the image is inverted.

For example, the refracting telescope shown in Figure 33.37 has an objective lens with focal length $f_o = 400\,\text{mm}$ and an eyepiece with focal length $f_e = 9.70\,\text{mm}$, which gives the telescope a magnification of

$$m = -\frac{f_o}{f_e} = -\frac{400\,\text{mm}}{9.7\,\text{mm}} = -41.$$

EXAMPLE 33.5 Magnification of a Refracting Telescope

The world's largest refracting telescope at that time was completed in 1897 and is still in use and housed at the Yerkes Observatory in Williams Bay, Wisconsin (between Chicago and Milwaukee). It has an objective lens of diameter 1.0 m (40 in) with a focal length of 19 m (62 ft).

PROBLEM

What should the focal length of the eyepiece be to give a magnification of magnitude 250?

SOLUTION

The focal length of the objective lens is given as $f_o = 19\,\text{m}$. The absolute value of the magnification is to be $|m| = 250$. The magnification is given by $|m| = f_o/f_e$. This gives us the focal length of the eyepiece lens as

$$f_e = \frac{f_o}{|m|} = \frac{19\,\text{m}}{250} = 0.076\,\text{m} = 7.6\,\text{cm}.$$

Reflecting Telescope

Most large astronomical telescopes are reflecting telescopes, with the objective lens replaced with a concave mirror. (However, the eyepiece of a reflecting telescope is still a lens.) An example of such a telescope is the Southern Astrophysical Research (SOAR) telescope shown in Figure 33.39, which has a 4.1-m diameter primary mirror. Large mirrors are necessary to gather as much light as possible to produce high-quality images from distant, faint astronomical objects. The light-gathering capability of a telescope is in practice much more important than the resulting magnification of the telescope.

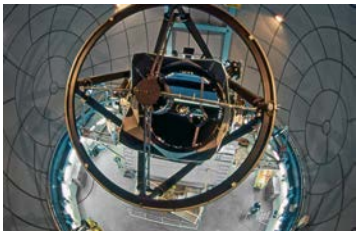

FIGURE 33.39 The SOAR telescope with a 4.1-m diameter primary mirror.

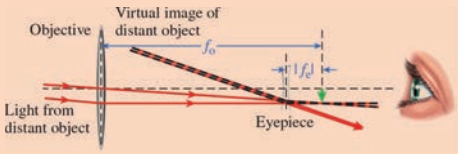
©Victor Krabbendam/Southern Astrophysical Research Telescope

Self-Test Opportunity 33.5

A refracting telescope using two converging lenses is often called a Keplerian telescope. The eyepiece lens is placed a distance $d = f_o + f_e$ from the objective lens. Another type of refracting telescope uses a converging lens for the objective lens and a diverging lens for the eyepiece lens.

The eyepiece lens in this telescope is placed at a distance $d = f_o + f_e$, where $f_e < 0$. This type of telescope is often called a Galilean telescope. Discuss some advantages of a Galilean telescope versus a Keplerian telescope.



Large mirrors are easier to fabricate and maintain in position than large lenses. Also, mirrors don't have chromatic aberration, so they work for a larger range of wavelengths. Finally, the size of refracting telescopes is limited because large lenses, which can be supported only around their edges, tend to sag due to their own weight. By contrast, modern reflecting telescopes use a large number (on the order of 100) individual computer-controlled force actuators on the backside of the mirror to keep it as closely as possible in the ideal parabolic shape required for optimum image quality. These force actuators typically can each exert pulling or pushing forces of the order of 100 N on the mirror. They enable the mirror surface to stay within a few tens of nanometers of the ideal parabolic shape, even as the entire telescope is gradually rotated and tilted to stay locked on the astronomical object that it is tracking through the night sky during long-exposure imaging.

Various types of reflecting telescopes have been developed. Figure 33.40 shows three simple examples. The simplest form of reflecting telescope incorporates a parabolic mirror and an eyepiece (Figure 33.40a). This geometry is impractical because the observer must be placed in the direction from which the light comes. In the Newtonian solution to a reflecting telescope, a plane mirror at an angle of 45° reflects the light outside the structure of the telescope to an eyepiece (Figure 33.40b). In the Cassegrain geometry, a secondary convex hyperboloid mirror, placed perpendicular to the optic axis of the mirror, reflects the light through a hole in the center of the mirror (Figure 33.40c). In the last two cases, the secondary mirror is small enough that it absorbs a small (but not insignificant!) fraction of the incoming light. In all three cases, an eyepiece is used to magnify the image produced by the objective mirror. The SOAR telescope shown in Figure 33.39 uses the geometry shown in Figure 33.40b.

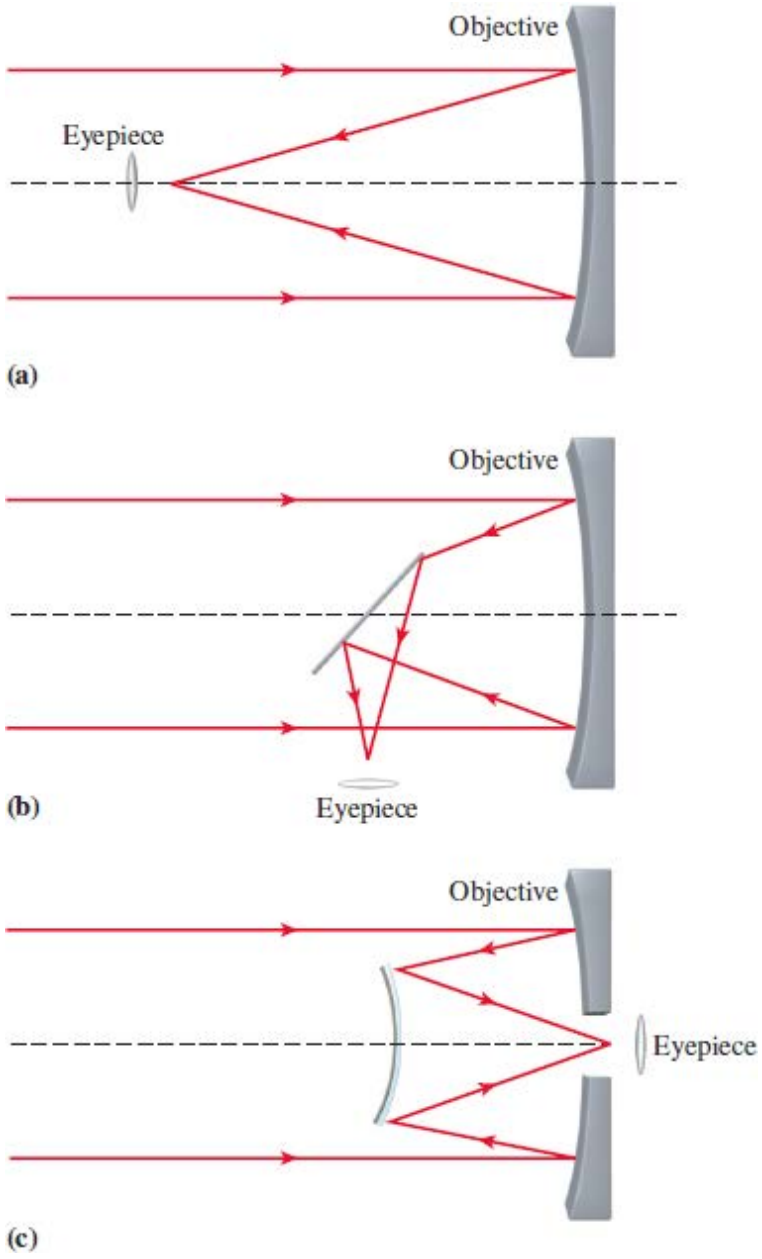


FIGURE 33.40 (a) Geometry of a standard reflecting telescope. (b) Geometry of a Newtonian reflecting telescope, with the eyepiece to the side. (c) Geometry of a Cassegrain reflecting telescope, with a secondary mirror and an eyepiece in the rear. (The relative sizes of the

secondary mirror and
eyepieces are not to scale
with the primary mirror and
are exaggerated.)

Hubble Space Telescope

The Hubble Space Telescope (HST), named for American astronomer Edwin Hubble (1889–1953), was deployed April 25, 1990, from the Space Shuttle (Figure 33.41). The HST orbits Earth 590 km above its surface, far above the atmosphere that disturbs the images gathered by ground-based telescopes. The HST is a reflecting telescope of Ritchey-Chrétian design arranged in Cassegrain geometry, but using a concave hyperbolic objective mirror, rather than a paraboloid mirror and a convex hyperbolic secondary mirror as is used in the traditional Cassegrain design. This design gives the HST a wide field of view and eliminates spherical aberration. The objective mirror is 2.40 m in diameter and has an effective focal length of 57.6 m. The secondary mirror is 0.267 m in diameter and is located 4.91 m from the objective mirror. The secondary mirror can be moved under ground control to produce the best focus. The eyepiece is replaced by a set of electronic instruments specialized for various astronomical tasks.

Concept Check 33.11

Suppose a reflecting telescope consists of a concave spherical mirror with a radius of curvature $R = 17.0\,\text{m}$ and an eyepiece lens of focal length $f_e = 29.0\,\text{cm}$. What is the magnitude of the magnification of this telescope?

a) 29.3

b) 45.0

c) 58.6

d) 66.1

e) 78.9

Concept Check 33.12

Reflecting telescopes with large mirror diameters are better than those with smaller diameters. Why?

a) Because they have a shorter focal length.

b) Because they have a longer focal length.

c) Because they have a greater magnification.

d) Because they can collect more light.

The original HST objective mirror was produced with a flaw caused by a defective testing instrument. The mirror had been polished very precisely, but unfortunately it was polished very precisely to a wrong shape. The maximum deviation from the perfect shape of the mirror was only 2.3 μm, but the resulting spherical aberrations were catastrophic (see Figure 33.42a). In

December 1993, a Space Shuttle Servicing Mission deployed the Corrective Optics Space Telescope Axial Replacement (COSTAR) package, which corrected the flaw in the objective mirror and allowed the HST to begin revolutionizing our understanding of the universe. The two images of the galaxy M100 shown in Figure 33.42 demonstrate the image quality of the HST before and after the installation of COSTAR. In February 1997, two new instrument packages were installed in the HST on Shuttle Servicing Mission 2. These instruments contained their own optical corrections. In December 1997, the Shuttle Servicing Mission 3A was launched to correct a serious problem with the HST's stabilizing gyroscopes. In March 2002, the Shuttle Servicing Mission 3B added several new instruments. Shuttle Servicing Mission 4 in May 2009 replaced two failed instruments (spectrograph and advanced camera) and installed two new instruments (spectrograph and wide field camera) as well as new batteries and gyroscopes.

NASA, STScI

James Webb Space Telescope

The replacement for the HST is the James Webb Space Telescope (JWST), named for NASA's second administrator, James E. Webb (1906–1992). The JWST was launched December 25, 2021. The objective mirror for the JWST is 6.5 m in diameter and is composed of 18 mirror segments. An artist's conception of the JWST is shown in Figure 33.43.

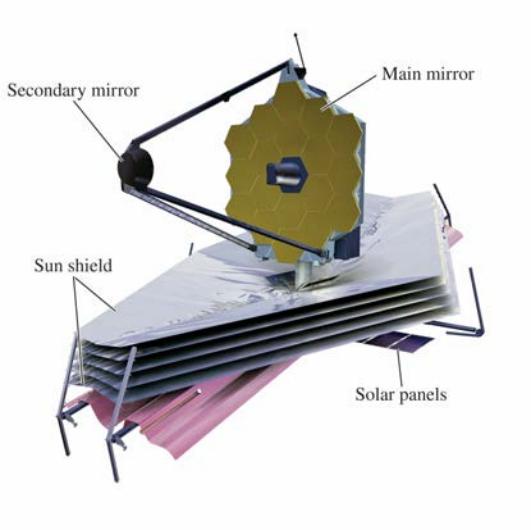

FIGURE 33.43 The James Webb Space Telescope. (Drawing from the Space Telescope Science Institute)

NASA

The JWST uses infrared light to study the universe. Infrared light can penetrate the dust clouds that occur in our galaxy and elsewhere and block visible light. The JWST orbits the Earth at a distance of 1.5 million km (about four times the Earth–Moon distance), in such a way that Earth will always be between the Sun and the JWST. Having the Sun always blocked by Earth allows continuous viewing and shields the cryogenic infrared detectors aboard the JWST from changes in sunlight. The JWST is also equipped with a multiple-layer sunshield as shown in Figure 33.43.

CHANDRA X-Ray Observatory

The JWST carries out observations using infrared light, which reflects well from mirrors. However, other types of electromagnetic waves do not reflect from the surfaces of mirrors. For example, if X-rays are incident on the surface of a mirror perpendicularly, they will penetrate the surface of the mirror rather than reflect. However, if the X-rays are incident on the surface of the mirror at a large angle, the X-rays will be reflected. The CHANDRA X-ray Observatory (CXO) produces images with X-rays using the mirrors shown in Figure 33.44a.

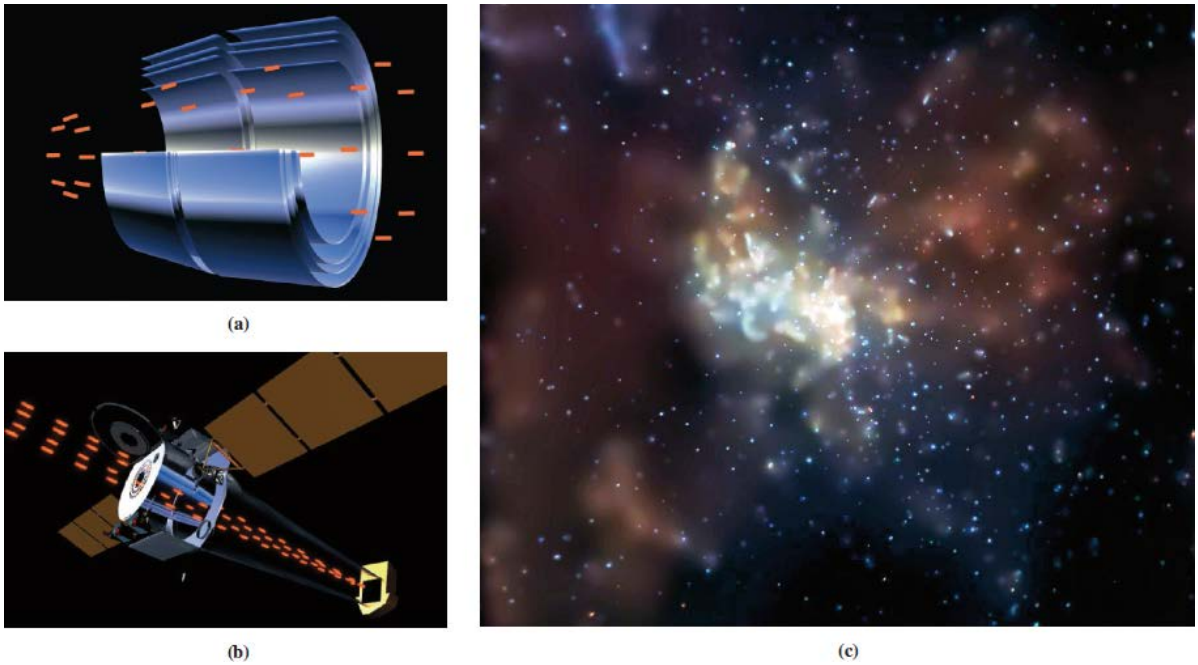

FIGURE 33.44 The CHANDRA X-ray Observatory. (a) The cylindrical mirrors used to focus X-rays. (b) The path of X-rays through CHANDRA. c) An X-ray image produced by CHANDRA of the center of the Milky Way Galaxy.

a: NASA/CXC/D.Berry; **b:** NASA/CXC/D.Berry & A.Hobart; **c:** NASA/CXC/MIT/F.K.Baganoff et al.

The mirrors of the CXO form images just as lenses and reflecting mirrors do (Figure 33.44b), although the geometry of the

X-ray lenses is different. These images formed using X-rays can give us information about high-energy regions of the universe such as the very active galactic center of the Milky Way Galaxy, shown in Figure 33.44c.

33.8 Laser Tweezers

After discussing the largest optical instruments with which we can explore the largest structures of the universe, we want to devote the last section of this chapter to an optical instrument with which we can manipulate some of the smallest structures.

As shown in Example 31.3, the force exerted on an object by light is on the order of 10^{-12} N$(= 1$ piconewton$)$. This force is too small to affect macroscopic objects. However, physicists using very intense lasers focused to a small area can exert forces sufficient to manipulate objects as small as a single atom. These devices are called optical traps or **laser tweezers.**

Laser tweezers are constructed by focusing an intense laser beam to a point using the objective lens of a microscope. The force exerted by a laser pointer on a piece of paper produces a force in the direction of the original laser beam. In the physical realization of laser tweezers, the laser beam is focused in such a way that the light is more intense in the middle of the light distribution. In addition, the focusing produces light rays that converge on a point.

Let's consider the effect of the focused laser light on a spherical, optically transparent object. This object could be a small plastic sphere or a living cell that is approximately spherical. Define the original direction of the laser light as the z-direction, so the xy-plane lies perpendicular to the incident direction. Figure 33.45a shows the object in the yz-plane, displaced slightly in the negative y-direction. Light coming from the center of the distribution of light is more intense and also (as we will see in Chapter 34) is refracted (or bent) downward. Light coming from the edge of the distribution is less intense and is refracted upward. The resultant change in momentum of the incident light rays in the y-direction is downward. To conserve momentum, the object must recoil in the positive y-direction. Thus, the intense focused light of the laser produces a restoring force on the object if it is not positioned at $y = 0$, and the object is trapped in the y-direction.

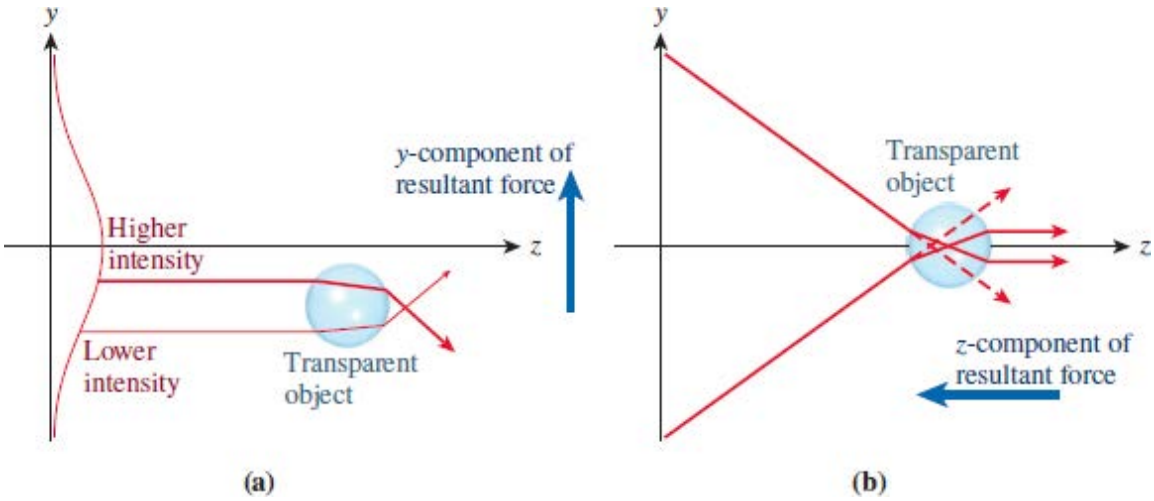

FIGURE 33.45 The effect of focused laser light on a small, spherical, optically transparent object. (a) The curved red line on the left represents the varying intensity of the wave. In addition, the restoring force in the *y*-direction is shown. (b) A restoring force also occurs in the *z*-direction.

In the *z*-direction, which is the direction of the incident laser light, trapping also occurs because of the converging rays produced by the focusing of the light by the lens (Figure 33.45b). In this case, the object is just to the right of the focus point. The incident rays are refracted such that they are more parallel to the incident direction than before. Thus, the component of the momentum of light in the *z*-direction has been increased and the transparent object must recoil in the opposite direction to conserve momentum. If the object were to the left of the focus point, it would experience a force to the right. Thus, the object is trapped in the direction parallel to the incident laser light as well as the direction perpendicular to the light.

This technique relies on the transmission of the incident light. If this technique is applied to an object that is not transparent, the incident light will be reflected and will produce a force pushing the object in the general direction of the incident light.

Laser tweezers have been used to trap cells, bacteria, viruses, and small polystyrene beads. They have also been used to

manipulate DNA strands and to study molecular-size motors.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- For images formed by lenses, the object distance, the image distance, and the focal length of the lens are related by the Thin-Lens Equation, $\frac{1}{d_\text{o}} + \frac{1}{d_\text{i}} = \frac{1}{f}$. Here d_o is always positive, whereas d_i is positive if the image is on the opposite side of the lens as the object and negative if on the same side. The focal length f is positive for converging lenses and negative for diverging lenses.
- The Lens-Maker's Formula relates the curvature of both sides of a lens and its index of refraction to its focal length, $\frac{1}{f} = (n-1)\left(\frac{1}{R_1} - \frac{1}{R_2}\right)$.
- The diopter is a dimensionless number defined as the inverse of the focal length in meters.
- The angular magnification of a simple magnifier with an image at infinity is given by $m_\theta \approx \frac{0.25\text{ m}}{f}$. (Assumed here is a typical value of 0.25 m for the near point of the average middle-aged person.)
- The linear magnification of a microscope is given by $m = -\frac{(0.25\text{ m})L}{f_\text{o} f_\text{e}}$, where L is the distance between the two lenses, f_o is the focal length of the objective lens, and f_e is the focal length of the eyepiece lens. (Final image assumed formed at distance of 0.25 m.)
- The angular magnification of a telescope is given by $m_\theta = -\frac{\theta_\text{e}}{\theta_\text{o}} = -\frac{f_\text{o}}{f_\text{e}}$, where f_o is the focal length of the objective lens or mirror and f_e is the focal length of the eyepiece lens.
- The f-number of a camera lens is defined as the focal length of the lens f divided by the diameter of the aperture

of the lens D, f-number $= \dfrac{\text{focal length}}{\text{aperture diameter}} = \dfrac{f}{D}$.

- The horizontal angle of view of a camera is $\alpha = 2\tan^{-1}\left(\dfrac{w}{2f}\right)$, where w is the width of the film or digital image sensor and f is the focal length of the camera lens.

ANSWERS TO SELF-TEST OPPORTUNITIES

33.1 The answer is different for real and imaginary images. For a real image you can exchange the object and image locations, and you still get a physical situation, because the light rays can travel forward or backward through the lens. In other words, if you place an object in Figure 33.4 where the image is now, you would get a reduced-size image. In Figure 33.5, however, the image is virtual and not obtained where the rays physically cross, but where the extrapolations of the rays cross. In this case, you cannot simply interchange image and object. For an object placed inside the focal length of a converging lens you *always* obtain an enlarged image.

33.2 a) plane mirror

b) diverging mirror

c) diverging lens

d) converging lens

33.3 Taking $x = 0$ in equation 33.9 gives us $f_{\text{eff}} = f_2 f_1/(f_2 + f_1)$. We can invert this equation to get

$$\frac{1}{f_{\text{eff}}} = \frac{f_2 + f_1}{f_2 f_1} = \frac{1}{f_1} + \frac{1}{f_2}.$$

33.4 The magnitude of the magnification is given by $|m| = d_{\text{i}}/d_o$. If the object distance is infinity, then $d_{\text{i}} = f$. Thus, the 200-mm focal length lens will produce a magnification of four times that of the normal 50-mm lens.

33.5 Comparing with Figure 33.38, we can see that a Galilean telescope produces an upright image, which is useful for terrestrial telescopes, opera glasses, and binoculars. The Keplerian telescope produces an inverted image. A Galilean telescope can be shorter

than a Keplerian telescope, which is also useful for optical devices such as opera glasses or binoculars.

PROBLEM-SOLVING GUIDELINES

Basically the same guidelines as in the previous chapter also apply here, because for lenses and optical instruments we simply use the same ray-tracing laws as for mirrors.

1. Drawing a large, clear, well-labeled diagram should be the first step in solving almost any optics problem. Include all the information you know and all the information you need to find. Remember that angles are measured from the normal to a surface, not to the surface itself.

2. You need to draw only two principal rays to locate an image formed by mirrors or lenses, but you should draw a third ray as a check that they are drawn correctly. Even if you need to solve a problem using the mirror equation or Thin-Lens Equation, an accurate drawing can help you approximate the answers as a check on your calculations. But keep in mind that in some lens configurations with large magnification factors, even minute drawing inaccuracies can translate into large errors in image size or location. So it is also not a good idea to rely strongly on your drawing alone.

3. When you calculate distances for mirrors or lenses, remember the sign conventions and be careful to use them correctly. If a diagram indicates an inverted image, say, but your calculation does not have a negative sign, go back to the starting equation and check the signs of all distances and focal lengths.

4. In problems involving two or more optical elements it is usually required to calculate the intermediate image position after each element. It may be advisable to compute this position numerically before proceeding to the next optical element in the calculation. Often this prevents the problem from getting too complex.

MULTIPLE-CHOICE QUESTIONS

33.1 For a microscope to work as intended, the separation between the objective lens and the eyepiece must be such that the intermediate image produced by the objective lens will occur at a distance (as measured from the optical center of the eyepiece)

a) slightly larger than the focal length.

b) slightly smaller than the focal length.

c) equal to the focal length.

d) The position of the intermediate image is irrelevant.

33.2 Which one of the following is not a characteristic of a simple two-lens astronomical refracting telescope?

a) The final image is virtual.

b) The objective forms a virtual image.

c) The final image is inverted.

33.3 A converging lens will be used as a magnifying glass. In order for this to work, the object must be placed at a distance

a) $d_o > f$.

b) $d_o = f$.

c) $d_o < f$.

d) None of the above.

33.4 An object is moved from a distance of 30 cm to a distance of 10 cm in front of a converging lens of focal length 20 cm. What happens to the image?

a) Image goes from real and upright to real and inverted.

b) Image goes from virtual and upright to real and inverted.

c) Image goes from virtual and inverted to real and upright.

d) Image goes from real and inverted to virtual and upright.

e) None of the above.

33.5 What type of lens is a magnifying glass?

a) converging

b) diverging

c) spherical

d) cylindrical

e) plain

33.6 LASIK surgery uses a laser to modify the

a) curvature of the retina.

b) index of refraction of the aqueous humor.

c) curvature of the lens.

d) curvature of the cornea.

33.7 What is the focal length of a flat sheet of transparent glass?

a) zero

b) infinity

c) thickness of the glass

d) undefined

33.8 Where is the image formed if an object is placed 25 cm from the eye of a nearsighted person. What kind of a corrective lens should the person wear?

a) Behind the retina. Converging lenses.

b) Behind the retina. Diverging lenses.

c) In front of the retina. Converging lenses.

d) In front of the retina. Diverging lenses.

33.9 An object is placed on the left of a converging lens at a distance that is less than the focal length of the lens. The image produced will be

a) real and inverted.

b) virtual and upright.

c) virtual and inverted.

d) real and upright.

33.10 What would you expect to happen to the magnitude of the power of a lens when it is placed in water ($n = 1.33$)?

a) It would increase.

b) It would decrease.

c) It would stay the same.

d) It would depend if the lens was converging or diverging.

33.11 An unknown lens forms an image of an object that is 24 cm away from the lens, inverted, and a factor of 4 larger in size than the object. Where is the object located?

a) 6 cm from the lens on the same side of the lens

b) 6 cm from the lens on the other side of the lens

c) 96 cm from the lens on the same side of the lens

d) 96 cm from the lens on the other side of the lens

e) No object could have formed this image.

33.12 A single lens with two convex surfaces made of sapphire with index of refraction $n = 1.77$ has surfaces with radii of curvature $R_1 = 27.0$ cm and $R_2 = -27.0$ cm. What is the focal length of this lens in air?

a) 17.5 cm

b) 27.0 cm

c) 30.7 cm

d) 40.8 cm

e) 54.0 cm

33.13 A single lens with two convex surfaces made of sapphire with index of refraction $n = 1.77$ has surfaces with radii of curvature $R_1 = 27.0$ cm and $R_2 = -27.0$ cm. What is the focal length of this lens in water $(n = 1.33)$?

a) 17.5 cm

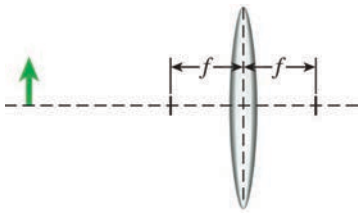
b) 27.0 cm

c) 30.7 cm

d) 40.8 cm

e) 54.0 cm

33.14 An object is placed 15.0 cm to the left of a converging lens with focal length $f = 5.00$ cm, as shown in the figure. Where is the image formed?



a) 1.25 cm to the right of the lens

b) 2.75 cm to the left of the lens

c) 3.75 cm to the right of the lens

d) 5.00 cm to the left of the lens

e) 7.50 cm to the right of the lens

33.15 The eyepiece for the Yerkes telescope has a focal length of approximately 10 cm. The Hubble Space Telescope can reach an effective angular magnification factor of 8000. What would the focal length of the objective lens at Yerkes need to be in order to reach the same factor of 8000?

a) 8 m

b) 80 m

c) 0.125 m

d) 0.00125 m

e) 800 m

33.16 Where is the image of the objective lens of a microscope located and what does it look like?

a) real and upright

b) real and inverted

c) virtual and upright

d) virtual and inverted

33.17 A pea sits at the focal point of a converging lens, 3 cm to the left of that lens on the optical axis. A second identical lens is at a distance of 12 cm to the right from the first one. Where is the image of the pea located, and is it real or virtual?

a) A virtual image 3 cm to the left of lens 2

b) A real image 3 cm to the left of lens 2

c) A virtual image 3 cm to the right of lens 2

d) A real image 3 cm to the right of lens 2

e) No image can be formed, because the 2 lenses are more than 2 focal lengths apart.

CONCEPTUAL QUESTIONS

33.18 Several small drops of paint (less than 1 mm in diameter) splatter on a painter's eyeglasses, which are approximately 2 cm in front of the painter's eyes. Do the dots appear in what the painter sees? How do the dots affect what the painter sees?

33.19 When a diver with 20/20 vision removes her mask underwater, her vision becomes blurry. Why is this the case? Does the diver become nearsighted (eye lens focuses in front of retina) or farsighted (eye lens focuses behind retina)? As the index of refraction of the medium approaches that of the lens, where does the object get imaged? Typically, the index of refraction for water is 1.33, while the index of refraction for the lens in a human eye is 1.40.

33.20 In H.G. Wells's classic story *The Invisible Man,* a man manages to change the index of refraction of his body to 1.0; thus, light would not bend as it enters his body (assuming he is in air and not swimming). If the index of refraction of his eyes were equal to one, would he be able to see? If so, how would things appear?

33.21 Astronomers sometimes place filters in the path of light as it passes through their telescopes and optical equipment. The filters allow only a single color to pass through. What are the advantages of this? What are the disadvantages?

33.22 Is it possible to start a fire by focusing the light of the Sun with ordinary eyeglasses? How, or why not?

33.23 Will the magnification produced by a simple magnifier increase, decrease, or stay the same when the object and the lens are both moved from air into water?

33.24 Is it possible to design a system that will form an image without lenses or mirrors? If so, how? and what drawbacks, if any, would it have?

33.25 A lens system widely used in machine vision for dimensional measurement is the so-called telecentric lens system. In its basic configuration, it consists of two thin lenses of focal lengths f_1 and f_2, respectively, placed a distance $d = f_1 + f_2$ apart, and a small circular aperture called a *stop* aperture placed at the common focal point between the two lenses. The purpose of such a system is to provide a magnification that is independent of the distance between the object and the lens system, within a specified range of distances that define the so-called *depth of field* of the system.

a) Draw a ray diagram through the system.

b) Determine the magnification of such a system.

c) Determine the requirements that must be met by the two lenses in order for a telecentric system to be able to image with maximum resolution an object with a diameter of 50.0 mm on a so-called $\frac{1}{2}$-inch CCD camera head (detector dimensions are $\sim 6.50\,\text{mm} \times 5.00\,\text{mm}$).

33.26 Lenses or lens systems for photography are rated by both focal length and "speed." The "speed" of a lens is measured by its *f*-number or *f*-stop, the ratio of its focal length to its aperture diameter. For many commercially available lenses this number is approximately a power of $\sqrt{2}$, e.g., 1.4, 2.0, 2.8, 4.0, etc.; the lens is provided with a mechanical iris diaphragm that can be set to different apertures or *f*-stops. The smaller the *f*-number, the "faster" the lens. "Faster" lenses are more expensive, as a wide aperture requires a higher-quality lens.

a) Explain the connection between *f*-number, (i.e., aperture diameter) and "speed."

b) Look up the necessary data and calculate the *f*-numbers of (the primary mirrors of) the Keck 10-meter telescope, the Hubble Space Telescope, and the Arecibo radio telescope.

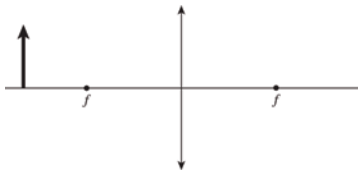
33.27 The *f*-number of a photographic system determines not just its speed but also its "depth of field," the range of distances over

which objects remain in acceptable focus. Low *f*-numbers correspond to small depth of field, high *f*-numbers to large depth of field. Explain this.

33.28 Mirrors for astronomical instruments are invariably *first-surface* mirrors: The reflective coating is applied on the surface exposed to the incoming light. Household mirrors, on the other hand, are *second-surface* mirrors: The coating is applied to the back of the glass or plastic material of the mirror. (You can tell the difference by bringing the tip of an object close to the surface of the mirror. Object and image will nearly touch with a first-surface mirror; a gap will remain between them with a second-surface mirror.) Explain the reasons for these design differences.

33.29 When sharing binoculars with a friend, you notice that you have to readjust the focus when he has been using it (he wears glasses, but removes them to use the binoculars). Why?

33.30 Using ray tracing in the diagram below, find the image of the object (upright arrow) in the following system having a diverging (double-concave) lens. Is the image real or virtual? Is the image height less than or greater than the object height?



33.31 You have made a simple telescope from two convex lenses. The objective lens is the one of the two lenses that is closer to the object being observed. What kind of image is produced by the eyepiece lens if the eyepiece is closer to the objective lens than the image produced by the objective lens?

33.32 What kind of lens is used in eyeglasses to correct the vision of someone who is

a) nearsighted?

b) farsighted?

33.33 A physics student epoxies two converging lenses to the opposite ends of a $2.0 \cdot 10^1$-cm-long tube. One lens has a focal

length of $f_1 = 6.0$ cm and the other has a focal length of $f_2 = 3.0$ cm. She wants to use this device as a microscope. Which end should she look through to obtain the highest magnification of an object?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 33.1

33.34 An object of height h is placed at a distance d_o on the left side of a converging lens of focal length $f (f < d_o)$.

a) What must d_o be in order for the image to form at a distance $3f$ on the right side of the lens?

b) What will be the magnification?

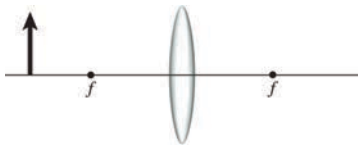
33.35 An object is 6.0 cm from a converging thin lens along the axis of the lens. If the lens has a focal length of 9.0 cm, determine the image magnification.

33.36 A biconvex *ice lens* is made so that the radius of curvature of the front surface is 15.0 cm and that for the back is 20.0 cm. Determine how far you would put dry twigs if you wish to start a fire with your ice lens.

33.37 As a high-power laser engineer you need to focus a 1.06-mm diameter laser beam to a 10.0-μm diameter spot 20.0 cm behind the lens. What focal length lens would you use?

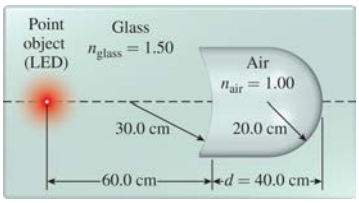
33.38 A plastic cylinder of length $3.0 \cdot 10^1$ cm has its ends ground to convex (from the rod outward) spherical surfaces, each having radius of curvature $1.0 \cdot 10^1$ cm. A small object is placed $1.0 \cdot 10^1$ cm from the left end. How far will the image of the object lie from the right end, if the index of refraction of the plastic is 1.5?

•**33.39** The object (upright arrow) in the following system has a height of 2.5 cm and is placed 5.0 cm away from a converging (convex) lens with a focal length of 3.0 cm. What is the magnification of the image? Is the image upright or inverted? Confirm your answers by ray tracing.



•**33.40** Demonstrate that the minimum distance possible between a real object and its real image through a thin convex lens is $4f$, where f is the focal length of the lens.

•**33.41** An air-filled cavity bound by two spherical surfaces is created inside a glass block. The two spherical surfaces have radii of 30.0 cm and 20.0 cm, respectively, and the thickness of the cavity is 40.0 cm (see diagram below). A light-emitting diode (LED) is embedded inside the block a distance of 60.0 cm in front of the cavity. Given $n_{\text{glass}} = 1.50$ and $n_{\text{air}} = 1.00$, and using only paraxial light rays (i.e., in the paraxial approximation):



a) Calculate the final position of the image of the LED through the air-filled cavity.

b) Draw a ray diagram showing how the image is formed.

Section 33.2

33.42 To study a tissue sample better, a pathologist holds a 5.00-cm focal length magnifying glass 3.00 cm from the sample. How much magnification can he get from the lens?

33.43 Suppose a magnifying glass has a focal length of 5.0 cm. Find the magnifying power of this glass when the object is placed at the near point.

33.44 What is the focal length of a magnifying glass if a 1.0-mm object appears to be 10. mm?

•**33.45** A person with a near-point distance of 24.0 cm finds that a magnifying glass gives an angular magnification that is 1.25 times larger when the image of the magnifier is at the near point than when the image is at infinity. What is the focal length of the magnifying glass?

Section 33.3

33.46 A beam of parallel light, 1.00 mm in diameter passes through a lens with a focal length of 10.0 cm. Another lens, this one of focal length 20.0 cm, is located behind the first lens so that the light traveling out from it is again parallel.

a) What is the distance between the two lenses?

b) How wide is the outgoing beam?

33.47 How large does a 5.0-mm insect appear when viewed with a system of two identical lenses of focal length 5.0 cm separated by a distance 12.0 cm if the insect is 10.0 cm from the first lens? Is the image real or virtual? Inverted or upright?

•**33.48** Three converging lenses of focal length 5.0 cm are arranged with a spacing of $2.0 \cdot 10^1$ cm between them, and are used to image an insect $2.0 \cdot 10^1$ cm away.

a) Where is the image?

b) Is it real or virtual?

c) Is it upright or inverted?

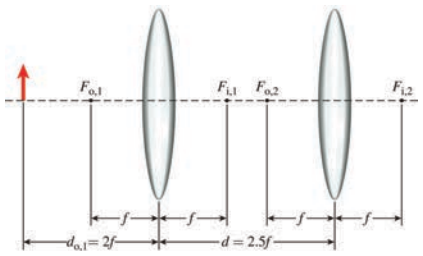
•**33.49** Two identical thin convex lenses, each of focal length *f,* are separated by a distance $d = 2.5f$. An object is placed in front of the first lens at a distance $d_{o,1} = 2f$.

a) Calculate the position of the final image of the object through the system of lenses.

b) Calculate the total transverse magnification of the system.

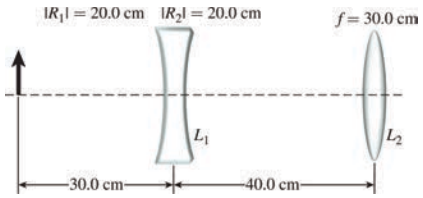
c) Draw the ray diagram for this system and show the final image.

d) Describe the final image (real or virtual, erect or inverted, larger or smaller) in relation to the initial object.



•**33.50** Two converging lenses with focal lengths 5.00 cm and 10.0 cm, respectively, are placed 30.0 cm apart. An object of height $h = 5.00$ cm is placed 10.0 cm to the left of the 5.00-cm lens. What will be the position and height of the final image produced by this lens system?

33.51 Two lenses are used to create an image for a source 10.0 cm tall that is located 30.0 cm to the left of the first lens, as shown in the figure. Lens L_1 is a biconcave lens made of crown glass (index of refraction $n = 1.55$) and has a radius of curvature of 20.0 cm for both surface 1 and 2. Lens L_2 is 40.0 cm to the right of the first lens L_1. Lens L_2 is a converging lens with a focal length of 30.0 cm. At what distance relative to the object does the image get formed? Determine this position by sketching rays and calculating algebraically.



••**33.52** Sophisticated optical systems can be analyzed and designed with the aid of techniques from linear algebra. Light rays (or particle beams) are described at any point along the axis of the system by a two-component column vector containing y, the distance of the ray from the optic axis, and dy/dx, the slope of the ray. Components of the system are described by 2×2 matrices which incorporate their effects on the ray; combinations of components are described by products of these matrices.

a) A thin lens does not alter the position of a ray, but increases (diverging) or decreases (converging) its slope an amount proportional to the distance of the ray from the axis. Construct the matrix for a thin lens of focal length f.

b) A space between components does not alter the slope of a ray; the distance of the ray from the axis changes by the slope of the ray times the length of the space. Write the matrix for a space of length x.

c) Write the matrix for the two-lens “zoom lens” system described in Section 33.3.

Section 33.4

33.53 The typical length of a human eyeball is 2.50 cm.

a) What is the effective focal length of the two-lens system made from a normal person's cornea and lens when viewing objects far away?

b) What is the effective focal length for viewing objects at the near point?

33.54 Using your answers from the previous question, and given that the cornea in a typical human eye has a fixed focal length of 2.33 cm, what range of focal lengths does the lens in a typical eye have?

33.55 Jane has a near point of 125 cm and wishes to read from a computer screen 40. cm from her eye.

a) What is the object distance?

b) What is the image distance?

c) What is the focal length?

d) What is the power of the corrective lens needed?

e) Is the corrective lens diverging or converging?

33.56 Bill has a far point of 125 cm and wishes to see distant objects clearly.

a) What is the object distance?

b) What is the image distance?

c) What is the focal length?

d) What is the power of the corrective lens needed?

e) Is the corrective lens diverging or converging?

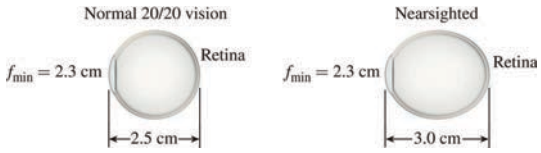
33.57 A person wearing bifocal glasses is reading a newspaper a distance of 25 cm. The lower part of the lens is converging for reading and has a focal length of 70. cm. The upper part of the lens is diverging for seeing at distances far away and has a focal length of 50. cm. What are the uncorrected near and far points for the person?

33.58 The radius of curvature for the outer part of the cornea is 8.0 mm, the inner portion is relatively flat. If the index of refraction of the cornea and the aqueous humor is 1.34:

a) Find the power of the cornea.

b) If the combination of the lens and the cornea has a power of 50. diopter, find the power of the lens (assume the two are touching).

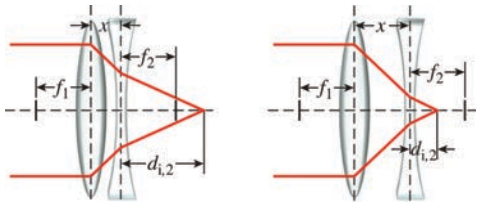
•33.59 As objects are moved closer to the human eye, the ciliary muscle causes the lens at the front of the eye to become more curved, thereby decreasing the focal length of the lens. The shortest focal length f_{min} of this lens is typically 2.3 cm. What is the closest one can bring an object to a normal human eye (see left side of figure below) and still have the image of the object projected sharply on the retina, which is 2.5 cm behind the lens? Now consider a nearsighted human eye that has the same f_{min} but is stretched horizontally, with a retina that is 3.0 cm behind the lens (see right side of figure below). What is the closest one can bring an object to this nearsighted human eye and still have the image of the object projected sharply on the retina. Compare the maximum angular magnification produced by this nearsighted eye with that of the normal eye.



•33.60 A person is nearsighted (myopic). The power of his eyeglass lenses is -5.75 diopters, and he wears the lenses 1.00 cm in front of his corneas. What is the prescribed power of his contact lenses?

Section 33.5

33.61 An amateur photographer attempts to build a custom zoom lens using a converging lens followed by a diverging lens. The two lenses are separated by a distance $x = 50.\ \text{mm}$ as shown below. If the focal length of the first lens is $2.0 \cdot 10^2$ mm and the focal length of the second lens is $-3.0 \cdot 10^2$ mm, what will the effective focal length of this compound lens be? What will f_{eff} be if the lens separation is changed to $1.0 \cdot 10^2$ mm?



33.62 For a certain camera, the distance between the lens and the film is 10.0 cm. You observe that objects that are very far away appear properly focused. How far from the film would you have to move the lens in order to properly focus an object 100. cm away?

33.63 A camera has a lens with a focal length of 60. mm. Suppose you replace the normal lens with a zoom lens whose focal length can be varied from 35. mm to 250. mm and use the camera to photograph an object very far away. Compared to a 60.-mm lens, what magnification of the image would be achieved using the 240.-mm focal length?

•**33.64** A camera lens usually consists of a combination of two or more lenses to produce a good-quality image. Suppose a camera lens has two lenses—a diverging lens of focal length 10.0 cm and a converging lens of focal length 5.00 cm. The two lenses are held 7.00 cm apart. A flower of length 10.0 cm, to be pictured, is held upright at a distance 50.0 cm in front of the diverging lens; the converging lens is placed behind the diverging lens. What are the location, orientation, size, and the magnification of the final image?

Section 33.6

33.65 A student finds a tube 20. cm long with a lens attached to one end. The attached lens has a focal length of 0.70 cm. The student wants to use the tube and lens to make a microscope with a magnification of $3.0 \cdot 10^2\times$. What focal length lens should the student attach to the other end of the tube?

33.66 The objective lens in a laboratory microscope has a focal length of 3.00 cm and provides an overall magnification of $1.00 \cdot 10^2$. What is the focal length of the eyepiece if the distance between the two lenses is 30.0 cm?

33.67 You have found in the lab an old microscope, which has lost its eyepiece. It still has its objective lens, and markings indicate that its focal length is 7.00 mm. You can put in a new eyepiece, which goes in 20.0 cm from the objective. You need a magnification of about 200. Assume you want the comfortable viewing distance for the final image to be 25.0 cm. You find in a drawer eyepieces marked 2.00-, 4.00-, and 8.00-cm focal length. Which is your best choice?

33.68 A microscope has a 2.00-cm focal length eyepiece and a 0.800-cm objective lens. For a relaxed normal eye, calculate the position of the object if the distance between the lenses is 16.2 cm.

•**33.69** Suppose you want to design a microscope so that for a fixed distance between the two lenses, the magnitude of the magnification will vary from 150 to 450 as you substitute eyepieces of various focal lengths.

a) If the longest focal length for an eyepiece is $6.0 \cdot 10^1$ mm, what will the shortest focal length be?

b) If you want the distance between the eyepiece and objective to be 35 cm, what should the focal length of the objective be?

Section 33.7

33.70 A refracting telescope has the objective lens of focal length 10.0 m. Assume it is used with an eyepiece of focal length 2.00 cm. What is the magnification of this telescope?

33.71 What is the magnification of a telescope with $f_o = 1.00 \cdot 10^2$ cm and $f_e = 5.00$ cm?

33.72 A simple telescope is formed using an eyepiece of focal length 25.0 mm and an objective of focal length 80.0 mm. Calculate the angle subtended by the image of the Moon when viewed through this telescope from the Earth.

33.73 Galileo discovered the moons of Jupiter in the fall of 1609. He used a telescope of his own design that had an objective lens with a focal length of $f_o = 40.0$ inches and an eyepiece lens with a focal length of $f_e = 2.00$ inches. Calculate the magnifying power of Galileo's telescope.

33.74 Two distant stars are separated by an angle of 35 arcseconds. If you have a refracting telescope whose objective lens focal length is 3.5 m, what focal length eyepiece do you need in order to observe the stars as though they were separated by 35 arcminutes?

•33.75 A 180× astronomical telescope is adjusted for a relaxed eye when the two lenses are 1.30 m apart. What is the focal length of each lens?

•33.76 Two refracting telescopes are used to look at craters on the Moon. The objective focal length of both telescopes is 95.0 cm and the eyepiece focal length of both telescopes is 3.80 cm. The telescopes are identical except for the diameter of the lenses. Telescope A has an objective diameter of 10.0 cm while the lenses of telescope B are scaled up by a factor of two, so that its objective diameter is 20.0 cm.

a) What are the angular magnifications of telescopes A and B?

b) Do the images produced by the telescopes have the same brightness? If not, which is brighter and by how much?

••**33.77** Some reflecting telescope mirrors utilize a rotating tub of mercury to produce a large parabolic surface. If the tub is rotating on its axis with an angular frequency ω, show that the focal length of the resulting mirror is: $f = g/2\omega^2$.

Additional Exercises

33.78 An object 4.0 cm high is projected onto a screen using a converging lens with a focal length of 35 cm. The image on the screen is 56 cm. Where are the lens and the object located relative to the screen?

33.79 A person with normal vision picks up a nearsighted friend's eyeglasses and attempts to focus on objects around her while wearing them. She is able to focus only on very distant objects while wearing the eyeglasses, and is completely unable to focus on objects that are near to her. Estimate the prescription of her friend's eyeglasses in diopters.

33.80 Suppose the near point of your eye is $2.0 \cdot 10^1$ cm and the far point is infinity. If you put on -0.20 diopter spectacles, what will be the range over which you will be able to see objects distinctly?

33.81 A fish is swimming in an aquarium at an apparent depth $d = 1.00 \cdot 10^1$ cm. At what depth should you grab in order to catch it?

33.82 A classmate claims that by using a 40.0-cm focal length mirror, he can project onto a screen a 10.0-cm tall bird located 100. m away. He claims that the image will be no less than 1.00 cm tall and inverted. Will he make good on his claim?

33.83 An object is 6.0 cm from a thin lens along the axis of the lens. If the lens has a focal length of 9.0 cm, determine the image distance.

33.84 A thin spherical lens is fabricated from glass so that it bulges outward in the middle on both sides. The glass lens has been ground so that the surfaces are part of a sphere with a radius of 25.0 cm on one side and a radius of 30.0 cm on the other. What is the power of this lens in diopters?

33.85 A diverging lens is fabricated from glass such that one surface of the lens is convex and the other surface is concave. The

glass lens has been ground so that the convex surface is part of a sphere with a radius of 45 cm and the concave surface is part of a sphere with a radius of $2.0 \cdot 10^1$ cm. What is the power of this lens in diopters?

33.86 A person who is farsighted can see clearly an object that is at least 2.5 m away. To be able to read a book $2.0 \cdot 10^1$ cm away, what kind of corrective glasses should he purchase?

33.87 You are experimenting with a magnifying glass (consisting of a single converging lens) at a table. You discover that by holding the magnifying glass 92.0 mm above your desk, you can form a real image of a light that is directly overhead. If the distance between the light and the table is 2.35 m, what is the focal length of the lens?

33.88 A girl forgets to put on her glasses and finds that she needs to hold a book 15 cm from her eyes in order to clearly see the print.

a) If she were to hold the book 25 cm away, what type of corrective lens would she need to use to clearly see the print?

b) What is the focal length of the lens?

33.89 The focal length of the lens of a camera is 38.0 mm. How far must the lens be moved to change focus from a person 30.0 m away to one that is 5.00 m away?

33.90 A telescope is advertised as providing a magnification of magnitude 41 using an eyepiece of focal length $4.0 \cdot 10^1$ mm. What is the focal length of the objective?

•33.91 Determine the position and size of the final image formed by a system of elements consisting of an object 2.0 cm high located at $x = 0$ m, a converging lens with focal length $5.0 \cdot 10^1$ cm located at $x = 3.0 \cdot 10^1$ cm and a plane mirror located at $x = 7.0 \cdot 10^1$ cm.

33.92 The distance from the lens (actually a combination of the cornea and the crystalline lens) to the retina at the back of the eye is 2.0 cm. If light is to focus on the retina,

a) what is the focal length of the lens when viewing a distant object?

b) what is the focal length of the lens when viewing an object 25 cm away from the front of the eye?

33.93 You visit your eye doctor and discover that you require lenses having a diopter value of -8.4. Are you nearsighted or farsighted? With uncorrected vision, how far away from your eyes must you hold a book to read clearly?

33.94 Jack has a near point of 32 cm and uses a magnifier of 25 diopter.

a) What is the magnification if the final image is at infinity?

b) What is the magnification if the final image is at the near point?

33.95 Where is the image and what is the magnification if you hold a 2.0-inch-diameter clear glass marble 1.0 ft in front of you?

•**33.96** A diverging lens with $f = -30.0$ cm is placed 15.0 cm behind a converging lens with $f = 20.0$ cm. Where will an object at infinity in front of the converging lens be focused?

•**33.97** An instructor wants to use a lens to project a real image of a light bulb onto a screen 1.71 m from the bulb. In order to get the image to be twice as large as the bulb, what focal length lens will be needed?

•**33.98** An old refracting telescope placed in a museum as an exhibit is 55 cm long and has magnification of 45. What are the focal lengths of its objective and eyepiece lenses?

•**33.99** A converging lens of focal length $f = 50.0$ cm is placed 175 cm to the left of a metallic sphere of radius $R = 100.$ cm. An object of height $h = 20.0$ cm is placed 30.0 cm to the left of the lens. What is the height of the image formed by the metallic sphere?

•**33.100** When performing optical spectroscopy (for example, photoluminescence or Raman spectroscopy), a laser beam is focused on the sample to be investigated by means of a lens having a focal distance f. Assume that the laser beam exits a pupil D_o in diameter that is located at a distance d_o from the focusing lens. For the case when the image of the exit pupil forms on the sample, calculate

a) at what distance d_i from the lens is the sample located.

b) the diameter D_i of the laser spot (image of the exit pupil) on the sample.

c) the numerical results for: $f = 10.0\,\mathrm{cm}$, $D_\mathrm{o} = 2.00\,\mathrm{mm}$, $d_\mathrm{o} = 1.50\,\mathrm{m}$.

•**33.101** For a person whose near point is 115 cm, so that he can read a computer monitor at 55 cm, what power of reading glasses should his optician prescribe, keeping the lens–eye distance of 2.0 cm for his spectacles?

•**33.102** A telescope has been properly focused on the Sun. You want to observe the Sun visually, but to protect your sight you don't want to look through the eyepiece; rather, you want to project an image of the Sun on a screen 1.5 m behind (the original position of) the eyepiece, and observe that. If the focal length of the eyepiece is 8.0 cm, how must you move the eyepiece?

MULTI-VERSION EXERCISES

33.103 A lens of a pair of eyeglasses with index of refraction 1.723 has a power of 4.29 D in air. What is the power of this lens if it is put in water with $n = 1.333$?

33.104 A lens of a pair of eyeglasses has a power of 5.55 D in air. The power of this same lens is 2.262 if it is put in water with $n = 1.333$. What is the index of refraction of this lens?

33.105 A lens of a pair of eyeglasses with index of refraction 1.735 has a power of 2.794 D in water, with $n = 1.333$. What is the power of this lens if it is put in air?

33.106 A telescope, consisting of two lenses, has an angular magnification of absolute value 81.4 and an objective lens with refractive power 0.234 D. What is the refractive power of the eyepiece of the telescope?

33.107 A telescope, consisting of two lenses, has an objective lens with refractive power 0.186 D and an eyepiece with focal length of 5.33 cm. What is the absolute value of the angular magnification of this telescope?

33.108 A telescope, consisting of two lenses, has an objective lens with focal length 646.7 cm and an eyepiece with focal length 5.41 cm. What is the absolute value of its angular magnification?

Soap bubbles consist of clear water with a bit of dish soap mixed in. Why, then, do we see the colors of the rainbow when we look at soap bubbles in the air (Figure 34.1)? It turns out that the optics of soap bubbles are not the same as the reflections and refractions that give rise to rainbows (Chapter 32). Instead, the colors of bubbles are due to interference of light of various wavelengths—a wave effect, not explained by geometric optics.

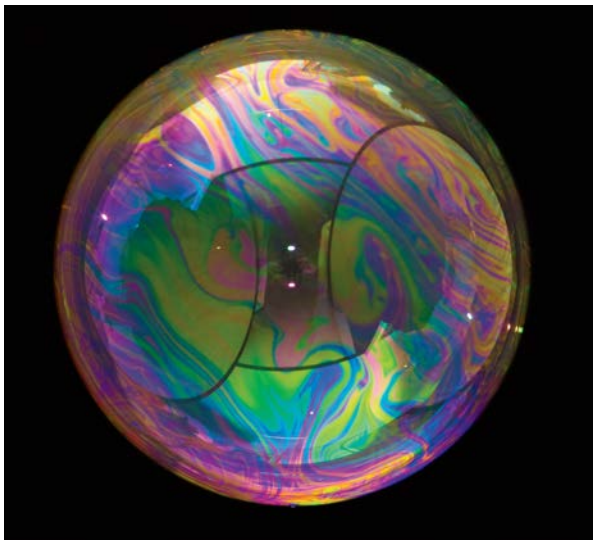

FIGURE 34.1 Soap bubble showing colors from interference phenomena.

MarcelClemens/Shutterstock.com

We have studied image formation by assuming that light travels as straight rays, without regard to the nature of light: for example, whether it consists of particles or waves. In this chapter, we look at optical effects best explained by the wave nature of light—a study sometimes called *physical optics,* as distinct from geometric optics. You may want to review material on waves in Chapter 15, especially the concept of interference of waves. We will also study a wave property called diffraction, which we did not discuss in Chapter 15 but which becomes important when dealing with very small wavelengths such as those of light. The two properties, interference and *diffraction*, explain not only the colors of soap bubbles, but also such issues as how well we can see distant objects as separate and not blurred together.

The material in this chapter does not completely answer the questions of what light is and how it behaves. We will see in following

chapters that wondering about the nature of light led to some of the greatest developments in physics in the 20th century, ideas that are often grouped together under the name *modern physics*. The ideas in this chapter will be pivotal in our examination of the modern understanding of light, matter, time, and space.

WHAT WE WILL LEARN

- The wave nature of light leads to phenomena that cannot be explained using geometric optics.
- Superposed light waves that are in phase interfere constructively; superposed light waves that are 180° out of phase interfere destructively.
- Superposed light waves that have traveled different distances can interfere constructively or destructively, depending on the path length difference.
- Light waves spread out after passing through a narrow slit or after encountering an obstacle. This spreading out is called *diffraction*.
- Light waves that have the same phase and frequency are called *coherent light waves*.
- Coherent light incident on one narrow slit produces a diffraction pattern; coherent light incident on two narrow slits produces an interference pattern.
- Interference can occur when light is is partially reflected from each of the two surfaces (front and back) of a thin film.
- An interferometer is a device designed to measure lengths or changes in length using the interference of light.
- Diffraction can limit the ability of a telescope or a camera to resolve distant objects.
- A diffraction grating has many narrow slits or rulings and can be used with a single-wavelength light source to produce an interference pattern that consists of narrow bright fringes separated by wide dark areas.
- X-ray diffraction can be used to study the atomic structure of materials.

34.1 Light Waves

We learned in Chapter 31 that light is an electromagnetic wave. However, normally we do not think of light as a wave, because its wavelength is so short that we usually do not notice its wave behavior. Thus, in Chapters 32 and 33, we discussed light as rays, a description that is appropriate for all physical situations where we can neglect the wavelength of light in comparison to all other physical dimensions. These rays travel in straight lines except when they are reflected off a mirror or refracted at the boundary between two optical media.

Now we want to address physical situations where we cannot approximate the wavelength of light as negligibly small any more. In this chapter, we discuss the wave nature of light, and we apply to light many of the wave concepts (superposition, coherence, interference, boundary reflection, and others) we developed in Chapter 15. This will sometimes lead to rather surprising results. But all of these results can be verified experimentally.

One way to reconcile the wave nature of light with the geometric optical properties of light is to use **Huygens's Principle,** developed by Dutch physicist Christiaan Huygens (1629–1695). Huygens proposed a wave theory of light in 1678, long before Maxwell developed his theories of light. Huygens's Principle states that every point on a propagating wave front serves as a source of spherical secondary wavelets. Later, the envelope of these secondary wavelets becomes a new wave front. If the original wave has frequency f and speed v, the secondary wavelets have the same f and v. Diagrams of phenomena based on Huygens's Principle are called *Huygens constructions*.

Figure 34.2 shows a Huygens construction for a plane wave. We start with a plane wave traveling at the speed of light, c. We assume point sources of spherical wavelets along the wave front, as shown. These wavelets also travel at c, so at a time Δt the wavelets have traveled a distance $c\Delta t$. Assuming many point sources along the wave front, Figure 34.2 shows that the envelope of these wavelets forms a new wave front parallel to the original wave front. Thus, the wave continues to travel in a straight line with the original frequency and speed.

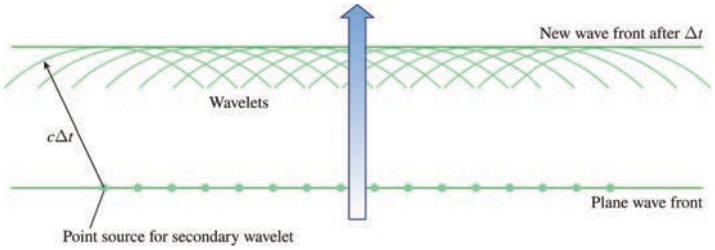

FIGURE 34.2 Huygens construction for a plane wave traveling vertically upward.

In Chapter 32, the index of refraction n in a medium was defined as the ratio of the speed of light in vacuum, c, to the speed of light in that medium, v:

$$n = \frac{c}{v}. \tag{34.1}$$

Using this definition, Snell's Law can be expressed as

$$n_1 \sin \theta_1 = n_2 \sin \theta_2. \tag{34.2}$$

Chapter 32 showed that this law correctly describes refraction phenomena at the boundaries between different media, but the derivation of Snell's Law was deferred to the present chapter. With Huygens's Principle in hand, we can now perform this derivation.

DERIVATION 34.1 Snell's Law

A Huygens construction can be used to derive Snell's Law for refraction between two optical media with different indexes of refraction. Assume a wave with wave fronts separated by a wavelength λ_1 traveling with speed v_1 in an optically clear medium and incident on the boundary with a second optically clear medium (Figure 34.3).

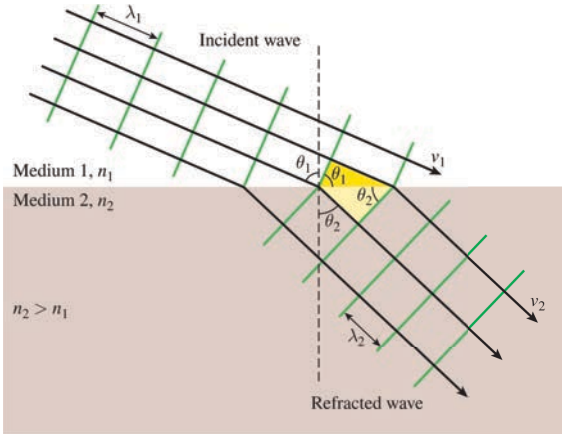

FIGURE 34.3 A Huygens construction of a wave traveling in an optical medium and incident on the boundary with a second optical medium. The green lines represent wave fronts; the black arrows denote rays.

The angle of the incident wave front (green line in medium 1) with respect to the boundary is θ_1, which is also the angle that the light ray (black arrow) makes with respect to a normal to the boundary. When the wave enters the second medium, it travels with speed v_2. According to Huygens's Principle, the wave fronts are the result of wavelet propagation at the speed of the original wave, so the separation of the wave fronts in the second medium can be written in terms of the wavelength in the second medium, λ_2. Thus, the time interval between wave fronts for the first medium is λ_1/v_1, and the time interval for the second medium is λ_2/v_2. The essential point is that this time interval is the same for waves on either side of the boundary. (If these intervals were not

equal, fronts would be appearing or disappearing mysteriously!) So, we have:

$$\frac{\lambda_1}{v_1} = \frac{\lambda_2}{v_2} \Leftrightarrow \frac{\lambda_1}{\lambda_2} = \frac{v_1}{v_2}.$$

Thus, the wavelengths of the light in the two media are proportional to the speeds of the light in those media.

We can get a relation between the angle of the incident wave fronts with the boundary, θ_1, and the angle of the transmitted wave fronts with the boundary, θ_2, by analyzing the yellow shaded region of Figure 34.3, shown in more detail in Figure 34.4.

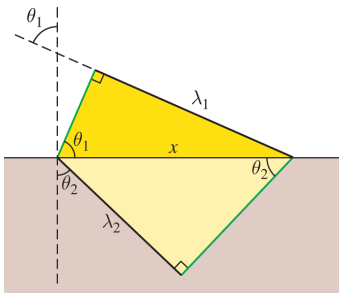

FIGURE 34.4
Expanded section of Figure 34.3, showing the incident wave front and its direction as well as the transmitted wave front and its direction.

From Figure 34.4, and using trigonometry, it follows that

$$\sin\theta_1 = \frac{\lambda_1}{x} \quad \text{and} \quad \sin\theta_2 = \frac{\lambda_2}{x}.$$

Dividing the first of these two equations by the other gives

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{\lambda_1}{\lambda_2} = \frac{v_1}{v_2}.$$

Given that the definition of the index of refraction n of an optical medium is $n = c/v$, where c is the speed of light in a vacuum and v is the speed of light in the optical medium,

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{v_1}{v_2} = \frac{c/n_2}{c/n_2} = \frac{n_2}{n_1},$$

or

$$n_1 \sin\theta_1 = n_2 \sin\theta_2,$$

which is Snell's Law.

Self-Test Opportunity 34.1

Water has an index of refraction of 1.33, which means that the wavelengths of light emitted from objects are different when propagating in water than when propagating in air. Does this mean that you see objects in different colors when looking at them underwater? (You can do this experiment in your bathtub, if you want.)

We have seen that the wavelength of light changes when going from vacuum to an optical medium with index of refraction greater than 1. Taking the result $\lambda_1/v_1 = \lambda_2/v_2$ from Derivation 34.1, with medium 1 being a vacuum while medium 2 has an index of refraction n, we can write

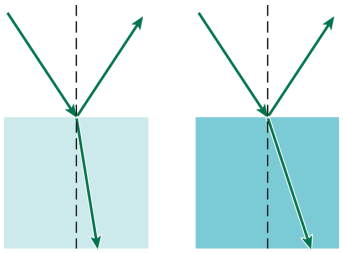
$$\lambda_n = \lambda\frac{v}{c} = \frac{\lambda}{n}.$$

Thus, the wavelength of light is shorter in a medium with an index of refraction greater than 1 than it is in a vacuum. The frequency f of this light can be calculated from $v = \lambda f$. The frequency f_n of light traveling in the medium is then given by

$$f_n = \frac{v}{\lambda_n} = \frac{c/n}{\lambda/n} = \frac{c}{\lambda} = f. \qquad \textbf{(34.3)}$$

Concept Check 34.1

Blocks of two different transparent materials are sitting in air and have identical light rays of the same wavelength incident on them at the same angle. Examining the figure, what can you say about the speed of light in these two blocks?



a) The speed of light is the same in both blocks.

b) The speed of light is greater in the block on the left.

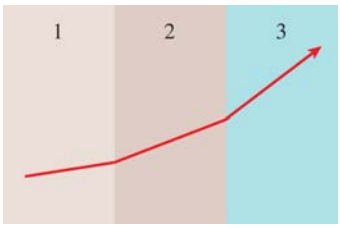
c) The speed of light is greater in the block on the right.

d) The relative speed of light in the two blocks cannot be determined from the information given.

Thus, the frequency of light traveling in an optical medium with $n > 1$ is the same as the frequency of that light traveling in a vacuum. (Equation 34.3 is equivalent to the statement made earlier that the time interval between wave fronts for the first medium equals the time interval between wave fronts for the second medium.)

Concept Check 34.2

A light ray passes through a stack of transparent plastic blocks, as shown in the figure. Which of the blocks has the highest index of refraction?



a) 1

b) 2

c) 3

d) They all have the same index of refraction.

e) The answer cannot be determined from the information given.

Coherent light is light made up of waves with the same wavelength that are in phase with each other. A useful source of coherent light is a laser. Light from light bulbs or sunlight, on the other hand, is **incoherent,** meaning that the waves may have different wavelengths and phase relationships with each other.

34.2 Interference

Sunlight is composed of light with a broad range of frequencies and corresponding wavelengths. We often see different colors separated out of sunlight after it refracts and reflects in raindrops, forming a rainbow. We also sometimes see various colors from sunlight due to constructive and destructive **interference** phenomena in thin transparent layers of materials, such as soap bubbles or thin films of oil floating on water. In contrast to a rainbow, this thin-film effect is due to interference.

The geometric optics of Chapters 32 and 33 cannot explain interference. Interference phenomena can be understood only by taking into account the wave nature of light. This section considers light waves that have the same wavelength in vacuum. Interference takes place when such light waves are superposed. If the light waves are in phase, they interfere constructively, as illustrated in Figure 34.5.

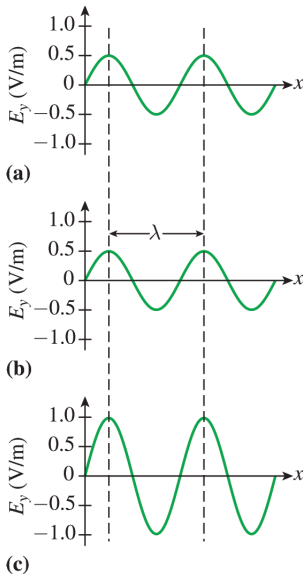


FIGURE 34.5 (a, b) Light waves in phase, with the same amplitude and wavelength, λ; (c) in-phase superposition of the two light waves demonstrates constructive interference, producing a wave with twice the amplitude.

In Figure 34.5a and Figure 34.5b, the electric field component in the y-direction is plotted for two electromagnetic waves traveling in the x-direction. The two waves are in phase. Saying that the two waves are in phase is the same as saying that the phase difference between the two waves is zero. A phase difference of 2π radians (360°), corresponding to starting with two waves in phase and then displacing one of the waves by one full wavelength, will also produce two waves that are in phase. If each light wave is traveling from its own point of origin, a phase difference will occur where they meet, related to the path difference between the two waves, even though they start in phase. The criterion for **constructive interference** is characterized by a path length difference, Δx, given by

$$\Delta x = m\lambda \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots). \tag{34.4}$$

Figure 34.5c shows the two waves constructively interfering. The amplitudes of the two waves add, giving a wave with the same frequency but twice the amplitude of the two original waves.

If the two identical light waves are out of phase by π radians (180°) (Figure 34.6a and Figure 34.6b), the amplitudes of the waves will sum to zero everywhere when they meet. This is the condition for **destructive interference** (Figure 34.6c).

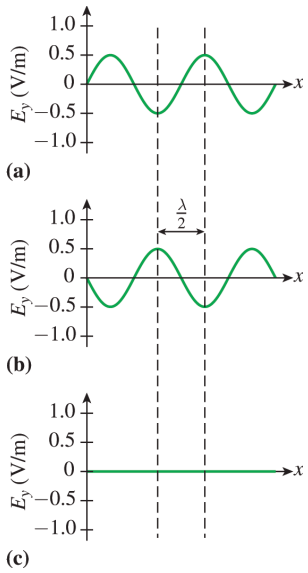

FIGURE 34.6 (a, b) Light waves out of phase by $\lambda/2$, with the same amplitude and wavelength; (c) superposition of the two light waves demonstrates destructive interference.

Figure 34.6a and Figure 34.6b show that this situation is equivalent to starting with two waves in phase and then displacing one of the waves by half of one wavelength $(\lambda/2)$. Again, if we think of the two light waves as being emitted from different sources, the phase difference can be related to the path difference. Destructive interference takes place if the path difference is a half wavelength plus an integer times the wavelength:

$$\Delta x = \left(m + \tfrac{1}{2}\right)\lambda \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots). \qquad \textbf{(34.5)}$$

The following subsections will discuss interference phenomena caused by light waves with the same wavelength that are initially in

phase but travel different distances or travel with different speeds (in different media) to reach the same point. At this point, the light waves are superposed and can interfere. Whether the interference is constructive or destructive for coherent light depends only on the path length difference, which is a recurring theme that will dominate all of the discussions that follow.

The different interference phenomena caused by various path differences of coherent light are summarized in Figure 34.7. Most of this chapter will explore the different conditions that lead to the interference patterns shown on the screens in the three parts of this figure. The following subsection explores pure double-slit interference (Figure 34.7a), which assumes that two very narrow slits of width comparable to the wavelength of the light are separated by a distance that is large compared to their individual widths. Section 34.3 will explore the case of coherent light hitting a single slit with a width a few times the wavelength of the coherent light hitting it (Figure 34.7b). That section will also combine the effects of both cases and discuss double-slit interference with diffraction (Figure 34.7c). Detailed discussion of these cases will clarify the idea that path length differences between coherent light waves are responsible for all of them.

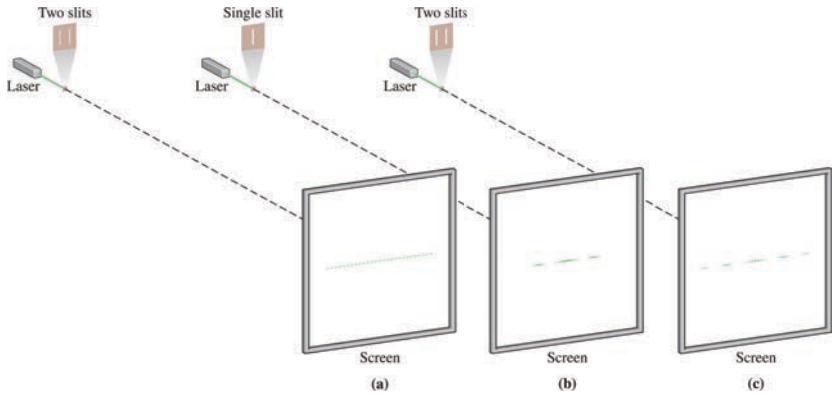

FIGURE 34.7 Coherent light from a laser is incident on three different slit arrangements, and the resulting patterns are observed on a translucent screen some distance away. (a) Two very narrow (width comparable to the wavelength of light) slits widely separated. (b) A single slit with width a few times the wavelength of light. (c) Two slits with width a few times the wavelength of light.

Double-Slit Interference

Our first example of the interference of light is **Young's double-slit experiment,** named for English physicist Thomas Young (1773–1829), who carried out this investigation in 1801. Assume that monochromatic coherent light such as that from a laser is incident on a pair of slits of width comparable to or even smaller than the wavelength of light, as shown in Figure 34.7a. (Strictly speaking, it is not necessary to use monochromatic coherent light from a laser to carry out this experiment, but doing so simplifies the following explanation of double-slit interference.)

For each slit, we use a Huygens construction, assuming that all the light passing through the slit is due to wavelets emitted from a single point at the center of the slit (Figure 34.8a). In this figure, spherical wavelets are emitted from this point. Assume that the slit is much narrower than the wavelength of light (the wavelength of green laser light is approximately 532 nm) so that the source of the wavelets can be represented with one point. Note that the slit opening is barely visible to the naked eye in this case. Even the two very narrow lines representing the magnified slits in Figure 34.7a are much too wide in comparison with the limiting case of extremely narrow slits that we are studying here.

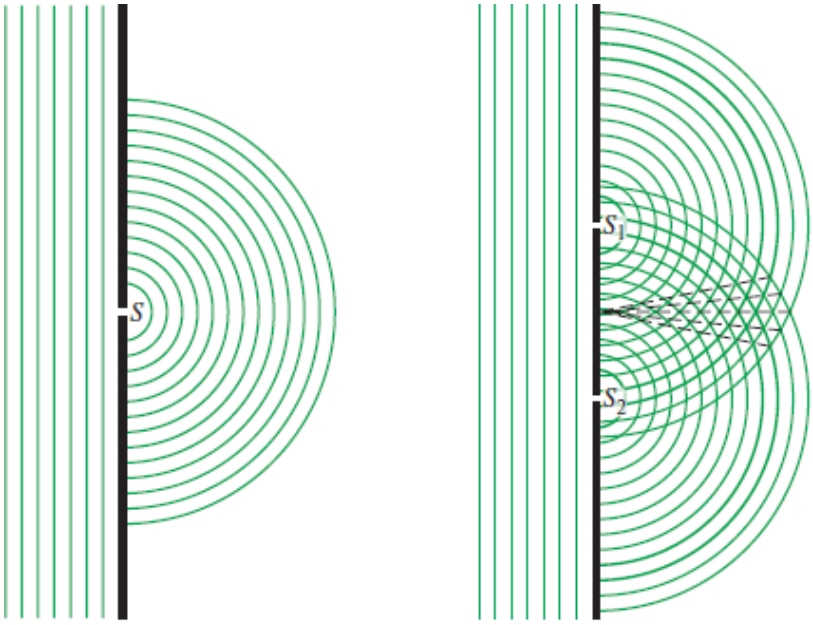

FIGURE 34.8 Huygens construction for a coherent light wave (green laser beam) incident from the left on (a) a single slit and (b) two slits, S_1 and S_2. The dashed lines indicate where constructive interference occurs.

Figure 34.8b shows two slits like the one in Figure 34.8a. A distance d separates the slits. Again, monochromatic coherent light is incident from the left and a source of spherical wavelets is at the center of each slit. The dashed lines represent lines along which constructive interference occurs. Placing a screen to the right of the slits will produce an alternating pattern of bright lines and dark lines, corresponding to constructive and destructive interference between the light waves emitted from the two slits.

To quantify these lines of constructive interference, we expand and simplify Figure 34.8b in Figure 34.9. In this figure, the two lines r_1 and r_2 represent the distances from the centers of slit S_1 and slit S_2, respectively, to a point P on a screen placed a distance L away from the slits. A line drawn from a point midway between the two slits to point P on the screen makes an angle θ with respect to a line drawn from the slits perpendicular to the screen. The point P on the screen is a distance y above this centerline.

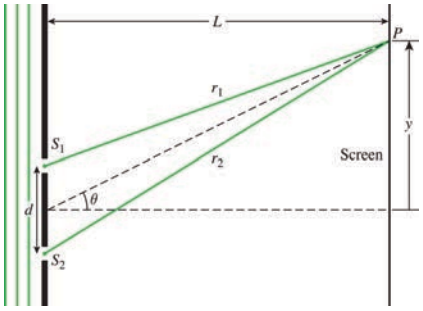

FIGURE 34.9 Expanded view of coherent light incident on two slits. The green lines to the right of the slits represent the distances light must travel from S_1 and S_2 to a point P on the screen.

To further quantify the two-slit geometry, we expand and simplify Figure 34.9 in Figure 34.10. In this figure, we assume that the screen has been placed a large distance L away from the slits, so the lines S_1P and S_2P are essentially parallel to each other and to the line drawn from the center of the two slits to point P. Another line is drawn from S_1 perpendicular to S_1P and S_2P, making a triangle with sides d, b, and Δx. The quantity Δx is the path length difference, $r_2 - r_1$.

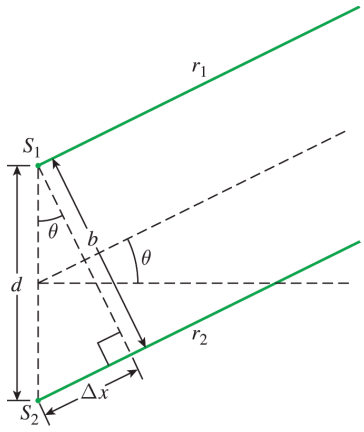

FIGURE 34.10
Expanded view of two slits, where the screen is placed far enough away that the green lines S_1P and S_2P are parallel.

This path length difference, $\Delta x = r_2 - r_1$, produces a phase difference for light originating from the two slits and illuminating the screen at point P. The path length difference can be expressed in terms of the distance d between the slits and the angle θ at which the light is observed:

$$\sin\theta = \frac{\Delta x}{d},$$

or

$$\Delta x = d\sin\theta.$$

For constructive interference, this path length difference must be an integer multiple of the wavelength of the incident light:

$$\Delta x = d \sin\theta = m\lambda \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots) \qquad \begin{pmatrix} \text{bright fring} \\ \text{constructiv} \end{pmatrix}$$

A bright fringe on the screen signals constructive interference.

For destructive interference, the path length difference must be an integer plus one-half times the wavelength:

$$\Delta x = d \sin\theta = \left(m + \tfrac{1}{2}\right)\lambda \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots) \qquad \begin{pmatrix} \text{dark} \\ \text{dest} \end{pmatrix}$$

A dark fringe on the screen signals destructive interference.

Note that for constructive interference and $m = 0$, we obtain $\theta = 0^\circ$, which means that $\Delta x = 0$ and there is a bright fringe at 0°. This bright fringe is called the *central maximum*. The integer m determines the **order** of the fringe. The order has a different meaning for bright fringes and for dark fringes. For example, using equation 34.6 with $m = 1$ gives the angle of the first-order bright fringe, $m = 2$ gives the second-order bright fringe, and so on. Using equation 34.7 with $m = 0$ gives the angle of the first-order dark fringe, $m = 1$ gives the second-order dark fringe, etc. For both bright and dark fringes, the first-order fringe is the one closest to the central maximum.

Concept Check 34.3

In a Young's double-slit experiment where $L = 1.0\,\text{m}$ and $d = 0.10\,\text{cm}$, light with a wavelength of 500. nm is used. There is a dark fringe at 0.75 mm to the left of the center of the diffraction pattern on the screen. What will happen to the intensity of the light at this location if one of the slits is covered up?

a) The intensity will decrease.

b) The intensity will increase.

c) Nothing will happen to the intensity.

d) It depends on which of the two slits is covered up.

For the bright fringes close to the central maximum, the angle θ is small and can be approximated by $\sin\theta \approx \tan\theta = y/L$ (see Figure 34.9). Thus, equation 34.6 can be expressed as

$$d\sin\theta = d\frac{y}{L} = m\lambda \quad (\text{for } m = 0, \pm1, \pm2, \ldots),$$

or

$$y = \frac{m\lambda L}{d} \quad (\text{for } m = 0, \pm1, \pm2, \ldots), \qquad \textbf{(34.8)}$$

which gives the distances along the screen of the bright fringes from the central maximum.

Similarly, the distances along the screen of the dark fringes from the central maximum can be expressed as

$$y = \frac{\left(m + \frac{1}{2}\right)\lambda L}{d} \quad (\text{for } m = 0, \pm1, \pm2, \ldots)\cdot \qquad \textbf{(34.9)}$$

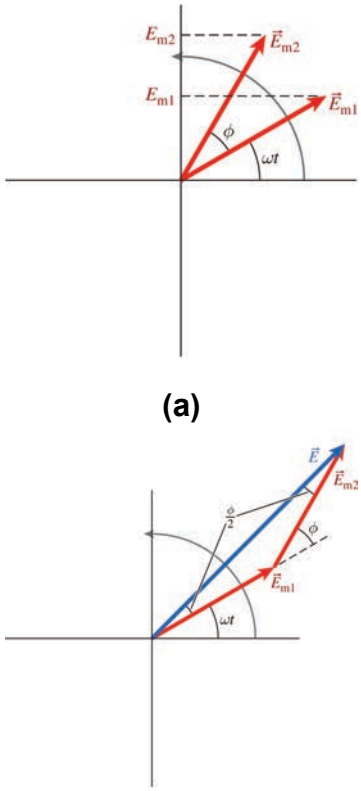
The positions of the centers of the bright and dark fringes are described by equations 34.8 and 34.9. But the intensity of the light at any point on the screen can also be calculated. We begin by assuming that the light emitted at each slit is in phase. The electric field of the light waves can be described by $\overrightarrow{E}_{\mathrm{m}} = E_{\max} \sin \omega t$, where $E_{\max}$ is the amplitude of the wave and ω is the angular frequency. When the light waves arrive at the screen from the two slits, they have traveled different distances, and so can have different phases. The electric field of the light arriving from S_1 and hitting a given point on the screen can be expressed as

$$\overrightarrow{E}_{\mathrm{m1}} = E_{\max} \sin (\omega t),$$

and the electric field of the light arriving at the same point from S_2 can be expressed as

$$\overrightarrow{E}_{\mathrm{m2}} = E_{\max} \sin (\omega t + \phi),$$

where ϕ is the phase constant of $\overrightarrow{E}_{\mathrm{m2}}$ with respect to $\overrightarrow{E}_{\mathrm{m1}}$. Figure 34.11a shows the two phasors $\overrightarrow{E}_{\mathrm{m1}}$ and $\overrightarrow{E}_{\mathrm{m2}}$.



(a)

(b)

FIGURE 34.11 (a) Two phasors $\vec{E}_{m1}$ and $\vec{E}_{m2}$ separated by a phase ϕ. (b) Sum of the two phasors $\vec{E}_{m1}$ and $\vec{E}_{m2}$

The sum of the two phasors $\vec{E}_{m1}$ and $\vec{E}_{m2}$is shown in Figure 34.11b, which also shows that the magnitude E of the sum of the two phasors is

$$E = 2E_{max} \cos(\phi/2).$$

Chapter 31 showed that the intensity of an electromagnetic wave is proportional to the square of the amplitude of the electric field; so we have

$$\frac{I}{I_{max}} = \frac{E^2}{E_{max}^2}.$$

Using the result for the magnitude of the electric field just obtained, we get

$$I = 4I_{\text{max}}\cos^2\left(\phi/2\right)$$

for the intensity of the total wave at point *P* as a function of the phase difference between the two light waves.

Now the phase difference must be related to the path length difference. Figure 34.10 shows that the path length difference Δx causes a phase shift given by

$$\phi = \frac{\Delta x}{\lambda}(2\pi),$$

because when $\Delta x = \lambda$, the phase shift is $\phi = 2\pi$. Noting that $\Delta x = d\sin\theta$, the phase constant can be expressed as

$$\phi = \frac{2\pi d}{\lambda}\sin\theta.$$

Thus, we can write an equation for the intensity of the light produced by the interference from two slits:

$$I = 4I_{\text{max}}\cos^2\left(\frac{\pi d}{\lambda}\sin\,\theta\right).$$

Finally, we can obtain an expression for the intensity pattern on a screen resulting from coherent light incident on two narrow widely separated slits using the approximation discussed before, which is valid near the central maximum and θ is small enough that $\sin\,\theta \approx \tan\,\theta = y/L$:

$$I = 4I_{\text{max}}\cos^2\left(\frac{\pi dy}{\lambda L}\right). \qquad \textbf{(34.10)}$$

For example, if the screen is $L = 2.0\,\text{m}$ away from the slits, the slits are separated by $d = 1.0 \cdot 10^{-5}\,\text{m}$, and the wavelength of the incident light is $\lambda = 550\,\text{nm}$, we get the intensity pattern shown in Figure 34.12. In this figure, the intensity varies from $4I_{\text{max}}$ to zero. Covering one slit produces an intensity of I_{max} at all values of y. Illuminating both slits with light that has random phases produces an intensity of $2I_{\text{max}}$ at all values of y. Only when both slits are illuminated with coherent light do we observe the oscillatory pattern with respect to y that is characteristic of two-slit interference.

Thin-Film Interference and Newton's Rings

Another way of producing interference phenomena is by using light that is partially reflected from the front and back surfaces of a thin film. A **thin film** is an optically clear material with a thickness on the order of a few wavelengths of light. Examples of thin films include the walls of soap bubbles and thin layers of oil floating on water. When the light reflected off the front surface interferes with the light reflected off the back surface of the thin film, we see the color corresponding to the particular wavelength of light that is interfering constructively.

Consider light traveling in an optical medium with index of refraction n_1 that strikes a second optical medium with index of refraction n_2, as illustrated in Figure 34.13.

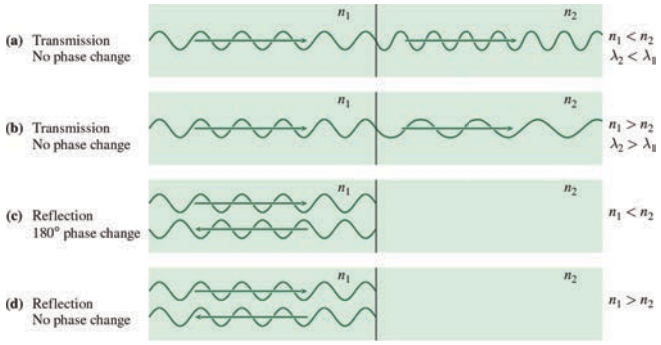

FIGURE 34.13 Light traveling in an optical medium with index of refraction n_1 is incident on a boundary with a second optical medium with index of refraction n_2. (a) Light is transmitted with no phase change for $n_1 < n_2$. (b) Light is transmitted with no phase change for $n_1 > n_2$. (c) Light is reflected with a 180° phase change for $n_1 < n_2$. (d) Light is reflected with no phase change for $n_1 > n_2$.

One possibility is that the light can be transmitted through the boundary, as illustrated in Figure 34.13a and Figure 34.13b. In these cases, the phase of the light does not change, independent of whether $n_1 < n_2$ or $n_1 > n_2$. A second possibility is that the light is reflected.

In this case, the phase of the light can change, depending on the index of refraction of the two optical media. If $n_1 < n_2$, the phase of the reflected wave is changed by 180° (corresponding to half a wavelength), as shown in Figure 34.13c. If $n_2 > n_1$, then no phase change occurs, as depicted in Figure 34.13d. (The reflected waves have been displaced vertically for clarity's sake!)

The reason for the phase change upon reflection follows from the theory of electromagnetic waves, and the derivation is beyond the scope of this book. However, in Section 15.4, we studied the reflection of waves on a string from a boundary, and this mechanical analog is sufficient to understand the basic reason for the 180° phase change in one case and no phase change in the other. Figure 34.14 shows a rigid (left) and a flexible (right) connection of a string to a wall. The reflection of light at the boundary between the optically less dense (lower value of n) medium and the optically more dense (higher value of n) medium corresponds to the situation on the left, and the reverse case to the situation on the right.

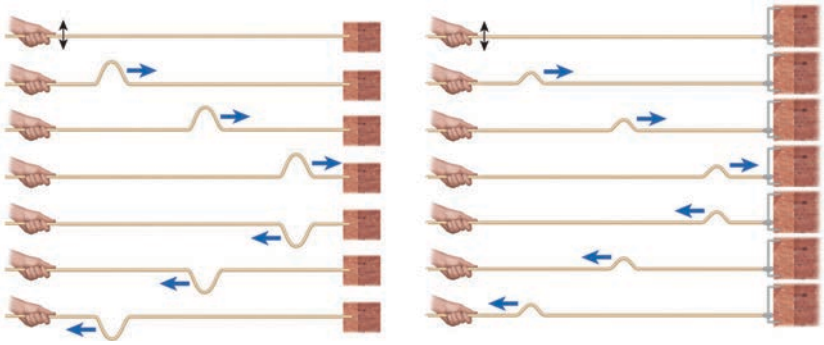

FIGURE 34.14 Sketch of the time sequence (top to bottom) of the reflection of a wave pulse on a string at a wall. Left: Rigid connection to the wall results in a 180° phase change in the reflected wave. Right: A movable connection to the wall results in no phase change.

Let's begin our analysis of thin films by studying a thin film of thickness t with index of refraction n and with air on both sides (Figure 34.15). Assume that monochromatic light is incident perpendicular to the surface of the film. For clarity and simplicity, we

show only the rays we are interested in, with a small nonzero angle of incidence so they can be distinguished. When the light wave reaches the boundary between air and the film, part of the wave is reflected and part of the wave is transmitted. The reflected wave undergoes a phase shift of half a wavelength when it is reflected because $n_{\text{air}} < n$. The light that is transmitted has no phase shift and continues to the back surface of the film. At the back surface, again part of the wave is transmitted and part of the wave is reflected. The transmitted light passes through the film completely. The reflected light has no phase shift because $n > n_{\text{air}}$, and it travels back to the front surface of the film. At the front surface, some of the light reflected from the back surface is transmitted and some is reflected. The transmitted light has no phase shift, and it emerges from the film and interferes with the light that was reflected when the original wave first struck the film. The transmitted and then reflected light has traveled a longer distance than the originally reflected light and has a phase shift determined by the path length difference. This difference is twice the thickness *t* of the film.

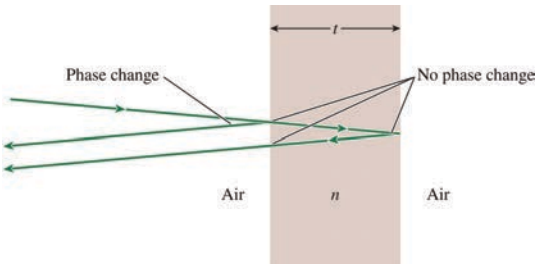

FIGURE 34.15 Light waves in air incident on a thin film with index of refraction *n* and thickness *t*.

The fact that the originally reflected light has undergone a phase shift of half a wavelength but the transmitted and then reflected light has not means that the criterion for *constructive* interference is given by $\Delta x = \left(m + \frac{1}{2}\right)\lambda = 2t$ (for $m = 0, 1, 2, \ldots$) The wavelength λ refers to the wavelength of the light traveling in the thin film, which has index of refraction *n*. The wavelength of the light traveling in air is

related to the wavelength of the light traveling in the film by $\lambda = \lambda_{\text{air}}/n$. We can then write

$$\left(m + \tfrac{1}{2}\right)\frac{\lambda_{\text{air}}}{n} = 2t \quad (\text{for } m = 0, 1, 2, \ldots) \qquad \begin{pmatrix}\text{thin film,}\\ \text{constructive inte}\end{pmatrix}$$

The minimum thickness, t_{min}, that will produce constructive interference corresponds to $m = 0$:

$$t_{\text{min}} = \frac{\lambda_{\text{air}}}{4n}. \qquad \textbf{(34.12)}$$

An oil slick or the wall of a soap bubble has varying thicknesses and thus affects different wavelengths differently, often creating a rainbow effect.

Concept Check 34.4

If the same coating material of the same thickness as in Example 34.1 were used on a different lens with an index of refraction less than that of the coating, the result would be

a) reduced reflection and thus *more* light entering the lens than would occur without the coating.

b) enhanced reflection and thus *less* light entering the lens than would occur without the coating.

c) the same amount of light entering the lens as would do so without the coating.

d) no light at all (or close to none) entering the lens.

EXAMPLE 34.1 Lens Coating

Many high-quality lenses are coated to prevent reflections. The coating is designed to set up destructive interference for light reflected from the surface of the lens. Assume that the coating is magnesium fluoride, which has $n_{\text{coating}} = 1.38$, and that the lens is glass with $n_{\text{lens}} = 1.51$.

PROBLEM

What is the minimum thickness of the coating that will produce destructive interference for light with a wavelength in air of 550 nm?

SOLUTION

Assume that the light is incident perpendicularly (or at least close to perpendicularly) on the surface of the coated lens (Figure 34.16). Light reflected at the surface of the coating undergoes a phase change of half a wavelength, because $n_{\text{air}} < n_{\text{coating}}$. The light transmitted through the coating has no phase change. Light reflected at the boundary between the coating and the lens also undergoes a phase change of half a wavelength, because $n_{\text{coating}} < n_{\text{lens}}$. This reflected light travels back through the coating and exits with no other phase change. Thus, both the light reflected from the coating and the light reflected from the lens have undergone a phase change of half a wavelength. Therefore, the criterion for destructive interference is

$$\left(m + \tfrac{1}{2}\right)\frac{\lambda_{\text{air}}}{n_{\text{coating}}} = 2t \quad (\text{for } m = 0, 1, 2, \ldots).$$

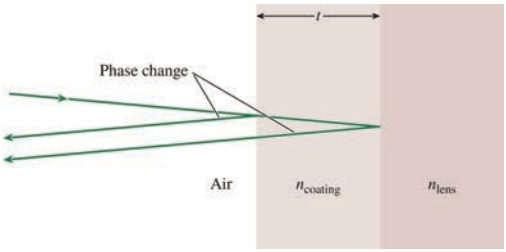

FIGURE 34.16
Light incident on a coated lens.

The minimum thickness of the coating that will produce destructive interference corresponds to $m = 0$:

$$t_{\text{min}} = \frac{\lambda_{\text{air}}}{4n_{\text{coating}}} = \frac{550 \cdot 10^{-9}\,\text{m}}{4\,(1.38)} = 9.96 \cdot 10^{-8}\,\text{m} = 99.6\,\text{nn}$$

Page 1056

Lens coatings that fulfill this destructive interference condition are referred to as *quarter-lambda coatings*. Because this type of coating causes destructive interference of reflected light, it prevents light from reflecting itself and thus allows more light to enter the lens than would do so if it were not present. Expensive camera lenses have quarter-lambda coatings for wavelengths in the middle of the optical wavelength band, around 500 nm. But remember that a quarter-lambda coating can work only if the index of refraction of the coating is less than that of the lens.

Concept Check 34.5

A thin soap film with index of refraction $n = 1.35$ hanging in air reflects predominantly red light with $\lambda = 682\,\text{nm}$. What is the minimum thickness of the film?

a) 89.5 nm

b) 126 nm

c) 198 nm

d) 302 nm

e) 432 nm

A phenomenon similar to thin-film interference is **Newton's rings.** This effect is an interference pattern caused by the reflection of light between two glass surfaces, a spherical surface and an adjacent flat surface, as shown in Figure 34.17.

FIGURE 34.17
Newton's rings produced with white light.

W. Bauer and G. D. Westfall

Newton's rings are caused by interference between light reflected from the bottom of the spherically curved glass and light reflected from the top of the flat plate of glass, as shown in Figure 34.18. (Note that the curvature of the spherical surface is exaggerated in this diagram. In real situations, R is much larger than x.)

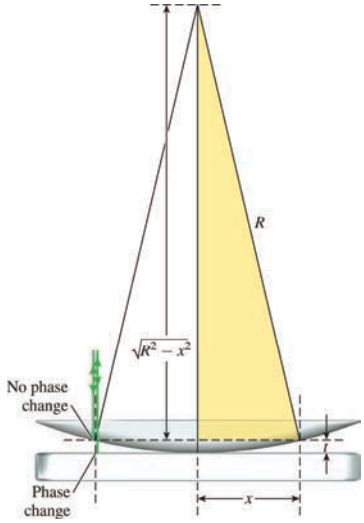

FIGURE 34.18 The geometry of Newton's rings. The bottom of the top piece of glass is a spherical surface, while the bottom plate is planar.

Newton's rings are concentric circles, alternately dark and bright. The dark circles correspond to destructive interference, and the bright circles correspond to constructive interference. The example shown in Figure 34.17 was produced with white light to show different colored rings. For the calculation of Newton's rings, we assume monochromatic, coherent light with wavelength λ in air. The distance between the curved surface and the flat surface, t, is a function of the horizontal distance from the point where the spherical surface touches the flat surface, as shown in Figure 34.18. The Pythagorean Theorem applied to the yellow triangle in Figure 34.18 gives the relationship

$$t = R - \sqrt{R^2 - x^2} = R - R\sqrt{1 - \left(\frac{x}{R}\right)^2},$$

where R is the radius of curvature of the spherical glass surface and x is the horizontal distance from the point where the curved glass touches the flat glass to the point where the light enters the glass.

As mentioned above, in Figure 34.18, the curvature of the spherical surface has been exaggerated for clarity. The actual glass surface used to produce Newton's rings has a large radius of curvature

compared with the distance from the touching point, so that $x/R \ll 1$. Thus, we can approximate

$$\sqrt{1-\left(\frac{x}{R}\right)^2} \approx 1-\frac{1}{2}\left(\frac{x}{R}\right)^2 \quad \left(\text{for } \frac{x}{R} \ll 1\right).$$

Now we can write an approximate expression for the distance between the surfaces:

$$t \approx R - R\left(1-\frac{1}{2}\left(\frac{x}{R}\right)^2\right) = \frac{1}{2}\frac{x^2}{R}.$$

The path length difference for the light reflecting off the bottom of the curved surface versus the light reflecting off the top of the flat surface is $2t$, which can be written

$$2t = 2\left(\frac{1}{2}\frac{x^2}{R}\right) = \frac{x^2}{R}.$$

The light reflecting off the bottom of the curved surface has no phase change because the index of refraction of glass is higher than the index of refraction of air. The light reflecting off the top of the flat glass plate suffers a phase change of half a wavelength because the index of refraction of glass is larger than the index of refraction of air. Thus, the criterion for constructive interference is

$$\left(m+\tfrac{1}{2}\right)\lambda = 2t \quad (\text{for } m = 0,1,2,\ldots).$$

Combining this constructive interference criterion with the result for the thickness, and defining x_m as the radius of the bright circle for a given m, gives

$$\left(m+\tfrac{1}{2}\right)\lambda = \frac{x_m^2}{R} \quad (\text{for } m = 0,1,2,\ldots),$$

which can be solved for the radius of the bright circles:

$$x_m = \sqrt{R\left(m + \tfrac{1}{2}\right)\lambda} \quad \left(\text{for } m = 0,1,2,\ldots, \text{ and } \tfrac{x_m}{R} \ll 1\right) \cdot ($$

SOLVED PROBLEM 34.1 Air Wedge

Light of wavelength $\lambda = 516\,\text{nm}$ is incident perpendicularly on two glass plates. The glass plates are spaced at one end by a thin piece of kapton film. Due to the wedge of air created by this film, 29 bright interference fringes are observed across the top plate, with a dark fringe at the end by the film.

PROBLEM

How thick is the film?

SOLUTION

THINK

Light passes through the top plate, reflects from the top surface of the bottom plate, and then interferes with light reflected from the bottom surface of the top plate. A phase change occurs when the light is reflected from the bottom plate, so the criterion for constructive interference is that the path length is equal to an integer plus one-half times the wavelength. The criterion for destructive interference is that the path difference is an integer times the wavelength.

SKETCH

Figure 34.19 is a sketch showing the two glass plates with a thin piece of film separating them at one end. Light is incident from the top.

FIGURE 34.19 Two glass plates with a thin film separating the plates at one end. The green arrows represent the incident light from the top. The angle of the light is exaggerated for clarity. The interfering light is reflected off the bottom of the top plate and the top of the bottom plate.

RESEARCH

At any point along the plates, the criterion for constructive interference is given by

$$2t = \left(m + \tfrac{1}{2}\right)\lambda,$$

where t is the separation between the plates, m is an integer, and λ is the wavelength of the incident light. There are 29 bright fringes visible. The first bright fringe corresponds to $m = 0$, and the 29th bright fringe corresponds to $m = 28$. Immediately past the 29th bright fringe is a dark fringe where the piece of film is located. The criterion for destructive interference is $2t = n\lambda$, where n is an integer.

SIMPLIFY

The dark fringe located at the end of the glass plate, where the film is located, is given by

$$2t = \left(28 + \tfrac{1}{2} + \tfrac{1}{2}\right)\lambda = 29\lambda,$$

where the factor $28 + \frac{1}{2}$ produces the constructive interference and the extra $\frac{1}{2}$ produces the dark fringe. Thus, we can solve for the separation of the plates, which corresponds to the thickness of the film:

$$t = \frac{29}{2}\lambda.$$

CALCULATE

Putting in the numerical values gives

$$t = \frac{29}{2}\left(516 \cdot 10^{-9}\text{m}\right) = 0.00000748\,\text{m}.$$

ROUND

We report our result to three significant figures:

$$t = 7.48 \cdot 10^{-6}\,\text{m}.$$

Page 1058

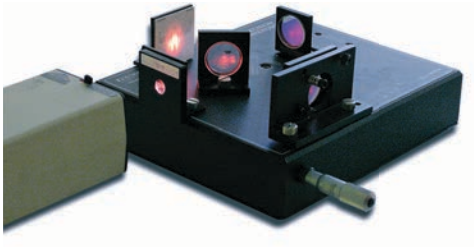
DOUBLE-CHECK

Occasionally throughout this book we need to add reminders that checking our results just for the right units and expected order of magnitude can do a lot to prevent simple errors. The meter is certainly the right unit for a physical length, in this case, the film thickness. At first glance, you may think that $\sim 10^{-5}$ m, on the order of $1/100$th of the thickness of a fingernail, may be impossibly thin for a solid film. However, an Internet search on *kapton film* will show that 7.5 μm is within the range of thicknesses in which kapton film is produced. Thus, our answer seems plausible.

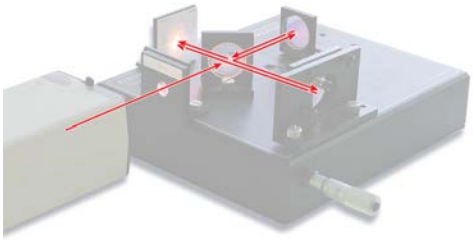
Interferometer

An **interferometer** is a device designed to measure lengths or small changes in length using the fringes produced by the interference of light. An interferometer can measure changes in lengths to an accuracy of a fraction of the wavelength of the light it is using. The interferometer described here is similar to, but simpler than, the one constructed by Albert Michelson at the Case Institute in Cleveland, Ohio, in 1887.

A photograph and a diagram of a commercial interferometer used in physics labs are shown in Figure 34.20. A more detailed drawing of this same interferometer is shown in Figure 34.21. This particular interferometer uses a laser light source that emits coherent light with wavelength $\lambda = 632.8\,\text{nm}$. The light passes through a defocusing lens that spreads out the very narrowly focused laser beam. The light then passes through a half-silvered mirror, m_1. Part of the light is reflected toward the adjustable mirror, m_3, and part of the light is transmitted to the movable mirror, m_2. The distance between m_1 and m_2 is x_2, and the distance between m_1 and m_3 is x_3. The transmitted light is totally reflected from m_2 back toward m_1. The reflected light is also totally reflected from m_3 back toward m_1. Part of the light reflected from m_2 is then reflected by m_1 toward the viewing screen; the rest of the light is transmitted and not considered in this analysis. Part of the light from m_3 is transmitted through m_1; the rest is reflected and not considered. The alignment of the light is such that the two beams that strike the viewing screen are collinear; the separation shown in Figure 34.21 is simply for clarity.



(a)



(b)

FIGURE 34.20 A Michelson-type interferometer used in an introductory physics laboratory. (a) Photograph; (b) schematic drawing of the light paths. The laser beam is split by the central half-silvered mirror. One part of the light continues in the same direction, is reflected, returns, and is reflected by the half-silvered mirror to the screen. A second part of the light is reflected by the half-silvered mirror, and is then reflected back through the half-silvered mirror to the screen.

W. Bauer and G. D. Westfall

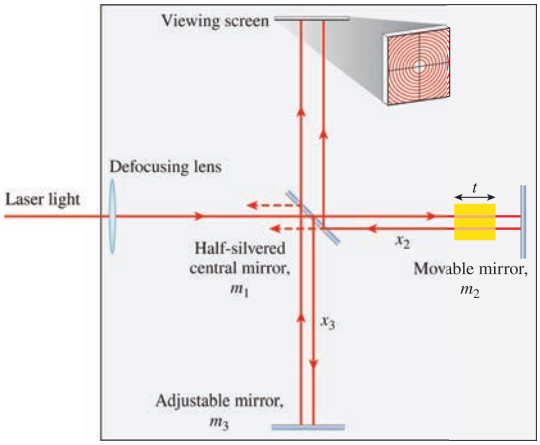


FIGURE 34.21 Top view of a Michelson-type interferometer, showing the detailed light path.

The light beams from mirrors m_2 and m_3 that strike the viewing screen interfere, based on their path length difference. Both beams undergo two reflections, each resulting in a phase change of 180°, so the condition for constructive interference is

$$\Delta x = m\lambda \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots).$$

The two different paths have a path length difference of

$$\Delta x = 2x_2 - 2x_3 = 2\,(x_2 - x_3).$$

The viewing screen displays concentric circles or linear fringes corresponding to constructive and destructive interference, depending on the type of defocusing lens used and the tilt of the mirrors. If the movable mirror, m_2, is moved a distance $\lambda/2$, the fringes shift by one fringe. Thus, this type of interferometer can be used to measure changes in distance on the order of a fraction of a wavelength of light, depending on how well the shift of the interference fringes can be measured.

Another type of measurement can be made with this interferometer by placing a material with index of refraction n and thickness t in the path of the light traveling to the movable mirror m_2, as depicted in Figure 34.21. The path length difference in terms of the

number of wavelengths will change because the wavelength of light in the material, λ_n, is different from the wavelength in air, λ. The wavelength in the material is related to the wavelength in air by

$$\lambda_n = \frac{\lambda}{n}.$$

Self-Test Opportunity 34.2

The wavelength of a monochromatic light source is measured using a Michelson interferometer. When the movable mirror is moved a distance $d = 0.250\ \text{mm}$, $N = 1200$ fringes move by the screen. What is the wavelength of the light?

Thus, the number of wavelengths in the material is

$$N_{\text{material}} = \frac{2t}{\lambda_n} = \frac{2tn}{\lambda}.$$

The number of wavelengths that would have been there if the light traveled through only air is

$$N_{\text{air}} = \frac{2t}{\lambda}.$$

Thus, the difference in the number of wavelengths is

$$N_{\text{material}} - N_{\text{air}} = \frac{2tn}{\lambda} - \frac{2t}{\lambda} = \frac{2t}{\lambda}(n-1). \qquad \textbf{(34.14)}$$

When the material is placed between m_1 and m_2, an observer will see a shift of one fringe for every wavelength shift in the path length difference. Thus, we can substitute the number of fringes shifted for $N_{\text{material}} - N_{\text{air}}$ in equation 34.14, and, given the index of refraction, we can obtain the thickness of the material. Alternatively, we can insert material with a well-known thickness and determine the index

of refraction. This can be done by rotating the material slowly and counting the fringes.

34.3 Diffraction

Any wave passing through an opening experiences diffraction. **Diffraction** means that the wave spreads out on the other side of the opening rather than the opening casting a sharp shadow. Diffraction is most noticeable when the opening is about the same size as the wavelength of the wave. With water surface waves, this is easily visualized: Figure 34.22 shows a satellite picture of a Caribbean resort that has a seawall to protect the beach from erosion; the diffraction of the ocean waves through the opening in the seawall is evident. The same effect applies to light waves. If light passes through a narrow slit, it produces a characteristic pattern of light and dark areas called a *diffraction pattern*. Light passing a sharp edge also exhibits a diffraction pattern.

FIGURE 34.22
Satellite image of diffraction of ocean waves passing through an opening in a seawall at a Caribbean resort.

GeoEye satellite image

Huygens's Principle describes this spreading out, and a Huygens construction can be used to quantify the diffraction phenomenon. For example, Figure 34.23a shows coherent light incident on an opening, which has a width comparable to the wavelength of the light. Rather than continuing in a narrow beam, the light spreads out on the other

side of the opening. We can describe this spreading out by using a Huygens construction and assuming that spherical wavelets are emitted at several points inside the opening. The resulting light waves on the right side of the opening undergo interference and produce a characteristic diffraction pattern.

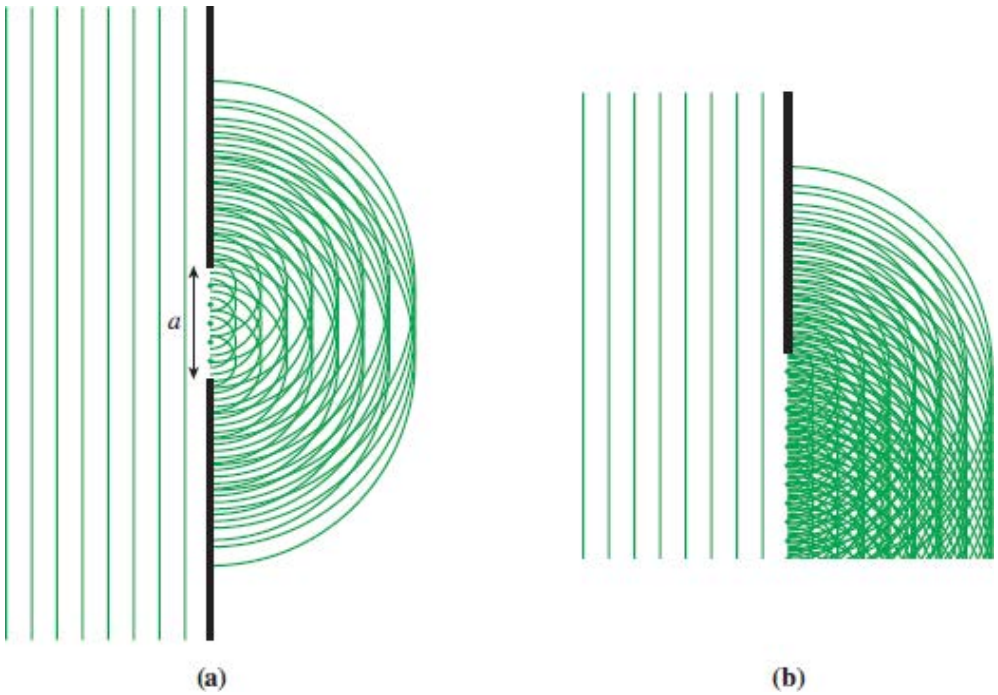

FIGURE 34.23 (a) Coherent light incident on an opening with a width comparable to the wavelength of the light. The dots represent sources of spherical wavelets in a Huygens construction. (b) Coherent light incident on a barrier. The light diffracts around the barrier

Light waves can also go around the edges of barriers, as shown in Figure 34.23b. In this case, the light far from the edge of the barrier continues to travel like the light waves shown in Figure 34.2. The light near the edge of the barrier seems to bend around the barrier, in a way that can be represented using point sources of wavelets near the edge.

Figure 34.24 shows a picture of an experiment, where light from a green laser is blocked by the vertical edge of a razor blade, and the resulting diffraction pattern is viewed on a distant screen. The bright spot is the central maximum and the less bright lines are higher-order diffraction maxima.

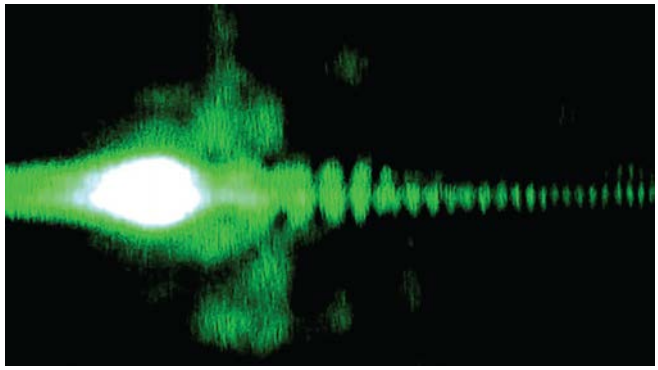

FIGURE 34.24 Light from a green laser incident on the vertical edge of a razor blade as viewed on a distant screen.

W. Bauer and G. D. Westfall

Diffraction phenomena cannot be explained by geometric optics. As we will see, diffraction effects rather than geometric effects often limit the resolution of an optical instrument. The following subsections will present a quantitative examination of single-slit diffraction, diffraction by a circular opening, and double-slit diffraction; Section 34.4 will consider diffraction by a grating. In all cases, similar relationships for the location of the diffraction maxima and minima result, modified only by the individual geometries.

Single-Slit Diffraction

Consider the diffraction of light through a single slit of width a, which is comparable to the wavelength of light passing through the slit, as illustrated in Figure 34.7b. The calculation is aided by a Huygens construction, as shown in Figure 34.23a.

Assume that the light passing through the single slit is described by spherical wavelets emitted from a distribution of points located in the slit. The light emitted from these points will superpose and interfere, based on the path length for each wavelet at each position. At a distant screen, we observe an intensity pattern characteristic of diffraction, consisting of bright and dark fringes. For the case of two-slit interference, we were able to work out the equations for the bright fringes based on constructive interference. For diffraction, we will restrict ourselves to analyzing the dark fringes of destructive interference.

To study this interference, we redraw and simplify Figure 34.23a as shown in Figure 34.25. Assume that coherent light with wavelength λ is incident on a slit with width a, producing an interference pattern on a screen a distance L away. We employ a simple method of analyzing pairs of light waves emitted from points in the slit. We start with light emitted from the top edge of the slit and from the center of the slit, as shown in Figure 34.25. To analyze the path difference, we show an expanded version of Figure 34.25 in Figure 34.26.

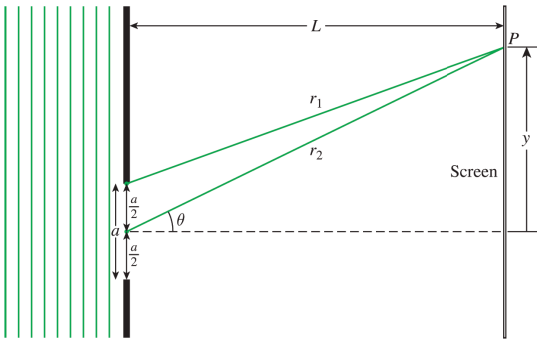

FIGURE 34.25 Geometry for determining the location of the first dark fringe from a single slit, using two rays from the slit.

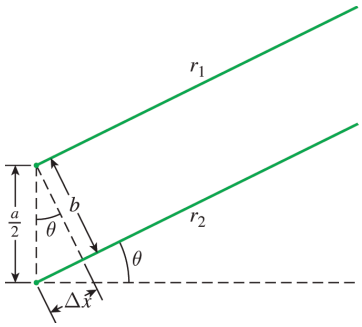

FIGURE 34.26
Expanded version of the geometry for determining the location of the first dark fringe from diffraction by a single slit.

For this quantitative analysis, we assume that the screen distance L is very large compared to the size of the slit opening, a.

Then, the two green lines representing paths of lengths r_1 and r_2 in Figure 34.26 are parallel and both make an angle θ with the line running perpendicularly from the center of the slit to the screen. Therefore, the path length difference for these two rays is given by

$$\sin\theta = \frac{\Delta x}{a/2} \Leftrightarrow \Delta x = \frac{1}{2}a\sin\theta.$$

The criterion for the first dark fringe is

$$\Delta x = \frac{a\sin\theta}{2} = \frac{\lambda}{2} \Rightarrow a\sin\theta = \lambda.$$

Although we chose one ray originating from the top edge of the slit and one from the middle of the slit to locate the first dark fringe, we could have used any two rays that originated at a distance $a/2$ apart inside the slit. That is, all wavelets can be paired up so that the separation within a pair is $a/2$ (Thus, we take into account the entire

slit.) Each pair destructively interferes, so an overall dark fringe appears on the screen.

Now consider four rays instead of two (Figure 34.27). Here we choose a ray from the top edge of the slit and three more rays originating from points spaced $a/4$ apart. The geometry in Figure 34.27 can be expanded to represent the case with the screen far away, as shown in Figure 34.28. Clearly, the path length difference between the pairs of rays labeled r_1 and r_2, r_2 and r_3, and r_3 and r_4 is given by

$$\sin\theta = \frac{\Delta x}{a/4} \Leftrightarrow \Delta x = \frac{1}{4}a\sin\theta.$$

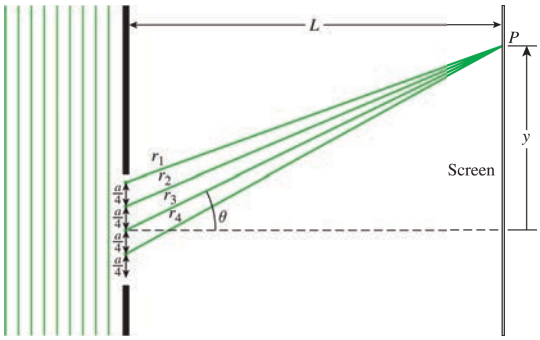

FIGURE 34.27 Geometry for determining the location of the second dark fringe from a single slit, using four rays from the slit.

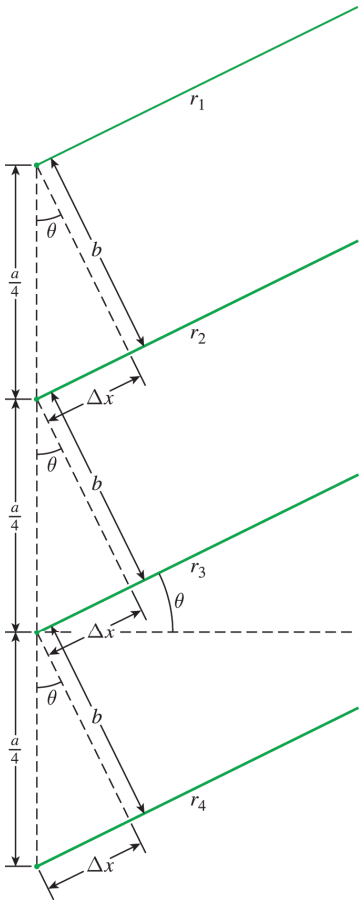

FIGURE 34.28
Expanded version of the geometry for determining the location of the second dark fringe from diffraction by a single slit.

The criterion for a dark fringe arising from these three pairs of rays is

$$\frac{a \sin \theta}{4} = \frac{\lambda}{2} \Rightarrow a \sin \theta = 2\lambda.$$

All wavelets could be grouped into four rays similar to those shown in Figure 34.28. Each group destructively interferes, so an overall dark fringe is visible on the screen. Thus, the condition $a \sin \theta = 2\lambda$ describes the second dark fringe.

At this point, we can easily generalize and take groups of six and eight rays and describe the third and fourth dark fringes, and so forth.

The result is that the dark fringes from single-slit diffraction can be described by

$$a \sin \theta = m\lambda \quad (\text{for } m = \pm 1, \pm 2, \pm 3, \ldots). \qquad \textbf{(34.15)}$$

If the screen is placed a sufficiently large distance from the slits, the angle θ is small and can be approximated by $\sin \theta \approx \tan \theta = y/L$. Thus, the position of the dark fringes on the screen can be expressed as

$$\frac{ay}{L} = m\lambda \quad (\text{for } m = \pm 1, \pm 2, \pm 3, \ldots),$$

or

$$y \frac{m\lambda L}{a} \quad (\text{for } m = \pm 1, \pm 2, \pm 3, \cdots) \quad \begin{pmatrix} \text{positions of} \\ \text{dark fringes} \end{pmatrix}. \textbf{(34.16)}$$

Detailed analysis of the spherical wavelets shows that the intensity I relative to I_0, the intensity at $\theta = 0^\circ$, is

$$I = I_0 \left(\frac{\sin \alpha}{\alpha} \right)^2, \qquad \textbf{(34.17)}$$

where

$$\alpha = \frac{\pi a}{\lambda} \sin \theta. \qquad \textbf{(34.18)}$$

Equation 34.17 shows that this expression for the intensity I is zero for $\sin \alpha = 0$ (unless $\alpha = 0^\circ$), which means that $\alpha = m\pi$ for

$m = 1, 2, 3, \ldots$. For the special case of $\alpha = 0^\circ$, corresponding to $\theta = 0^\circ$, we use

$$\lim_{\alpha \to 0} \left(\frac{\sin \alpha}{\alpha} \right) = 1.$$

Therefore,

$$m\pi = \frac{\pi a}{\lambda} \sin \theta \quad (\text{for } m = \pm 1, \pm 2, \pm 3, \ldots),$$

or

$$a \sin \theta = m\lambda \quad (\text{for } m = \pm 1, \pm 2, \pm 3, \ldots),$$

which gives the same result for the diffraction minima as equation 34.15.

For dark fringes close to the central maximum, the angle θ is small and can be approximated by $\sin \theta \approx \tan \theta = y/L$. Thus, equation 34.18 can be expressed as

$$\alpha = \frac{\pi a y}{\lambda L}. \tag{34.19}$$

For example, if the screen is $L = 2.0$ m away from the slit, the slit has a width of $a = 5.0 \cdot 10^{-6}$ m, and the wavelength of the incident light is $\lambda = 550$ nm, we get the intensity pattern shown in Figure 34.29. An intensity distribution like that shown in Figure 34.29 is called a *Fraunhofer diffraction pattern.*

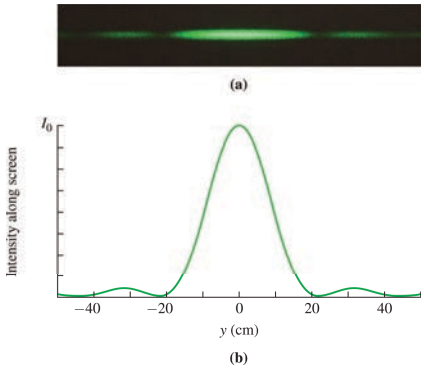

FIGURE 34.29 Intensity pattern for diffraction through a single slit. (a) Photograph of the light on the screen. (b) Graph of the intensity along the screen.

a: W. Bauer and G. D. Westfall

SOLVED PROBLEM 34.2 Width of Central Maximum

The single-slit diffraction pattern shown in Figure 34.30 was produced with light of wavelength $\lambda = 510.0\,\text{nm}$. The screen on which the pattern was projected was located a distance $L = 1.40\,\text{m}$ from the slit. The slit had a width of $a = 0.100\,\text{mm}$.

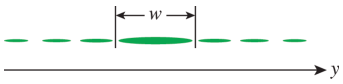

FIGURE 34.30
Single-slit diffraction pattern observed on a screen.

PROBLEM

What is the width w of the central maximum? (The width is equal to the distance between the two first diffraction minima located on either side of the center.)

SOLUTION

THINK

The diffraction pattern produced by light incident on a single slit peaks at $y = 0$ and falls to a minimum on both sides of the peak. The first minimum corresponds to $m = 1$. Therefore, the width of the central maximum is equal to twice the y-coordinate of the first minimum.

SKETCH

Figure 34.30 serves as our sketch, on which the width, w, of the maximum is indicated.

RESEARCH

The locations of the dark fringes corresponding to diffraction minima on a screen when the screen is sufficiently far from the slit are given by equation 34.16:

$$y = \frac{m\lambda L}{a} \quad (\text{for } m = \pm 1, \pm 2, \pm 3, \ldots),$$

where λ is the wavelength of the light incident on the single slit, m is the order of the minimum, L is the distance from the slit to the screen, and a is the width of the slit. For single-slit diffraction, the position $y = 0$ corresponds to the position of the central maximum. The first diffraction minimum corresponds to $m = 1$. Therefore, the distance Δy from the central minimum to the position of the first minimum is given by

$$\Delta y = \frac{\lambda L}{a}.$$

SIMPLIFY

The width of the central maximum, w, is then

$$w = 2\Delta y = \frac{2\lambda L}{a}.$$

CALCULATE

Putting in the numerical values gives us

$$w = \frac{2(510.0 \cdot 10^{-9}\ \text{m})(1.40\ \text{m})}{(1.00 \cdot 10^{-4}\ \text{m})} = 0.01428\ \text{m}.$$

ROUND

We report our result to three significant figures:

$$w = 0.01428\ \text{m} = 14.3\ \text{cm}.$$

DOUBLE-CHECK

The width of the central maximum projected on the screen is relatively small. A slit that is large compared with the wavelength of light shows little diffraction, while a slit that has a width comparable to or smaller than the wavelength of light produces a broad diffraction pattern. The ratio of the wavelength of the light to the slit width is

$$\frac{\lambda}{a} = 510.0\,\text{nm}/1.00 \cdot 10^{-4}\,\text{m} = 0.00510.$$

Thus, our finding of a narrow central maximum appears reasonable.

Concept Check 34.6

With single-slit diffraction, how does the intensity of the second-order maxima depend on the wavelength of the light?

a) The intensity rises linearly with the wavelength.

b) The intensity increases as the square of the wavelength.

c) The intensity is proportional to the sine of the wavelength.

d) The intensity decreases as the inverse of the wavelength squared.

e) The intensity is independent of the wavelength.

Diffraction by a Circular Opening

So far, we have considered interference through two slits and diffraction through a single slit. Now we consider diffraction of light through a circular opening. Diffraction through a circular opening applies to observing objects with telescopes having circular mirrors/lenses or with cameras having circular lenses. The **resolution** of a telescope or a camera (that is, its ability to distinguish two point objects as being separate) is limited by diffraction.

The first diffraction minimum for light with wavelength λ passing through a circular opening with diameter d is given by

$$\sin\theta = 1.22\frac{\lambda}{d}, \qquad \textbf{(34.20)}$$

where θ is the angle from the perpendicular line through the center of the opening to the first diffraction minimum. This result is similar to the result from a single slit except for the factor 1.22. We will not derive this expression here. Figure 34.31 shows a diffraction pattern for red laser light with wavelength $\lambda = 633\,\text{nm}$ passing through a circular opening with diameter 0.040 mm and projected on a screen located 1.00 m from the opening. The diameter of the innermost dark circle is measured to be 3.9 cm. The first diffraction minimum is clearly visible in Figure 34.31.

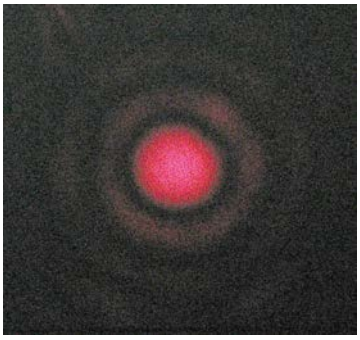

FIGURE 34.31 The diffraction pattern for red laser light with $\lambda = 633\,\text{nm}$ passing through a circular opening with diameter 0.040 mm and projected on a distant screen.

W. Bauer and G. D. Westfall

Figure 34.32 depicts three different situations for the observation of two distant point objects using a lens. In Figure 34.32a, the angular separation is clearly large enough to resolve the objects. In Figure 34.32b, the angular separation is large enough to just barely resolve the objects. In Figure 34.32c, the angular separation is too small to resolve the objects.

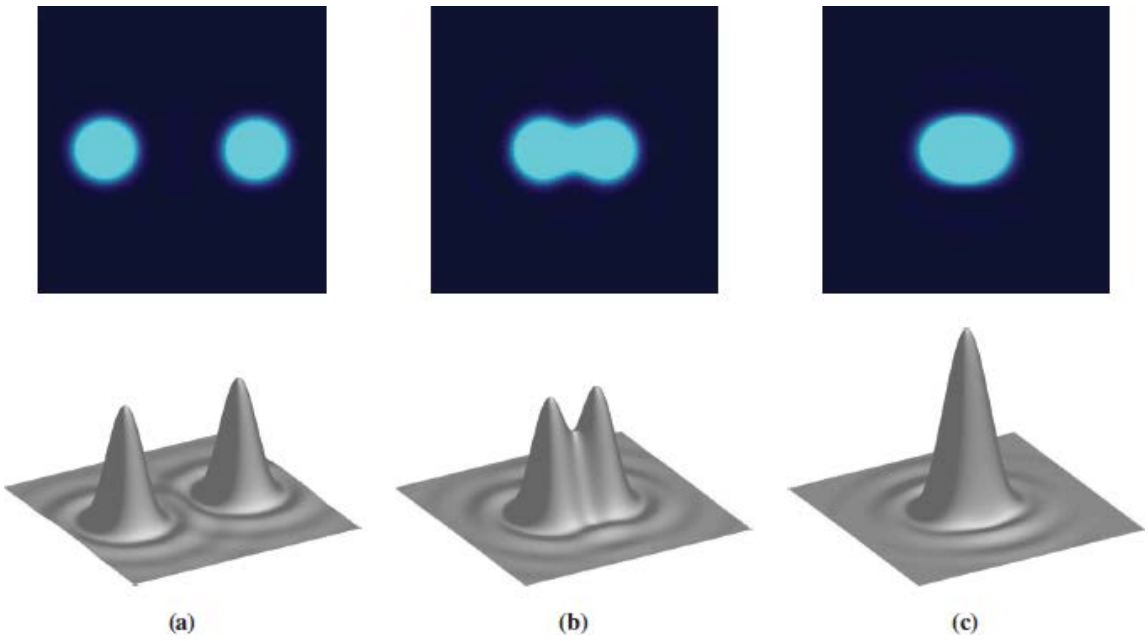

FIGURE 34.32 Diffraction through a circular opening: representing the image you might see with a lens observing two distant point objects. The top row presents a two-dimensional representation of each intensity pattern, and the bottom row shows a three-dimensional representation. (a) The angular separation is large enough to clearly resolve the two objects; (b) the angular separation is marginally large enough to resolve the two objects; (c) the angular separation of the two objects is too small to allow them to be resolved.

W. Bauer and G. D. Westfall

Concept Check 34.7

Imagine placing a circular disk in a beam of monochromatic coherent light. If diffraction occurs at the edge of the disk, the center of the shadow of the disk on a screen is

a) a bright spot.

b) darker than the rest of the shadow.

c) bright or dark, depending on the distance between the disk and the screen.

d) as dark as the rest of the shadow, which is less dark than it would be if there were no diffraction.

If a circular lens is used to observe two distant point objects, whose angular separation is small (such as two stars), diffraction limits the ability of the lens to distinguish these two objects. The criterion for being able to separate two point objects is based on the idea that if the central maximum of the first object is located at the first diffraction minimum of the second object, the objects are just resolved. This criterion, called **Rayleigh's Criterion,** is expressed as

$$\theta_{\mathrm{R}} = \sin^{-1}\left(\frac{1.22\lambda}{d}\right), \qquad \textbf{(34.21)}$$

where θ_{R} is the minimum resolvable angular separation in radians, λ is the wavelength of the light used to observe the objects, and d is the diameter of the lens or mirror.

EXAMPLE 34.2 Rayleigh's Criterion for the Hubble Space Telescope

PROBLEM

The diameter of the main mirror in the Hubble Space Telescope (Figure 34.33) is 2.4 m. What is the minimum angular resolution of the Hubble Space Telescope for green light?

FIGURE 34.33 The main mirror of the Hubble Space Telescope has a diameter of 2.4 m. The hyperbolic shape of the mirror is precise to 32 nm, which means that if the mirror were the size of Earth, any bumps in the glass would be 17 cm high or less.

NASA, 1990

SOLUTION

Using Rayleigh's Criterion, with green light of wavelength $\lambda = 550\,\text{nm}$, we get

$$\theta_\text{R} = 1.22\frac{550 \cdot 10^{-9}\,\text{m}}{2.4\,\text{m}} = 2.8 \cdot 10^{-7}\,\text{rad} = 1.6 \cdot 10^{-5}$$

which corresponds to the angle subtended by a dime (diameter of 17.9 mm) located 64 km away.

Concept Check 34.8

You are driving your car and listening to music on the radio. Your car is equipped with AM radio ($f \approx 1\text{MHz}$), FM radio ($f \approx 100\text{MHz}$), and XM satellite radio ($f = 2.3\text{GHz}$). You enter a tunnel with a circular opening of diameter 10 m. Which kind of radio signal will you be able to receive the longest as you continue to move into the tunnel?

a) AM

b) FM

c) XM

Self-Test Opportunity 34.3

Can individual watchtowers on the Great Wall of China be seen by astronauts on the Space Shuttle orbiting the Earth at an altitude of 190 km? Assume that the Great Wall is 10.0 m wide.

SOLVED PROBLEM 34.3 Spy Satellite

You have been assigned the job of designing a camera lens for a spy satellite. This satellite will orbit the Earth at an altitude of 201 km. The camera is sensitive to light with a wavelength of 607 nm. The camera must be able to resolve objects on the ground that are 0.490 m apart.

Page 1065

PROBLEM

What is the minimum diameter of the lens?

SOLUTION

THINK

The resolution of this camera lens will be limited by diffraction. We can apply Rayleigh's Criterion to calculate the minimum diameter of the lens, given the angle subtended by two objects on the ground as viewed from the spy satellite orbiting above.

SKETCH

Figure 34.34 shows a sketch of the spy satellite observing two objects on the ground.

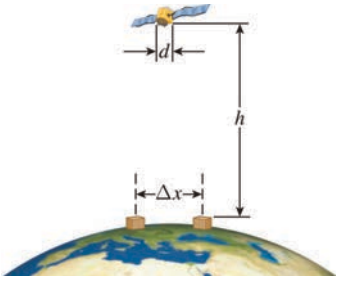

FIGURE 34.34 A spy satellite at height h observing two objects on the ground a distance Δx apart.

RESEARCH

The Rayleigh Criterion for resolving two objects separated by an angle θ_{R} using light with wavelength λ is given by

$$\theta_{\mathrm{R}} = \sin^{-1}\left(\frac{1.22\lambda}{d}\right),$$

where d is the diameter of the circular camera lens in the spy satellite.

The angle required for the performance requirement of the spy satellite is given by

$$\theta_{\mathrm{s}} = \tan^{-1}\left(\frac{\Delta x}{h}\right),$$

where Δx is the distance between the two objects on the ground and h is the height of the spy satellite above the ground.

SIMPLIFY

We can equate θ_{R} and θ_{s} to get

$$\sin^{-1}\left(\frac{1.22\lambda}{d}\right) = \tan^{-1}\left(\frac{\Delta x}{h}\right).$$

Solving for the diameter of the camera lens gives us

$$d = \frac{1.22\lambda}{\sin\left(\sin^{-1}\left(\frac{\Delta x}{h}\right)\right)}.$$

CALCULATE

Putting in the numerical values gives us

$$d = \frac{1.22\left(607.10^{-9}\ \mathrm{m}\right)}{\sin\left(\tan^{-1}\left(\dfrac{0.490\ \mathrm{m}}{201\cdot 10^{3}\ \mathrm{m}}\right)\right)} = 0.30377\ \mathrm{m}.$$

ROUND

We report our result to three significant figures:

$$d = 0.304\,\text{m}.$$

DOUBLE-CHECK

To double-check our result, we make the small-angle approximation for the Rayleigh Criterion and the angle subtended by the two objects. For the case where the wavelength of light is much smaller than the aperture of the camera, we can write

$$\sin\left(\theta_\text{R}\right) = \frac{1.22\lambda}{d} \approx \theta_\text{R}.$$

For the angle at the camera in the spy satellite, we can write

$$\tan\left(\theta_\text{s}\right) = \frac{\Delta x}{h} \approx \theta_\text{s}.$$

Thus,

$$\frac{1.22\lambda}{d} = \frac{\Delta x}{h},$$

which can be solved for the minimum diameter of the camera lens:

$$d = \frac{1.22\lambda h}{\Delta x} = \frac{1.22\left(607\cdot 10^{-9}\ \text{m}\right)\left(201.10^{3}\ \text{m}\right)}{0.490\,\text{m}} = 0.304\,\text{m}$$

This agrees with our result within round-off error. Thus, our result seems reasonable.

Double-Slit Diffraction

Section 34.2 discussed the interference pattern produced by two slits. That analysis assumed that the slits themselves were very narrow compared with the wavelength of light, $a \ll \lambda$ For these narrow slits, the diffraction maximum is very wide, with peaks in the intensity that have the same value at all angles (see Figure 34.12).

However, with double slits for which the condition $a \ll \lambda$ is not met, as illustrated in Figure 34.7c, not all the interference fringes have the same intensity. For diffraction effects, the intensity of the interference pattern from double slits can be shown to be given by

$$I = I_0 \cos^2\beta\left(\frac{\sin\alpha}{\alpha}\right)^2, \qquad \textbf{(34.22)}$$

where $\alpha = \pi a \sin\theta/\lambda$, $\beta = \pi d \sin\theta/\lambda$, and d is the distance between the slits. If the screen is placed a sufficiently large distance from the slits, the angle θ is small and can be approximated by $\sin\theta \approx \tan\theta = y/L$. Then α and β can be approximated as $\alpha = \pi a y/\lambda L$ and $\beta = \pi d y/\lambda L$.

If the screen is $L = 2.0$ m away from the slits, each slit has a width of $a = 5.0 \cdot 10^{-6}$ m, the slits are $d = 1.0 \cdot 10^{-5}$ m apart, and the wavelength of the incident light is $\lambda = 550$ nm, we get the intensity pattern shown by the dark green line in Figure 34.35.

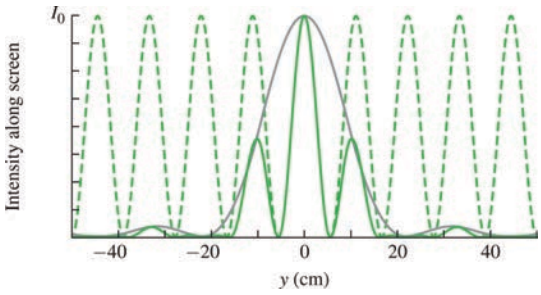

FIGURE 34.35 Intensity pattern from a double slit. The dark green line is the observed intensity pattern. The faint gray line is the intensity for a single slit with the same width as the two slits. The faint green line is the intensity distribution for two very narrow slits separated by the same distance as the double slits that produced the dark green line.

Figure 34.35 shows that the positions of the maxima on the screen are not changed from those for two very narrow slits. However, the maximum intensity is modulated by the diffraction intensity distribution, shown in faint gray. The diffraction pattern in Figure 34.35 forms an envelope for the interference intensity distribution. If one of the two slits were covered, only the diffraction pattern would be seen.

Figure 34.36 shows a photograph of an interference/diffraction pattern from a double slit projected on a screen that is 2 m away using light of wavelength $\lambda = 532\,\text{nm}$ from a green laser. The slits have a width of $a = 4.52 \cdot 10^{-5}\,\text{m}$ and are $d = 3.00 \cdot 10^{-4}\,\text{m}$ apart. The central maxima, which consist of all the two-slit maxima located within the single-slit central maximum envelope, are intentionally overexposed in the photograph to allow the secondary maxima to be observed. Figure 34.36 also shows the predicted intensity pattern, effectively overexposed by choosing the maximum value of the plotted intensity to be 38% of the maximum predicted intensity, which allows the secondary maxima to be visible. The first two single-slit diffraction minima on each side of the central maxima are marked with dashed lines.

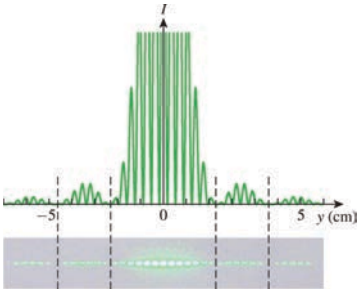

FIGURE 34.36
Photograph of the intensity pattern produced by a double slit illuminated by green light from a laser is below the graph of the intensity of the light. The central lines extend above the plotted scale in the vertical direction but have been cut off to allow the lower-intensity lines to be visible. The predicted intensity pattern is shown for $a = 0.0452$ mm, $d = 0.300$ mm, and $\lambda = 532$ nm. The dashed lines mark the diffraction minima.

34.4 Gratings

We have discussed diffraction and interference for a single slit and for two slits. How do diffraction and interference apply to a system of many slits? Putting many slits together forms a device called a **diffraction grating.** A diffraction grating has a large number of slits, or rulings, placed very close together. A diffraction grating can also be constructed using an opaque material containing grooves rather than slits; this type is called a *reflection* grating. A diffraction grating produces an intensity pattern consisting of narrow bright fringes separated by wide dark areas. This characteristic pattern results because having many slits means there can be destructive interference a small distance away from the maxima.

A portion of a diffraction grating is shown in Figure 34.37. This drawing shows coherent light with wavelength λ incident on a series of narrow slits, each separated by a distance d. A diffraction pattern is produced on a screen a long distance L away.

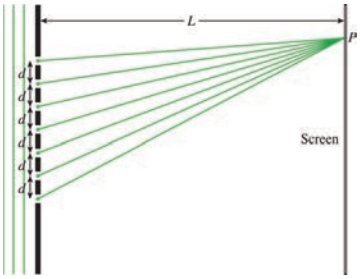

FIGURE 34.37 A portion of a diffraction grating.

Figure 34.37 can be expanded, as we did for the single-slit and double-slit cases (again using the limit that $L \gg d$ so that all of the rays drawn are parallel), to enable us to analyze the path length difference for the light from each of the slits to the screen (Figure 34.38). We assume that L is so large that the light rays are approximately parallel to one another.

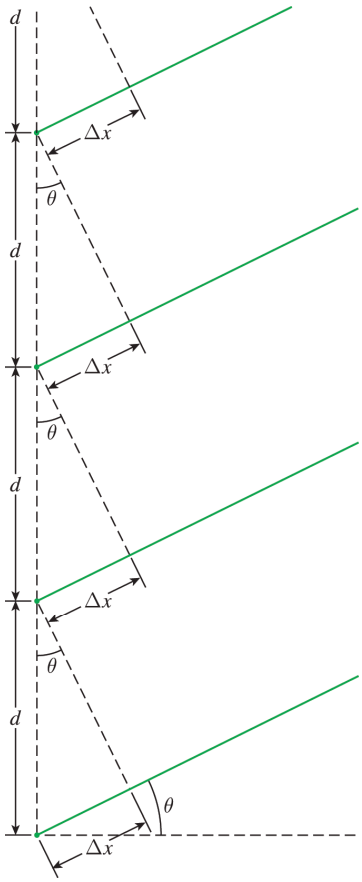

FIGURE 34.38
Expanded drawing of the geometry for a diffraction grating, assuming that the screen is far away compared to the spacing between the slits of the grating.

The distance d is called the *grating spacing*. If the grating's width is W, the number N of slits (or rulings) is $N = W/d$. Diffraction gratings are often specified in terms of the number n_1 of slits (or rulings) per unit length. We can obtain d from the specified n_1 using $d = 1/n_1$.

Let's calculate the path length differences for the paths shown in Figure 34.38. Using an adjacent pair of rays, the path length difference is $\Delta x = d \sin \theta$. To produce bright lines, or constructive interference, this path length difference must be an integer multiple of the wavelength, so

$$d \sin \theta = m\lambda \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots). \qquad \textbf{(34.23)}$$

The values of m correspond to different bright lines. For $m = 0$, we have the central maximum at $\theta = 0$. For $m = 1$, we have the first-order maximum. For $m = 2$, we have the second-order maximum, and so on. Typically, diffraction gratings are designed to produce large angular separations between the maxima, so we do not make the small-angle approximation when discussing diffraction gratings.

Because diffraction gratings produce widely spaced narrow maxima, they can be used to determine the wavelength of monochromatic light by rearranging equation 34.23,

$$\lambda = \frac{d}{m} \sin \theta \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots). \qquad \textbf{(34.24)}$$

Monochromatic light incident on a diffraction grating produces lines on a screen at widely separated angles. For example, when a focused laser beam strikes a diffraction grating, a set of widely spaced spots is created, as illustrated in Figure 34.39.

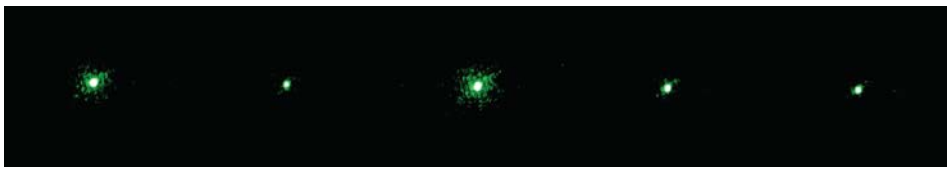

FIGURE 34.39 The diffraction pattern produced on a screen by green laser light incident on a diffraction grating with grating spacing $n_l = 787$ slits/cm. The spots corresponding to the central maximum, to $m = \pm 1$, and to $m = \pm 2$ are shown.

W. Bauer and G. D. Westfall

In addition, diffraction gratings can be used to separate out different wavelengths of light from a spectrum of wavelengths. For example, sunlight is dispersed into multiple sets of rainbow-like colors as a function of θ. If the light is composed of several discrete wavelengths, the light is separated into sets of lines corresponding to each of those wavelengths.

The quality of a diffraction grating can be quantified in terms of its dispersion. The **dispersion** is the measure of the ability of a diffraction grating to spread apart the various wavelengths in a given order. Dispersion is defined by $D = \Delta\theta/\Delta\lambda$, where $\Delta\theta$ is the angular separation between two lines with wavelength difference $\Delta\lambda$. We can get an expression for the dispersion by differentiating equation 34.24 with respect to λ:

$$\frac{d\theta}{d\lambda} = \frac{d}{d\lambda}\left(\sin^{-1}\left(\frac{m\lambda}{d}\right)\right) = \frac{1}{\sqrt{1-\left(\frac{m\lambda}{d}\right)^2}}\frac{m}{d} = \frac{m}{\sqrt{d^2-(m}}$$

Concept Check 34.9

Figure 34.39 shows that the diffraction pattern from a grating has bright spots that are widely separated. By contrast, the double-slit pattern in Figure 34.36 has broad maxima closely spaced. Why?

a) because the condition for constructive interference is fulfilled for only a very few angles for a grating

b) because the condition for destructive interference is almost always fulfilled for a grating

c) (a) and (b)

d) because the slits in the grating are so small

e) none of the above

Because $m\lambda/d = \sin\theta$, we can express $d\theta/d\lambda$ as

$$\frac{d\theta}{d\lambda} = \frac{1}{\sqrt{1-\sin^2\theta}}\frac{m}{d} = \frac{m}{d\cos\theta},$$

where we have used the identity $\sin^2\theta + \cos^2\theta = 1$. Taking intervals of θ and λ that are not too large, we can write an expression for the dispersion of a diffraction grating:

$$D = \frac{\Delta\theta}{\Delta\lambda} = \frac{m}{d\cos\theta} \quad (\text{for } m = \pm 1, \pm 2, \pm 3, \ldots). \tag{34.25}$$

The dispersion of a diffraction grating increases as the distance d between slits gets smaller, and as the order m gets higher. Note that the dispersion does not depend on the number of slits, N.

The **resolving power**, R, of a diffraction grating is a measure of its ability to resolve closely spaced maxima. This ability depends on the width of each maximum. Consider a diffraction grating used to resolve light of two wavelengths, λ_1 and λ_2, with $\lambda_{\text{ave}} = (\lambda_1 + \lambda_2)/2$ and $\Delta\lambda = |\lambda_2 - \lambda_1|$. We define the resolving power of the grating as

$$R = \frac{\lambda_{\text{ave}}}{\Delta\lambda_{\text{min}}}, \tag{34.26}$$

where $\Delta\lambda_{\text{min}}$ is the minimum value of $\Delta\lambda$ for which the wavelengths are resolved.

In order to discuss the resolving power, we need an expression for the width of each maximum. The width of each maximum is determined by the position of the first minimum on one side of the central maximum. We define the angular half-width, θ_{hw}, of the maximum as the angle between the maximum and this first minimum (Figure 34.40).

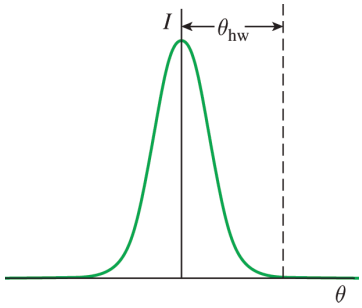

FIGURE 34.40 The angular half-width of the central maximum for a diffraction grating.

Equation 34.25 tells us the angular spread for a given $\Delta\lambda$. The two wavelengths can barely be resolved if this spread $\Delta\theta = \theta_{hw}$. To determine the position of the first minimum, we do a single-slit diffraction analysis using the whole grating as the single slit (Figure 34.41). This approach is justified if the number of slits N is large. In any case, it provides a useful and meaningful approximation, while a precise mathematical calculation would tend to obscure the physics involved.

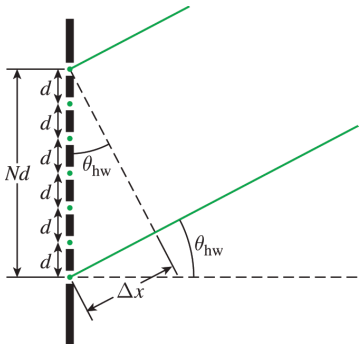

FIGURE 34.41 Calculation of the half-width of the central maximum for a diffraction grating, treating the entire grating as a single slit.

The angle of the first minimum for single-slit diffraction can be obtained from the condition $a \sin\theta = \lambda$, where Nd is substituted for the slit width a : $Nd \sin\theta_{\text{hw}} = \lambda$. Because θ_{hw} is small, we can write $\sin\theta_{\text{hw}} \approx \theta_{\text{hw}}$, or

$$\theta_{\text{hw}} = \frac{\lambda}{Nd}.$$

We can show (though we don't do so here) that the width of the maxima for other orders can be written as

$$\theta_{\text{hw}} = \frac{\lambda}{Nd\cos\theta},$$

where θ is the angle corresponding to the maximum intensity for the particular order. Substituting θ_{hw} for $\Delta\theta$ in equation 34.25, we get

$$\frac{\Delta\theta}{\Delta\lambda} = \frac{\lambda}{Nd\cos\theta\Delta\lambda} = \frac{m}{d\cos\theta},$$

or

$$R = \frac{\lambda}{\Delta\lambda} = Nm, \qquad \textbf{(34.27)}$$

where we have taken $\lambda \approx (\lambda + (\lambda + \Delta\lambda))/2$. Note that the resolving power of a diffraction grating depends only on the total number of slits and the order.

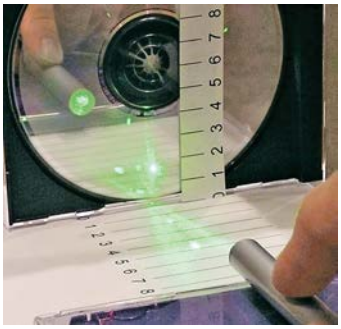
EXAMPLE 34.3 CD or DVD as Diffraction Grating

Diffraction gratings can take the form of a series of narrow slits that light passes through or a series of closely spaced grooves that reflect light. The resulting diffraction pattern is the same. We can therefore think of the spiral grooves of a CD or a DVD as a diffraction grating. In Figure 34.42, a DVD is shown reflecting various colors from sunlight.

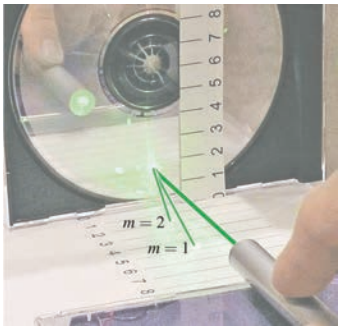
FIGURE 34.42
Different colors resulting from constructive interference of sunlight striking a blank DVD.

W. Bauer and G. D. Westfall

If we shine a green laser pointer with wavelength 532 nm perpendicular to the surface of a CD, we observe a diffraction pattern in the form of bright spots on a screen placed perpendicular to the CD at a perpendicular distance $L = 1.6\,\text{cm}$ away from the point where the laser beam hits the CD (Figure 34.43 and Figure 34.44). The spacing between the grooves in the CD is $d = 1.60 \cdot 10^{-6}\text{m} = 1.6\,\mu\text{m}$.



(a)



(b)

FIGURE 34.43 Using a CD as a diffraction grating. (a) A green laser pointer shining perpendicularly on the bottom surface of a CD. (b) Green lines illustrate the light from the laser pointer, and the order of each diffraction spot is labeled. The vertical and horizontal rulers have markings every centimeter.

W. Bauer and G. D. Westfall

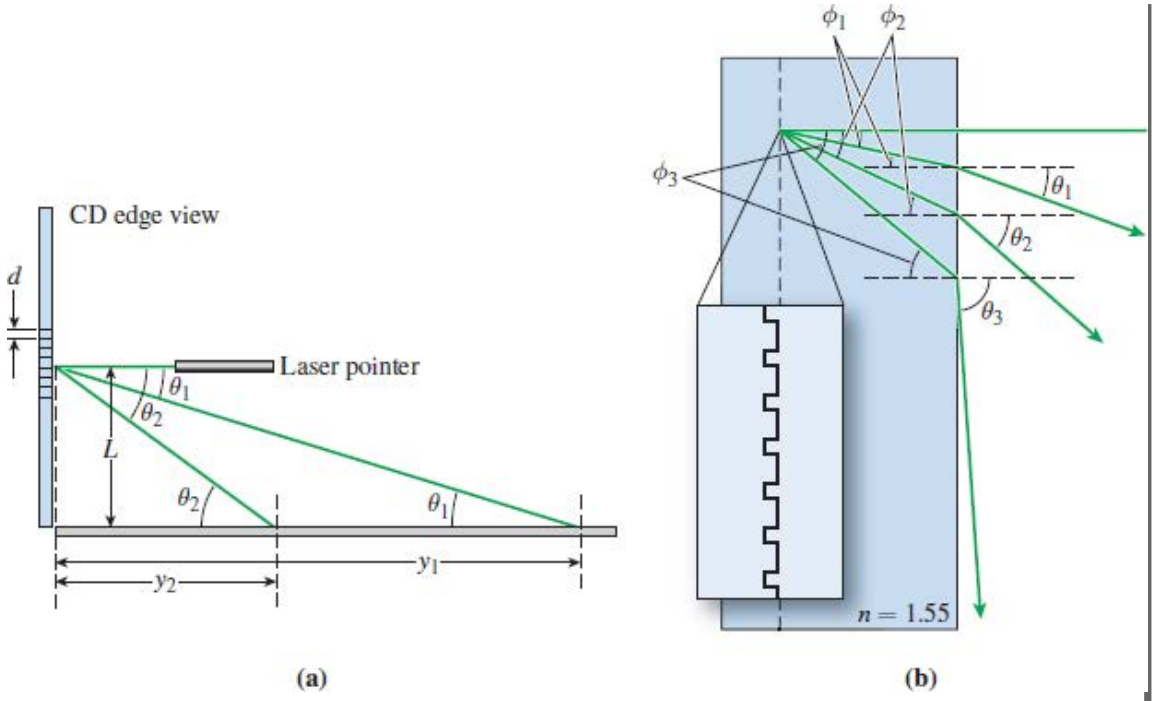


FIGURE 34.44 Geometry of using a CD as a diffraction grating. (a) Side view of the geometry of the measurement shown in Figure 34.43. A horizontal white screen is used to locate the diffraction maxima. (b) Expanded drawing of the diffraction grating inside the polycarbonate CD, illustrating the diffraction and refraction that occur.

PROBLEM

What is the horizontal distance from the surface of the CD edge to the spots observed on the screen?

SOLUTION

We start with our expression for the angle of constructive interference from a diffraction grating,

$$d \sin \phi_{\mathrm{m}} = m\lambda \quad (\text{for } m = 0, \pm 1, \pm 2, \pm 3, \ldots),$$

where d is the distance between adjacent grooves, λ is the wavelength of the light, m is the order, and ϕ_m is the angle of the mth order maximum.

The wavelength that we need for this calculation is the wavelength of light in the polycarbonate plastic from which the

CD is made, which has an index of refraction $n = 1.55$; this wavelength is: $\lambda = \lambda_{\text{air}}/n$. Thus, the condition for the diffraction maxima is given by

$$d \sin \phi_m = \frac{m\lambda_{\text{air}}}{n} \Leftrightarrow n \sin \phi_m = \frac{m\lambda_{\text{air}}}{d}.$$

This light ray must next pass through the surface of the CD, where it is refracted. Applying Snell's Law at the surface and taking $n_{\text{air}} = 1$, we get

$$n \sin\phi_m = 1 \cdot \sin \theta_m = \sin \theta_m = \frac{m\lambda_{\text{air}}}{d}.$$

We can rewrite this equation as $d \sin \theta_m = m\lambda_{\text{air}}$, which is exactly what we would have gotten if we had treated the CD as a diffraction grating in air.

Starting with $m = 0$, we find that the central maximum produces a spot at $\theta_0 = 0^\circ$, which means that the spot is produced in front of the laser pointer. You can see this diffraction maximum in the reflection of the laser pointer from the surface of the CD in Figure 34.43.

Moving to $m = 1$, we find the angle of the first-order diffraction maximum, θ_1:

$$\theta_1 = \sin^{-1}\left(\frac{\lambda_{\text{air}}}{d}\right) = \sin^{-1}\left(\frac{532 \cdot 10^{-9}\text{m}}{1.60 \cdot 10^{-6}\text{m}}\right) = 19.4^\circ.$$

Looking at Figure 34.44a, we can see that $\tan \theta_1 = L/y_1$, so we calculate the distance of the first-order spot along the screen as $y_1 = (1.6\text{ cm})/\left(\tan 19.4^\circ\right) = 4.54\text{ cm}$. The photograph in Figure 34.43 shows that this calculation is in good agreement with what we observe for $m = 1$.

The angle of the second-order maximum is given by

$$\theta_2 = \sin^{-1}\left(\frac{2\lambda_{\text{air}}}{d}\right) = \sin^{-1}\left(\frac{2.532 \cdot 10^{-9}\text{ m}}{1.60 \cdot 10^{-6}\text{ m}}\right) = 41.7^\circ.$$

Thus, the position of the second-order spot is $y_2 = (1.6\,\text{cm})/(\tan 41.7^\circ) = 1.80\,\text{cm}$, which is also in good agreement with what we observe for $m = 2$ in Figure 34.43.

The angle of the third-order maximum is

$$\theta_3 = \sin^{-1}\left(\frac{3\lambda_{\text{air}}}{d}\right) = \sin^{-1}\left(\frac{3.532 \cdot 10^{-9}\,\text{m}}{1.60 \cdot 10^{-6}\,\text{m}}\right) = 85.9^\circ.$$

The position of the third-order spot is $y_3 = (1.6\,\text{cm})/(\tan 85.9^\circ) = 0.11\,\text{cm}$. The third-order spot is not clearly visible in Figure 34.43 because the third-order maximum is dimmer than the first and second maxima and because the angle at which the spot must be observed is very close to 90°.

What about a fourth-order maximum? For the angle of this maximum, we would have $\theta_4 = \sin^{-1}(4\lambda_{\text{air}}/d)$. However, for this order, $4\lambda_{\text{air}}/d = 4\,(532\,\text{nm})/(1.6\,\mu\text{m}) = 1.33$, which cannot occur because $|\sin\theta| \leq 1$. Therefore, only three spots can appear on the screen, only two of which are easily visible.

If we carried out the same experiment using a red laser with $\lambda_{\text{air}} = 633\,\text{nm}$, we would get only two maxima, occurring at $\theta_1 = 23.3^\circ$ and $\theta_2 = 52.3^\circ$.

Self-Test Opportunity 34.4

What maxima would you observe if you repeated the experiment of Example 34.3 with a DVD and a green laser pointer? (The separation between grooves on a DVD is 740 nm compared with 1600 nm for a CD.)

Blu-Ray Discs

Now we want to explore how Blu-ray discs and other optical discs store digital information, and how computers and consumer electronic devices read them. CDs, DVDs, and Blu-ray optical discs all operate on similar principles. Figure 34.45c and Figure 34.45d show schematic cross sections of a Blu-ray disc.

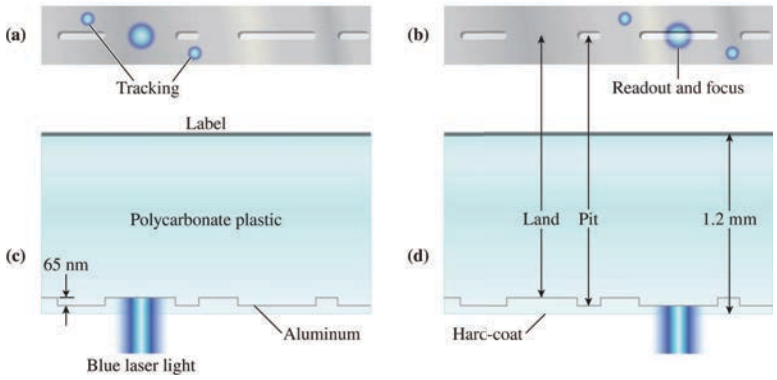

FIGURE 34.45 Cross section of a Blu-ray disc. (a) View from the bottom showing the laser data beam reflecting from only the aluminum land. (b) View from the bottom showing the laser data beam reflecting from both aluminum land and pit simultaneously. (c) Edge view showing the laser data beam focused on the aluminum land. (d) Edge view showing the laser beam focused on the aluminum pit (and land).

A Blu-ray disc, like a CD or DVD, stores digital information in terms of ones and zeros. These ones and zeros are encoded in the location of the edges of the high (land) areas and low (pit) areas in the aluminum layer shown in Figure 34.45. The high and low areas rotate with the Blu-ray disc and pass over a blue solid-state laser that emits light with a wavelength of $\lambda = 405$ nm in air. A schematic diagram of the blue laser assembly is shown in Figure 34.46.

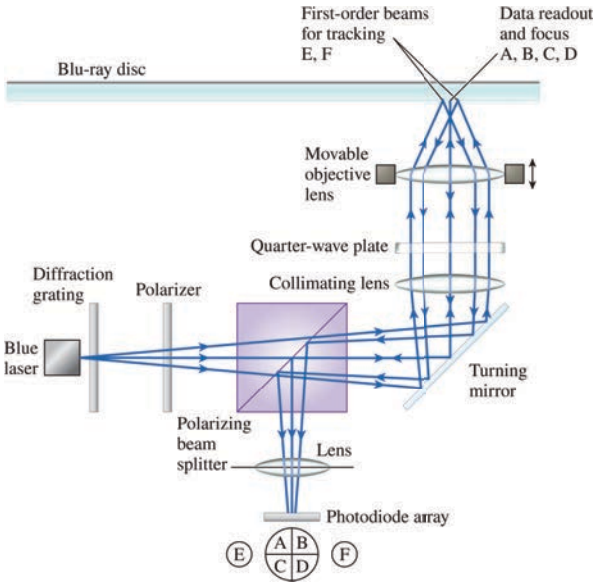

FIGURE 34.46 A schematic diagram of the blue laser assembly of a Blu-ray disc reader.

The Blu-ray player incorporates several concepts of wave optics presented in this chapter, including a diffraction grating and destructive interference, as well as polarization, which was discussed in Chapter 31. A solid-state laser produces light with wavelength $\lambda = 405$ nm in air. This wavelength is shorter than the wavelength of the laser light used to read CDs by a factor of almost 2. The shorter wavelength allows the land and pit areas to be smaller, which allows more data to be stored. This light is passed through a diffraction grating. The central maximum and the two first-order maxima are shown in Figure 34.46. The higher-order maxima are not used. The light in the central maximum is used to read the data from the disc and to maintain the focus of the beam. The light from the two first-order maxima is used for tracking the data on the disc.

After passing through the diffraction grating, the light passes through a polarizer and then proceeds to a polarizing beam splitter. The light is directed upward with a turning mirror. The light is then focused on the Blu-ray disc after passing through a quarter-wave plate that rotates the polarization. The effect of the polarizing elements is to separate the light reflected from the Blu-ray disc surface and direct it

into the photodiode array while minimizing the direct light from the laser traveling into the photodiode array.

When the light from the central maximum is shining completely on the land, as illustrated in Figure 34.45a and Figure 34.45c, all the light is reflected into the photodiode. When the light from the laser is shining on a pit, as shown in Figure 34.45b and Figure 34.45d, light is reflected from both the pit and the land. In this case, the light that reflects from the land area travels farther than the light reflected from the pit area. In both cases, the light undergoes a phase change when it is reflected. Thus, the analysis of destructive interference due to a coating on a lens can be applied to this case. We denote the difference in height between the land and pit areas as *t,* so the path length difference for the light from the high and low areas is $2t$. The criterion for destructive interference is

$$\left(m + \frac{1}{2}\right)\frac{\lambda_{\text{air}}}{n_{\text{polycarbonate}}} = 2t \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots),$$

where $n_{\text{polycarbonate}}$ is the index of refraction of the polycarbonate of which the Blu-ray disc is made and λ_{air} is the wavelength of the light emitted by the laser. For $m = 0$,

$$t = \frac{\lambda_{\text{air}}}{4n_{\text{polycarbonate}}}.$$

For the Blu-ray laser, $\lambda_{\text{air}} = 405\,\text{nm}$ and the refractive index of the polycarbonate is 1.58; therefore, the thickness required for destructive interference is

$$t = \frac{\lambda_{\text{air}}}{4n_{\text{polycarbonate}}} = \frac{405\,\text{nm}}{4\,(1.58)} = 64.1\,\text{nm},$$

which is close to the difference between the high and low areas shown in Figure 34.45.

As the disc spins, the land and pit areas pass over the laser. When the land areas are over the laser, all of the light is reflected and the photodiode registers a given voltage. When the pit areas pass over the laser, part of the light is lost to destructive interference and the photodiode reads a lower voltage. Whenever the voltage changes—from high to low, or low to high—the Blu-ray player records a one.

Otherwise, the player records a zero. This pattern of zeros and ones is translated into the normal digital code used in computers by the 8-14 method, which converts the 14 bits encoded on the disc into 8 bits of digital information. In addition, 3 bits are added to each set of 14 bits to allow the reader to maintain its tracking. The light from the central maximum is projected onto a photodiode that is segmented into four parts, A, B, C, and D, as shown in Figure 34.46. The balance of these four signals is used to adjust the distance of the movable objective lens from the surface of the disc. The tracking is done by comparing the signals from the two first-order maxima that are registered in the photodiode as E and F, as shown in Figure 34.46.

A Blu-ray disc is similar to a CD or a DVD except that the high and low areas are smaller. The distance between grooves is 1.6 μm on a CD and 0.74 μm on a DVD. In addition, a DVD uses a laser that emits light with a wavelength of 650 nm, while a CD uses a laser with a wavelength of 780 nm. A Blu-ray disc uses a groove spacing of 0.32 μm and can hold 25 gigabytes of digital information. A CD can hold up to 700 megabytes of digital information, while a DVD can hold 4.7 gigabytes.

X-Ray Diffraction and Crystal Structure

Wilhelm Röntgen (1845–1923) discovered X-rays in 1895. His experiments suggested that X-rays were electromagnetic waves with a wavelength of about 10^{-10} m. At about the same time, the study of crystalline solids suggested that their atoms were arranged in a regular repeating pattern with a spacing of about 10^{-10} m between the atoms. Putting these two ideas together, Max von Laue (1879–1960) proposed in the early 1900s that a crystal could serve as a three-dimensional diffraction grating for X-rays. In 1912, von Laue, Walter Friederich (1883–1963), and Paul Knipping (1883–1935) did the first **X-ray diffraction** experiment, which showed diffraction of X-rays by a crystal. Soon afterward, Sir William Henry Bragg (1862–1942) and his son William Lawrence Bragg (1890–1971) derived Bragg's Law (given below) and carried out a series of experiments involving X-ray diffraction by crystals.

Let's assume we have a cubic crystal, with each atom in the lattice a distance a away from its neighboring atoms in all three directions (Figure 34.47). We can imagine various planes of atoms in this crystal. For example, the horizontal planes are composed of atoms spaced a distance a apart, with the planes themselves spaced a distance a from one another. If X-rays are incident on these planes, the rows of atoms in the crystalline lattice can act like a diffraction grating for the X-rays. The X-rays can be thought of as scattering from the atoms (Figure 34.48).

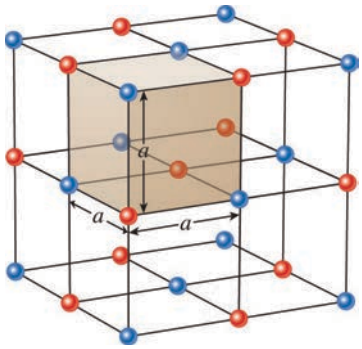

FIGURE 34.47 A cubic crystal lattice with interatomic spacing a.

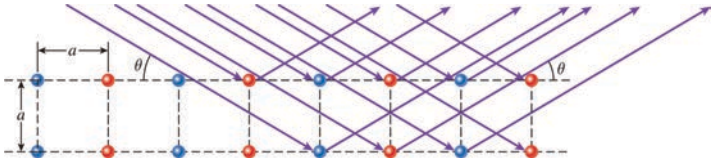

FIGURE 34.48 Schematic diagram of X-rays scattering off planes of atoms in a crystal.

Interference effects are caused by path length differences. When X-rays scatter off one plane, all the waves remain in phase as long as the incident angle equals the reflected angle. However, for two adjacent planes, Figure 34.49 shows that the path length difference for the scattered X-rays from the two planes is

$$\Delta x = \Delta x_1 + \Delta x_2 = 2a \sin\theta, \qquad \textbf{(34.28)}$$

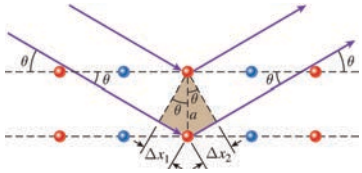

FIGURE 34.49 Path length difference for X-rays scattered from two adjacent planes.

where θ is the angle between the incoming X-rays and the plane of atoms. (Note that unfortunately this convention is different from that used for all the other cases we have considered, where the angle is always measured relative to the surface normal!) Thus, the criterion for constructive interference due to Bragg scattering is given by

$$2a \sin\theta = m\lambda \quad (\text{for } m = 0, \pm 1, \pm 2, \ldots). \qquad \textbf{(34.29)}$$

This equation is known as **Bragg's Law.**

When X-rays are incident on a crystal, several different planes can function as diffraction gratings. Some examples are illustrated in Figure 34.50. These planes do not have the spacing a between them.

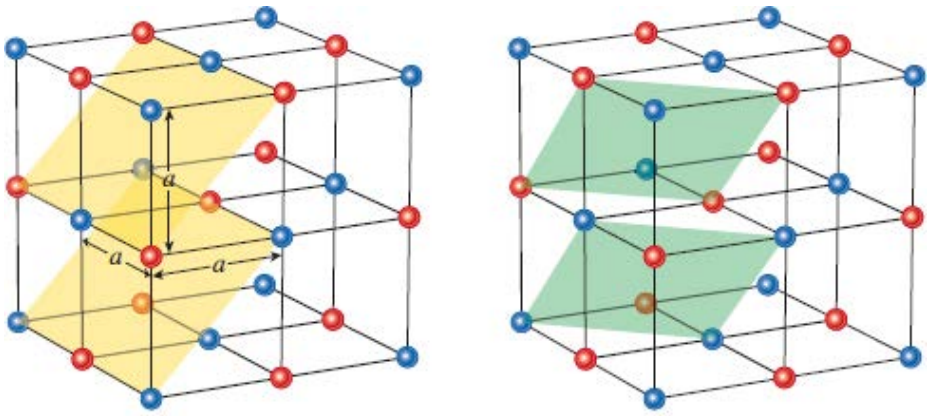

FIGURE 34.50 Examples of planes that could function as diffraction gratings for X-rays in a cubic crystalline lattice.

To study the atomic structure of a substance using X-ray diffraction, X-rays can be scattered nearly parallel to the surface of a sample (Figure 34.51a). Alternatively, the X-rays can be transmitted through the sample and detected on the opposite side of the sample (Figure 34.51b). For the parallel scattering method, the angle of incidence θ should equal the angle of observation. For the transmission method, the observed angle is twice the Bragg angle θ. By measuring the intensity of the X-rays as a function of θ, we can determine details of the structure of the material being studied.

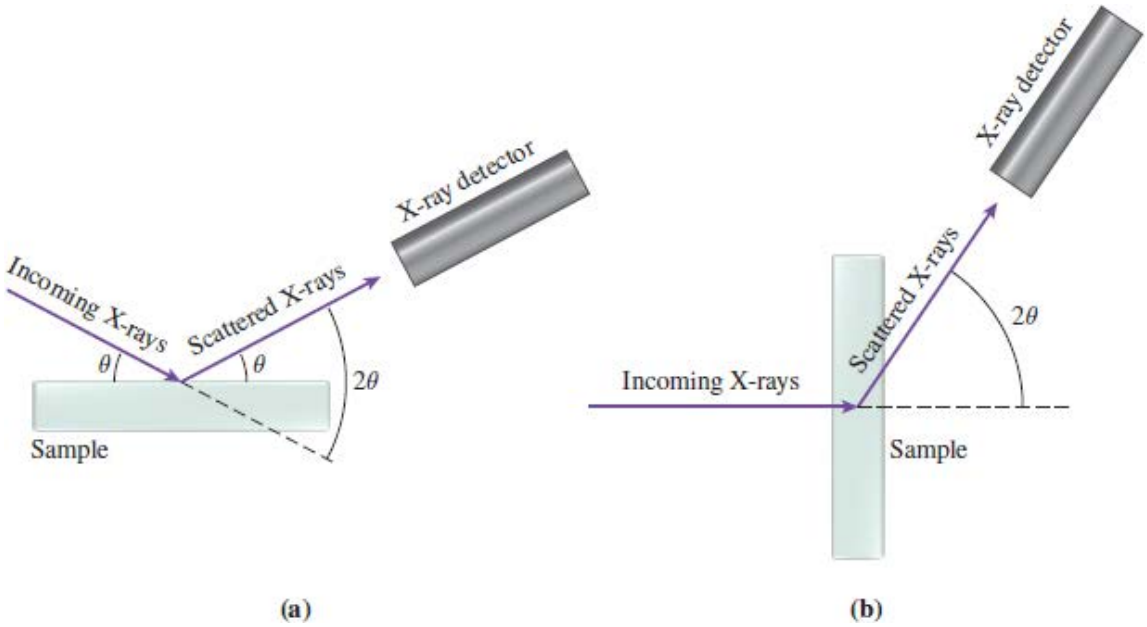

FIGURE 34.51 Two geometries for studying the atomic structure of a sample using X-ray diffraction. (a) X-rays scattered nearly parallel to the surface; (b) X-rays transmitted through the sample.

Figure 34.52 shows a sample image obtained from the scattering of X-rays by a protein, known as "3Clpro," which was fixed in a crystalline structure. The small gray and black dots in the image constitute the diffraction pattern of the protein. The concentric rings are a result of X-rays scattering off water molecules, which surround the protein and are oriented in random directions. The white horizontal bar with the small white square in the middle of the image is the beam stop, which prevents the X-rays that did not scatter from reaching the detector and damaging it. From the diffraction patterns obtained using many different orientations of the sample relative to the X-ray beam, computer analysis can reconstruct the three-dimensional spatial structure.

Modern particle accelerators—such as the National Synchrotron Light Source II at Brookhaven National Laboratory, the Advanced Light Source at Lawrence Berkeley National Laboratory, or the Advanced Photon Source at Argonne National Laboratory (Figure 34.53), and many others around the world—are used to produce high-quality, intense beams of X-rays to carry out research in condensed matter and materials science. Similar scattering information can be gathered by bombarding crystalline structures with intense neutron beams. (To understand how this works, you have to wait until we examine quantum mechanics in Chapter 37.) Intense neutron beams for materials science research are used at the Spallation Neutron Source at Oak Ridge National Laboratory. These huge X-ray and neutron scattering facilities cost hundreds of millions of dollars but are absolutely essential tools for investigating the nanoscale structure of materials. They are the basic research tools needed to achieve modern and future nanotechnology advances.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- Huygens's Principle states that every point on a propagating wave front serves as a source of spherical secondary wavelets. A geometric analysis based on this principle is called a Huygens construction.
- The condition for two coherent waves with wavelength λ to interfere constructively is $\Delta x = m\lambda$ (for $m = 0, \pm 1, \pm 2, \ldots$), where Δx is the path length difference between the two waves.
- The condition for two coherent waves with wavelength λ to interfere destructively is $\Delta x = \left(m + \frac{1}{2}\right)\lambda$ (for $m = 0, \pm 1, \pm 2, \ldots$) where Δx is the path length difference between the two waves.
- The angle of a bright fringe from two narrow slits spaced a distance d apart and illuminated by coherent light with wavelength λ is given by $d \sin\theta = m\lambda$ (for $m = 0, \pm 1, \pm 2, \ldots$ On a screen a distance L away, the position y of the bright fringe from the central maximum along the screen is given by $y = \frac{m\lambda L}{d}$ (for $m = 0, \pm 1, \pm 2, \ldots$).
- The angle of a dark fringe from two narrow slits spaced a distance d apart and illuminated by coherent light with wavelength λ is given by $d \sin\theta = \left(m + \frac{1}{2}\right)\lambda$ (for $m = 0, \pm 1, \pm 2, \ldots$). On a screen a distance L away, the position y of the dark fringe from the central maximum along the screen is given by $y = \frac{\left(m + \frac{1}{2}\right)\lambda L}{d}$ (for $m = 0, \pm 1, \pm 2, \ldots$).
- The condition for constructive interference for light with wavelength λ_{air} in a thin film of thickness t and index of

refraction n in air is $\left(m+\frac{1}{2}\right)\frac{\lambda_{\text{air}}}{n}=2t$ (for $m=0,1,2,\ldots$).

- The radii of the bright circles in Newton's rings are given by $x_m=\sqrt{R\left(m+\frac{1}{2}\right)\lambda}$ (for $m=0,1,2,\ldots$), where R is the radius of curvature of the upper curved glass surface and λ is the wavelength of the incident light.
- The angle of a dark fringe from a single slit of width a illuminated by light with wavelength λ is given by $a\sin\theta=m\lambda$ (for $m=\pm1,\pm2,\pm3,\ldots$).
- The angle θ of the first minimum from a circular aperture with diameter d illuminated with light of wavelength λ is $\sin\theta=1.22\frac{\lambda}{d}$. This equation also supplies Rayleigh's Criterion. The angle in the equation expresses the minimum resolvable angle between two distant objects for a telescope primary lens or mirror or a camera lens with diameter d.
- The angle θ of the maxima from a diffraction grating illuminated with light of wavelength λ is given by $\theta=\sin^{-1}\left(\frac{m\lambda}{d}\right)$ (for $m=0,\pm1,\pm2,\ldots$), where d is the distance between the slits (or rulings) of the grating.
- The dispersion of a diffraction grating is given by $D=\frac{m}{d\cos}$ (for $m=\pm1,\pm2,\pm3,\ldots$), where d is the distance between the slits (or rulings) of the grating.
- The resolving power of a diffraction grating is given by $R=Nm$ (for $m=1,2,3,\ldots$), where N is the number of slits (or rulings) in the grating.
- For X-rays scattering off planes of atoms separated by a distance a, the condition for constructive interference is $2a\sin\theta=m\lambda$ (for $m=0,1,2,\ldots$). The angle θ is the angle between incoming X-rays and the plane of atoms and the angle of observation of the X-rays.

ANSWERS TO SELF-TEST OPPORTUNITIES

34.1 There is no change in colors. After all, the light has to propagate through your eyeball before it reaches your retina, and the index of refraction of your eyeball does not change when your head is underwater.

34.2 $\lambda = \dfrac{2d}{N} = \dfrac{2\left(0.25 \cdot 10^{-3}\ \text{m}\right)}{1200} = 4.17 \cdot 10^{-7}\ \text{m} = 417\ \text{nm}.$

34.3 Assume that $\lambda = 550\ \text{nm}$ and that the diameter of the human pupil is $d = 7.00\ \text{mm}$.

$$\theta_{\text{R}} = \sin^{-1}\left(\frac{1.22\lambda}{d}\right) = 6.71 \cdot 10^{-5}\ \text{rad}$$

$$\theta_{\text{wall}} = \frac{y}{L} = \frac{10.0\ \text{m}}{190.10^{3}\ \text{m}} = 5.26 \cdot 10^{-5}\ \text{rad}$$

Individual watchtowers on the Great Wall of China are difficult to see from the orbiting Space Shuttle.

34.4 The first maximum would be $\theta_1 = \sin^{-1}\left(532\ \text{nm}/740\ \text{nm}\right) = 46.0^\circ$. No other maxima are possible.

PROBLEM-SOLVING GUIDELINES

1. A sketch of the optical situation is almost always helpful. It is simplest to use rays, not wave fronts, but remember that you are dealing with wave effects. Use the diagram to clearly identify any path differences involved in the problem situation.

2. The basic idea of wave optics is that constructive interference occurs when the path difference is an integer number of wavelengths, while destructive interference occurs when the path difference is an odd-integer number of half wavelengths. Always start with this concept and take into account any additional phase changes due to reflection.

3. Remember that a phase change occurs when light traveling in a less dense medium reflects from a more dense medium. If light reflects from a less dense medium, no phase change occurs.

MULTIPLE-CHOICE QUESTIONS

34.1 Suppose the distance between the slits in a double-slit experiment is $2.00 \cdot 10^{-5}$ m. A beam of light with a wavelength of 750 nm is shone on the slits. What is the angular separation between the central maximum and an adjacent maximum?

a) $5.00 \cdot 10^{-2}$ rad

b) $4.50 \cdot 10^{-2}$ rad

c) $3.75 \cdot 10^{-2}$ rad

d) $2.50 \cdot 10^{-2}$ rad

34.2 When two light waves, both with wavelength λ and amplitude A, interfere constructively, they produce a light wave of the same wavelength but with amplitude $2A$. What is the intensity of this light wave?

a) same intensity as the original waves

b) double the intensity of the original waves

c) quadruple the intensity of the original waves

d) Not enough information is given.

34.3 A laser beam with wavelength 633 nm is split into two beams by a beam splitter. One beam goes to mirror 1, a distance L from the beam splitter, and returns to the beam splitter, while the other beam goes to mirror 2, a distance $L + \Delta x$ from the beam splitter, and returns to the beam splitter. The beams then recombine and travel to a detector together. If $L = 1.00000$ m and $\Delta x = 1.00$ mm, which best describes the kind of interference observed at the detector? (*Hint:* To double-check your answer, you may need to use a formula that was originally intended for combining two beams in a different geometry.)

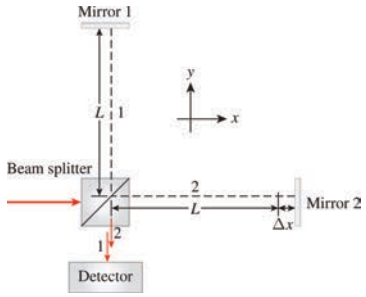
a) purely constructive

b) purely destructive

c) mostly constructive

d) mostly destructive

e) neither constructive nor destructive



34.4 Which type of the light incident on a grating with 1000 rulings with a spacing of 2.00 μm would produce the largest number of maxima on a screen 5.00 m away?

a) blue light of wavelength 450 nm

b) green light of wavelength 550 nm

c) yellow light of wavelength 575 nm

d) red light of wavelength 625 nm

e) need more information

34.5 If the wavelength of light illuminating a double slit is halved, the fringe spacing is

a) halved.

b) doubled.

c) not changed.

d) changed by a factor of $1/\sqrt{2}$.

34.6 A red laser pointer shines light with a wavelength of 635 nm on a diffraction grating with 300 slits/mm. A screen is placed a distance of 2.0 m behind the diffraction grating to observe the diffraction pattern. How far away from the central maximum will the next bright spot be on the screen?

a) 39 cm

b) 76 cm

c) 94 cm

d) 4.2 m

e) 9.5 cm

34.7 Newton's rings are interference patterns caused by the reflection of light between two glass surfaces. What color is the center of Newton's rings produced with white light?

a) white

b) black

c) red

d) violet

34.8 In Young's double-slit experiment, both slits were illuminated by a laser beam and the interference pattern was observed on a screen. If the viewing screen is moved farther from the slits, what happens to the interference pattern?

a) The pattern gets brighter.

b) The pattern gets brighter, and the maxima are closer together.

c) The pattern gets less bright, and the maxima are farther apart.

d) There is no change in the pattern.

e) The pattern becomes unfocused.

f) The pattern disappears.

34.9 Light of wavelength $= 560.0$ nm enters a block of clear plastic from air at an incident angle of $\theta_{\mathrm{i}} = 36.1^\circ$ with respect to the normal. The angle of refraction is $\theta_{\mathrm{r}} = 21.7^\circ$. What is the speed of the light inside the plastic?

a) $1.16 \cdot 10^8$ m/s

b) $1.31 \cdot 10^8$ m/s

c) $1.67 \cdot 10^8$ m/s

d) $1.88 \cdot 10^8$ m/s

e) $3.00 \cdot 10^8$ m/s

34.10 Huygens's Principle says that each point of a wave front in a slit is a point source of light emitting a spherical wavelet. A Huygens construction applies

a) to any point anywhere in the path of the wave front.

b) to any point in the path of the wave front where matter is present.

c) only in slits.

34.11 If Huygens's Principle holds everywhere, why does a laser beam not spread out?

a) All the light waves that spread in the perpendicular direction from the beam interfere destructively.

b) It does spread out, but the spread is so small that we don't notice it.

c) Huygens's Principle isn't true in general; it only applies to slits, edges, and other obstacles.

d) Lasers employ additional special beams to keep the main beam from spreading.

34.12 A pair of thin slits is separated by a distance $d = 1.40$ mm and is illuminated with light of wavelength 460.0 nm. What is the separation between adjacent interference maxima on a screen a distance $L = 2.90$ m away?

a) 0.00332 mm

b) 0.556 mm

c) 0.953 mm

d) 1.45 mm

e) 3.23 mm

CONCEPTUAL QUESTIONS

34.13 What happens to a double-slit interference pattern if

a) the wavelength is increased?

b) the separation between the slits is increased?

c) the experimental apparatus is placed in water?

34.14 Estimate the frequency of an ultrasonic (sound) wave for which diffraction effects would be as small as they are for visible light.

34.15 Why are radio telescopes so much larger than optical telescopes? Does an X-ray telescope also have to be larger than an optical telescope?

34.16 Can light pass through a single slit narrower than its wavelength? If not, why not? If so, describe the distribution of the light beyond the slit.

34.17 One type of hologram consists of bright and dark fringes produced on photographic film by interfering laser beams. If the hologram is illuminated with white light, the image will be reproduced multiple times, in different pure colors at different sizes.

a) Explain why.

b) Which colors correspond to the largest and smallest images, and why?

34.18 A double slit is positioned in front of an incandescent light bulb. Will an interference pattern be produced?

34.19 Many astronomical observatories, especially radio observatories, are coupling several telescopes together. What are the advantages of this?

34.20 In a single-slit diffraction pattern, there is a bright central maximum surrounded by successively dimmer higher-order maxima. Farther away from the central maximum, eventually no more maxima are observed. Is this because the remaining maxima are too dim? Or is there an upper limit to the number of maxima that can be observed, no matter how good the observer's eyes, for a given slit and light source?

34.21 Which close pair of stars will be more easily resolvable with a telescope: two red stars or two blue ones? Assume the binary star systems are the same distance from Earth and are separated by the same angle.

34.22 A red laser pointer shines on a diffraction grating, producing a diffraction pattern on a screen behind the grating. If the red laser pointer is replaced with a green laser pointer, will the green bright spots on the screen be closer together or farther apart than the red bright spots were?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 34.1

34.23 A helium-neon (He-Ne) laser has a wavelength of 632.8 nm.

a) What is the wavelength of this light as it passes through Lucite with index of refraction $n = 1.500$?

b) What is the speed of the light in the Lucite?

34.24 It is common knowledge that the visible light spectrum extends approximately from 400 nm to 700 nm. Roughly, 400 nm to 500 nm corresponds to blue light, 500 nm to 550 nm corresponds to green, 550 nm to 600 nm to yellow-orange, and above 600 nm to red. In an experiment, red light with a wavelength of 632.8 nm from a He-Ne laser is refracted into a fish tank filled with water (with index of refraction 1.333). What is the wavelength of the laser light in water, and what color will it have in water?

Section 34.2

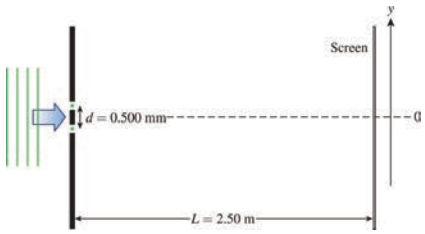
34.25 What minimum path length difference is needed to cause a phase shift of $\pi/4$ in light of wavelength 700. nm?

34.26 Coherent, monochromatic light of wavelength 450.0 nm is emitted from two locations and detected at another location. The path length difference between the two routes taken by the light is 20.25 cm. Will the two light waves interfere destructively or constructively at the detection point?

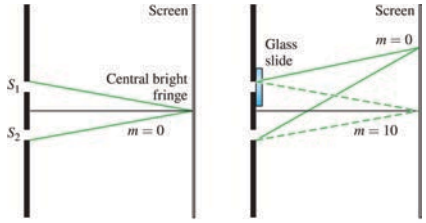
34.27 A Young's double-slit experiment is performed with monochromatic green light ($\lambda = 540$ nm). The separation between the slits is 0.100 mm, and the interference pattern on a screen has the first side maximum 5.40 mm from the center of the pattern. How far away from the slits is the screen?

34.28 For a double-slit experiment, two 1.50-mm-wide slits are separated by a distance of 1.00 mm. The slits are illuminated by laser light with wavelength 633 nm. If a screen is placed 5.00 m away from the slits, determine the separation of the bright fringes on the screen.

•**34.29** Coherent monochromatic light with wavelength $\lambda = 514$ nm is incident on two thin slits that are separated by a distance $d = 0.500$ mm. The intensity of the radiation at a screen 2.50 m away is 180.0 $\mathrm{W/cm^2}$. Determine the position $y_{1/3}$ at which the intensity at the central peak (at $y = 0$) drops to $I_0/3$ (where I_0 is the intensity at $\theta = 0^\circ$).



•**34.30** In a double-slit experiment, He-Ne laser light of wavelength 633 nm produced an interference pattern on a screen placed some distance from the slits. When one of the slits was covered with a thin glass slide of thickness 12.0 μm the central bright fringe shifted to the point occupied earlier by the 10th dark fringe (see the figure). What is the index of refraction of the glass slide?



(a) Without the glass slide (b) With glass slide

34.31 Suppose the thickness of a thin soap film $(n = 1.32)$ surrounded by air is nonuniform and gradually tapers. Monochromatic light of wavelength 550 nm illuminates the film. At the thinnest end, a dark fringe is observed. How thick is the film at the two dark fringes closest to that fringe?

34.32 White light $(400.\ \text{nm} < \lambda < 700.\ \text{nm})$ shines onto a puddle of water $(n = 1.33)$. There is a thin (100.0 nm thick) layer of oil $(n = 1.47)$ on top of the water. What wavelengths of light would you see reflected?

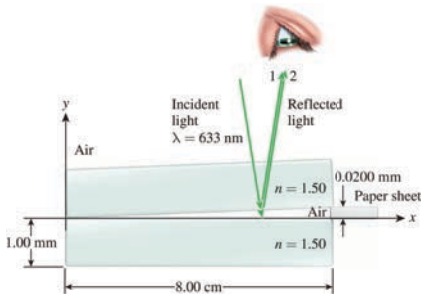
34.33 Some mirrors for infrared lasers are constructed with alternating layers of hafnia and silica. Suppose you want to produce constructive interference from a thin film of hafnia $(n = 1.90)$ on BK-7 glass $(n = 1.51)$ using infrared radiation of wavelength 1.06 μm. What is the smallest film thickness that would be appropriate, assuming that the laser beam is oriented at right angles to the film?

34.34 Sometimes thin films are used as filters to prevent certain colors from entering a lens. Suppose an infrared filter is to be designed to prevent 800.0-nm light from entering a lens. Find the minimum thickness for a film of MgF_2 that will prevent this light from entering the lens.

•34.35 White light shines on a sheet of mica that has a uniform thickness of 1.30 μm. When the reflected light is viewed using a spectrometer, it is noted that light with wavelengths of 433.3 nm, 487.5 nm, 557.1 nm, 650.0 nm, and 780.0 nm is not present in the reflected light. What is the index of refraction of the mica?

•34.36 A single beam of coherent light $\left(\lambda = 633.10^{-9}\ \text{m}\right)$ is incident on two glass slides, which are touching at one end and are separated by a 0.0200-mm-thick sheet of paper on the other end, as shown in

the figure. Beam 1 reflects off the bottom surface of the top slide, and beam 2 reflects off the top surface of the bottom slide. Assume that all the beams are perfectly vertical and are perpendicular to both slides, that is, the slides are nearly parallel (the angle is exaggerated in the figure); the beams are shown at angles in the figure so that they are easier to identify. Beams 1 and 2 recombine at the location of the eye. The slides are 8.00 cm long. Starting from the left end $(x = 0)$, at what positions, x_{bright}, do bright bands appear to the observer above the slides? How many bright bands are observed?



•**34.37** A common interference setup for seeing Newton's rings consists of a plano-convex lens placed on a plane mirror and illuminated from above at normal incidence with monochromatic light. In an experiment using a plano-convex lens with focal length $f = 80.00$ cm and index of refraction $n_1 = 1.500$, the radius of the third bright circle is found to be 0.8487 mm. Determine the wavelength of the monochromatic light.

34.38 A Michelson interferometer is used in a class of commercially available optical instruments called *wavelength meters*. In a wavelength meter, the interferometer is illuminated simultaneously with parallel beams from a reference laser of known wavelength and an unknown laser. The movable mirror of the interferometer is then displaced by a distance Δd, and the number of fringes produced by each laser and shifting past a reference point (a photo detector) is counted. In a given wavelength meter, a red He-Ne laser $(\lambda_{\text{Red}} = 632.8\,\text{nm})$ is used as a reference laser. When the movable mirror of the interferometer is displaced by a distance Δd, the shifting of $\Delta N_{\text{red}} = 6.000 \cdot 10^4$ red fringes and $\Delta N_{\text{unknown}} = 7.780 \cdot 10^4$ fringes is observed by the photo detector.

a) Calculate the wavelength of the unknown laser.

b) Calculate the displacement, Δd, of the movable mirror.

34.39 Monochromatic blue light $(\lambda = 449)$ is beamed into a Michelson interferometer. How many fringes shift on the screen when the movable mirror is moved a distance $d = 0.381$ mm?

•**34.40** At the Long-baseline Interferometer Gravitational-wave Observatory (LIGO) facilities in Hanford, Washington, and Livingston, Louisiana, laser beams of wavelength 550.0 nm travel along perpendicular paths 4.000 km long. Each beam is reflected along its path and back 100 times before the beams are combined and compared. If a gravitational wave increases the length of one path and decreases the other, each by 1.000 part in 10^{21}, what is the resulting phase difference between the two beams?

Section 34.3

34.41 Light of wavelength 653 nm illuminates a single slit. If the angle between the first dark fringes on either side of the central maximum is 32.0°, what is the width of the slit?

34.42 An instructor uses light of wavelength 633 nm to create a diffraction pattern with a slit of width 0.135 mm. How far away from the slit must the instructor place the screen in order for the full width of the central maximum to be 5.00 cm?

34.43 What is the largest slit width for which there are no minima when the wavelength of the incident light on the single slit is 600. nm?

34.44 Plane microwaves are incident on a single slit of width 2.00 cm. The second minimum is observed at an angle of 43.0°. What is the wavelength of the microwaves?

34.45 The Large Binocular Telescope (LBT), on Mount Graham near Tucson, Arizona, has two 8.4-m-diameter primary mirrors. The mirrors are centered a distance of 14.4 m apart, thus producing a mirror with an effective diameter of 14.4 m. What is the minimum angular resolution of the LBT for green light ($\lambda = 550\,\text{nm}$)?

34.46 A canvas tent has a single, tiny hole in its side. On the opposite wall of the tent, 2.0 m away, you observe a dot (due to sunlight incident upon the hole) of width 2.0 mm, with a faint ring around it. What is the size of the hole in the tent? (Assume a wave length of 570 nm for the sunlight.)

34.47 Calculate and compare the angular resolutions of the Hubble Space Telescope (aperture diameter, 2.40 m; wavelength, 450. nm), the Keck Telescope (aperture diameter, 10.0 m; wavelength, 450. nm), and the Arecibo radio telescope (aperture diameter, 305 m; wavelength, 0.210 m). Assume that the resolution of each instrument is limited by diffraction.

34.48 The Hubble Space Telescope is capable of resolving optical images to an angular resolution of $2.80 \cdot 10^{-7}$rad with its 2.40-m mirror (see Figure 34.33). How large would a radio telescope have to be in order to image an object with the same resolution, assuming that the wavelength of the radio waves emitted by the object is 10.0 cm?

34.49 Think of the pupil of your eye as a circular aperture 5.00 mm in diameter. Assume you are viewing light of wavelength 550. nm, to which your eyes are maximally sensitive.

a) What is the minimum angular separation at which you can distinguish two stars?

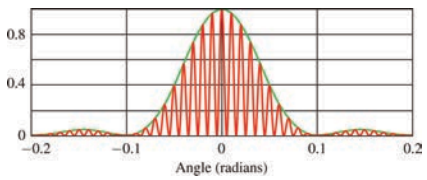
b) What is the maximum distance at which you can distinguish the two headlights of a car mounted 1.50 m apart?

34.50 A red laser pointer shines light with a wavelength of 635 nm on a double slit, producing a diffraction pattern on a screen that is 1.60 m behind the double slit. The central maximum of the diffraction pattern has a width of 4.20 cm, and the fourth bright spot is missing on both sides. What is the width of the individual slits, and what is the separation between them?

•34.51 A double slit is opposite the center of a 1.8-m-wide screen that is 2.0 m away. The slit separation is 24 μm, and the width of each slit is 7.2 μm. How many bright fringes are visible on the screen, including the central maximum, if the slit is illuminated by 600.-nm light?

•34.52 A two-slit apparatus is covered with a red (670-nm) filter. When white light shines on the filter, nine interference maxima appear on a screen, within the 4.50-cm-wide central diffraction maximum. When a blue (450-nm) filter replaces the red filter, how many interference maxima will there be in the central diffraction maximum, and how wide will that diffraction maximum be?

34.53 The intensity pattern observed in a two-slit experiment is presented in the figure. The red line represents the actual intensity measured as a function of angle, while the green line represents the envelope of the single-slit interference pattern.



a) Determine the slit width a in terms of the wavelength λ of the light used in the experiment.

b) Determine the center-to-center slit separation d in terms of the wavelength λ.

c) Using the information in the graph, determine the ratio of slit width a to the center-to-center separation between the slits, d.

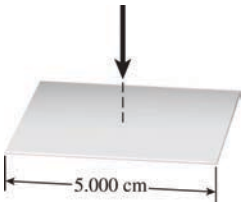
d) Can you calculate the wavelength of light, actual slit separation, and slit width?

Section 34.4

34.54 Two different wavelengths of light are incident on a diffraction grating. One wavelength is 600. nm, and the other is unknown. If the third-order bright fringe of the unknown wavelength appears at the same position as the second-order bright fringe of the 600.-nm light, what is the value of the unknown wavelength?

34.55 Light from an argon laser strikes a diffraction grating that has 7020 slits per centimeter. The central and first-order maxima are separated by 0.332 m on a wall 1.00 m from the grating. Determine the wavelength of the laser light.

•**34.56** A 5.000-cm-wide diffraction grating with 200 slits is used to resolve two closely spaced lines (a doublet) in a spectrum. The doublet consists of two wavelengths, $\lambda_a = 629.8\,\text{nm}$ and $\lambda_b = 630.2\,\text{nm}$. The light illuminates the entire grating at normal incidence. Calculate to *four significant digits* the angles θ_{1a} and θ_{1b} with respect to the normal at which the first-order diffracted beams for the two wavelengths, λ_a and λ_b respectively, will be reflected from the grating. Note that this is not 0°! What order of diffraction is required to resolve these two lines using this grating?



•**34.57** A diffraction grating has $4.00 \cdot 10^3$ slits/cm and has white light $(400. - 700.\ \text{nm})$ incident on it. What wavelength(s) will be visible at 45.0°?

34.58 What is the wavelength of the X-rays if first-order Bragg diffraction is observed at 23.0°? relative to the crystal surface, with an interatomic distance of 0.256 km?

Additional Exercises

34.59 How many slits per centimeter must a grating have if there are to be no second-order maxima or minima for any visible wavelength $(400. - 700.\ \text{nm})$?

34.60 Many times, radio antennas occur in pairs. They then produce constructive interference in one direction while producing destructive interference in another direction—acting as a directional antenna—so that their emissions don't overlap with nearby stations. How far apart at a minimum should a local radio station, operating at 88.1 MHz, place its pair of antennas operating in phase so that no emission occurs along a line 45.0° from the line joining the antennas?

34.61 A laser produces a coherent beam of light that does not spread (diffract) as much in comparison to light from other sources, like an incandescent bulb. Lasers therefore have been used for very accurate measurements of large distances, such as the distance between the Moon and the Earth. In one such experiment, a laser pulse (wavelength of 633 nm) is fired at the Moon. What should be the size of the circular aperture of the laser source in order to produce a central maximum of 1.00-km diameter on the surface of the Moon? The distance between the Moon and the Earth is $3.84 \cdot 10^5 \text{km}$.

34.62 A diffraction grating with exactly 1000 slits per centimeter is illuminated by a He-Ne laser of wavelength 633 nm.

a) What is the highest order of diffraction that could be observed with this grating?

b) What would be the highest order if there were exactly 10,000 slits per centimeter?

34.63 The thermal stability of a Michelson interferometer can be improved by submerging it in water. Consider an interferometer that is submerged in water, measuring light from a monochromatic source that is in air. If the movable mirror moves a distance $d = 0.200\,\text{mm}$, exactly $N = 800$ fringes are shifted on the screen. What is the original wavelength (in air) of the monochromatic light?

34.64 A Blu-ray player uses a blue laser that produces light with a wavelength in air of 405 nm. If the disc is protected with

polycarbonate ($n = 1.58$), determine the minimum thickness of the disc for destructive interference. Compare this value to that for CDs illuminated by infrared light.

34.65 An airplane is made invisible to radar by coating it with a 5.00-mm-thick layer of an antireflective polymer with index of refraction $n = 1.50$. What is the wavelength of the radar waves for which the plane is made invisible?

34.66 Coherent monochromatic light passes through parallel slits and then onto a screen that is at a distance $L = 2.40$ m from the slits. The narrow slits are a distance $d = 2.00 \cdot 10^{-5}$ m apart. If the minimum spacing between bright spots is $y = 6.00$ cm, find the wavelength of the light.

34.67 Determine the minimum thickness of a soap film $(n = 1.32)$ that would produce constructive interference when illuminated by light of wavelength 550. nm.

34.68 You are making a diffraction grating that is to be used to resolve the two spectral lines in the sodium D doublet, at wavelengths of 588.9950 nm and 589.5924 nm, by at least 2.00 mm on a screen that is 80.0 cm from the grating. The rulings are to cover a distance of 1.50 cm on the grating. What is the minimum number of rulings you should have on the grating?

34.69 A Michelson interferometer is illuminated with a 600.-nm light source. How many fringes are observed to shift if one of the mirrors of the interferometer is moved a distance of 200. mm

34.70 What is the smallest object separation you can resolve with your naked eye? Assume that the diameter of your pupil is 3.5 mm and that your eye has a near point of 25 cm and a far point of infinity.

34.71 With a telescope with an objective of diameter 12.0 cm, how close can two features on the Moon be and still be resolved? Take the wavelength of the light to be 550. nm, near the center of the visible spectrum.

34.72 There is air on both sides of a soap film. What is the smallest thickness that the soap film $(n = 1.420)$ can have and appear dark if illuminated with 500-nm light?

34.73 X-rays with a wavelength of 1.00 nm are scattered off two small tumors in a human body. If the two tumors are a distance of 10.0 cm away from the X-ray detector, which has an entrance aperture of diameter 1.00 mm, what is the minimum separation between the two tumors that will allow the X-ray detector to determine that there are two tumors instead of one?

•**34.74** Glass with an index of refraction of 1.50 is inserted into one arm of a Michelson interferometer that uses a 600.-nm light source. This causes the fringe pattern to shift by exactly 1000 fringes. How thick is the glass?

•**34.75** White light is shone on a very thin layer of mica $(n = 1.57)$, and above the mica layer, interference maxima for light of two wavelengths (and no other in between) are seen: 516.9 nm and 610.9 nm. What is the thickness of the mica layer?

•**34.76** A Newton's ring apparatus consists of a convex lens with a large radius of curvature *R* placed on a flat glass disc. (a) Show that the horizontal distance *x* from the center, the thickness *d* of the air gap, and the radius of curvature *R* are related by $x^2 = 2Rd$. (b) Show that the radius of the *n*th constructive interference ring is given by $x_n = \left[\left(n + \frac{1}{2}\right)\lambda R\right]^{1/2}$. (c) How many bright rings may be seen if the apparatus is illuminated by red light of wavelength 700. nm with $R = 10.0$ m and the plane glass disc diameter 5.00 cm?

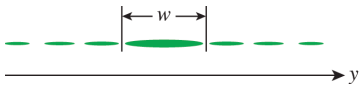
MULTI-VERSION EXERCISES

34.77 In a double-slit experiment, the slits are $2.49 \cdot 10^{-5}$m apart. If light of wavelength 477 nm passes through the slits, what will be the distance between the third-order and fourth-order bright fringes on a screen 1.23 m away?

34.78 In a double-slit experiment, the slits are $3.41 \cdot 10^{-5}$m apart. The distance between the second-order and third-order bright fringes on a screen 1.63 m away is 2.30 cm. What is the wavelength of the light?

34.79 A double-slit experiment using light of wavelength 485 nm produces an interference pattern on a screen that is 2.01 m away from the slits. The distance between the first-order and third-order maxima on the screen is measured to be 4.50 cm. What is the separation between the slits?

34.80 A double-slit experiment using light of wavelength 489 nm produces an interference pattern on a screen. The slit separation is $1.25 \cdot 10^{-2}$ mm. The distance between the first-order and fourth-order maxima on the screen is measured to be 28.05 cm. What is the distance between the slits and the screen?



34.81 The single-slit diffraction pattern shown in the figure was produced with light of wavelength 495 nm. The screen on which the pattern was projected is located a distance of 2.77 m from the slit. The slit has a width of 2.73 mm. What is the width w of the central maximum?

34.82 The single-slit diffraction pattern shown in the figure was produced with light from a laser. The screen on which the pattern was projected is located a distance of 3.17 m from the slit. The slit has a width of 0.555 mm. The width of the central maximum is $w = 5.81$ mm. What is the wavelength of the laser light?

34.83 The single-slit diffraction pattern shown in the figure was produced with light of wavelength 503 nm. The screen on which the pattern was projected is located a distance of 3.55 m from the slit. The width of the central maximum is $w = 5.71$ mm. What is the width of the slit?

34.84 The single-slit diffraction pattern shown in the figure was produced with light of wavelength 507 nm incident on a slit of width 0.693 mm. The width of the central maximum is $w = 5.75$ mm. How far is the screen on which the pattern was projected from the slit?

The picture in Figure 35.1 is not a cluster of stars, as you might assume at first glance. Instead, the central bright spot is a galaxy at a great distance from Earth, and the four spots around it are all images of an even more distant object behind it. The path traveled by the light from the more distant object (called a *quasar*, or *quasi-stellar object*) is curved by the gravitational pull of the intermediate galaxy to form four surrounding images. The fact that light can be bent by gravitation was not predicted by Newton's laws but was deduced from Einstein's theory of relativity. The image in the photograph, called *Einstein's Cross*, is one of many observations that confirm Einstein's theory of relativity.

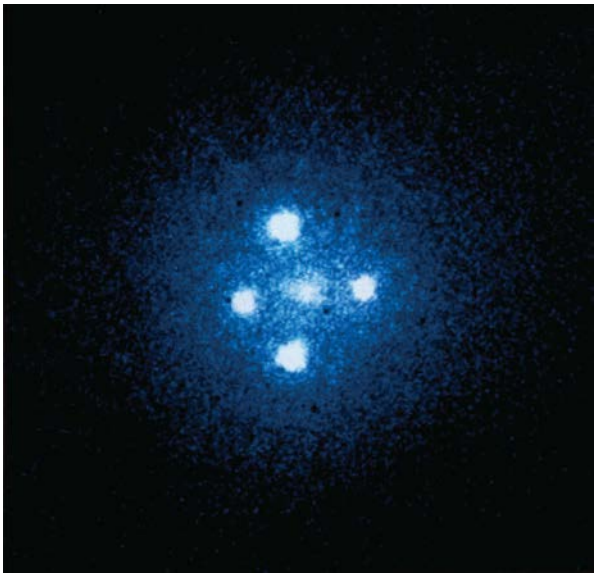

FIGURE 35.1 A photograph of Einstein's Cross, which is formed by gravitational lensing of a distant quasar by the galaxy in the center.

NASA, ESA, and STScI

The theory of relativity changes our understanding of space and time in very basic ways. And some of its consequences seem contradictory to our everyday experiences. The idea that a meter stick in a train station may not be the same length for a person standing in the station as for a person passing by on a train seems preposterous. Some people believe that relativity is impossible and claim that it only describes human perceptions or is "only a theory." However, relativity has been tested as much as any idea in science and has been confirmed every time. Time and space are not independent of the reference frame, and it is not just a wild idea or an optical illusion—it is how our universe works.

This chapter focuses primarily on the special theory of relativity, which is called *special* because it deals with the special case of motion with constant velocity, that is, with zero acceleration. Brief mention will be made of some ideas from the general theory of relativity, which does deal with accelerated motion. Although the concepts may seem strange at first, the mathematics are not particularly difficult. Newtonian mechanics can be thought of as a special case of Einstein's work, giving the same results in ordinary situations. But special relativity arrives at

quite different results for motion at a significant fraction of the speed of light. These results play a major role in the physics of the very small (high-energy particle physics and quantum mechanics) and the physics of the very large (astronomy and cosmology).

WHAT WE WILL LEARN

- Light always moves at the same speed in vacuum, independent of the velocity of the source or the observer.
- The two postulates of special relativity are (1) all physical laws are the same in all inertial reference frames and (2) the speed of light in vacuum is invariant. Inertial frames are reference frames that move with constant velocity.
- From the postulates of special relativity, it follows that measurements of time and space intervals are different for different observers who move relative to each other.
- For high speeds, the Lorentz transformation must be used between reference frames instead of the Galilean transformation.
- Velocities do not add linearly. Velocity addition must be done using a Lorentz transformation so that it conforms to the postulate that the speed of light cannot be exceeded.
- Kinetic energy and momentum and their relationship need new definitions.
- All of Newtonian mechanics derives from relativistic mechanics as a limiting case for speeds small compared to the speed of light.

35.1 Space, Time, and the Speed of Light

Chapters 15 and 16 demonstrated that mechanical waves and sound waves need a medium in which to propagate. Chapter 31 showed that light is an electromagnetic wave, and that all electromagnetic waves can propagate through vacuum. However, this knowledge is relatively new in science, only a little more than 100 years old. Up until 1887, scientists believed that light needed a medium in which to propagate, and they called this medium the *luminiferous aether,* or simply the **aether.** (There is another spelling, *ether,* for this medium, but since it is also used as the name for a chemical compound, we avoid it here.) This idea of the aether brought up a question: What exactly is this medium? Light from very distant stars and galaxies reaches our eyes, so it is evidently able to propagate outside of Earth's atmosphere. This observation implies that all of space must be filled with this medium. How could this medium be detected?

If all of space were filled with aether, then Earth would have to move relative to this aether on its path around the Sun. Chapter 3 demonstrated that the motion of the medium makes a clear difference to a trajectory. For example, an airplane moving through wind has a different ground speed if it moves perpendicularly to the wind than if it moves with or against the wind. Chapter 16 showed that this same basic principle applies to the propagation of sound waves though a medium.

In the 19th century, huge efforts were made to measure the speed of light. From the point of view of science history, this quest is a fascinating story in itself. However, detecting the aether does not require knowing the precise speed of light. It only requires knowing that the motion of Earth relative to the aether would imply different speeds of light measured in the lab, depending on the direction of the light's velocity with respect to the aether. This effect is exactly what Albert Michelson and Edward Morley at the Case Institute in Cleveland, Ohio, set out to measure in 1887. They

used an ingenious device called an *interferometer* (see Chapter 34, which includes a picture of a Michelson-type interferometer).

What they found stunned the world of physics: a null result! There was no measurable difference! Light moves with exactly the same speed in every direction, and no change in motion relative to the aether could be detected.

Page 1082

Physicists struggled to explain this astounding result. Two leading theorists, Hendrik Lorentz (1853–1928) and George Fitzgerald (1851–1922), came up with the idea that objects moving through the aether become length-contracted just enough to offset the change in the speed of light with direction. It took the genius of Albert Einstein (1879–1955), however, to make the conceptual leap required for a new insight and its astounding consequences: The aether does not exist. Thinking through the fact that the speed of light is constant for all observers, independent of the observer's motion, led Einstein to the formulation of the theory of special relativity, the subject of this chapter.

Einstein's Postulates and Reference Frames

In 1905, a 26-year-old Swiss patent clerk, fresh out of a rather undistinguished university physics career, wrote three scientific articles that shook the scientific world. And what's more amazing, he did this in his spare time! These three papers were

1. A paper explaining that the *photoelectric effect* is due to the quantum nature of light. This explanation earned Einstein the 1921 Nobel Prize in Physics. We will consider this effect in Chapter 36.
2. A paper explaining that *Brownian motion*, which is the motion of very small particles in water or other solutions, is due to collisions with molecules and atoms. This result provided compelling arguments that atoms really exist. (This fact was not at all clear before Einstein's work.)
3. Finally, and most important for this chapter, a paper presenting the theory of special relativity.

Einstein stated two postulates, from which all of special relativity followed. To understand this, we first need a definition: An **inertial reference frame** is a reference frame in which an object accelerates only when a net external force is acting on it. An inertial reference frame moves with constant velocity with respect to any other inertial reference frame. A noninertial frame is a frame for which the point of origin experiences an acceleration. For example, a diver who jumps off a diving board and is in free fall is not in an inertial reference frame, because she is experiencing a net acceleration. Unless stated otherwise, the phrase *reference frame* in this chapter refers to an *inertial* reference frame. With this definition, we can state Einstein's postulates:

> Postulate 1: The laws of physics are the same in every inertial reference frame, independent of the motion of the reference frame.
>
> Postulate 2: The speed of light, c, is the same in every inertial reference frame.

The value of the speed of light is

$$c = 299{,}792{,}458\,\mathrm{m/s}. \qquad \textbf{(35.1)}$$

As was noted in Chapter 1, this value for the speed of light is the accepted exact value, because it serves as the basis for the definition of the SI unit of the meter. Handy approximate values for the speed of light are $c \approx 186,000\,\mathrm{mi/s}$, or $c \approx 1\,\mathrm{ft/ns}$ in British units, and the very commonly used $c \approx 3 \cdot 10^8\,\mathrm{m/s}$.

The first of Einstein's two postulates should not raise any objections. In its motion around the Sun, the Earth moves through space with a speed of more than $29\,\mathrm{km/s} \approx 685,000\,\mathrm{mph}$. Because the Earth orbits very nearly in a circle, the Earth's velocity vector relative to the Sun continually changes direction. However, we still expect that a physics measurement follows laws of nature that are independent of the season in which the measurement is made (neglecting minor effects due to the small accelerations of the Earth and of the Sun relative to the Milky Way).

The second postulate explains the null result that Michelson and Morley measured. However, this idea is not quite so easy to digest. Let's conduct a thought experiment: Suppose you are flying in a rocket through space with a speed of $c/2$, directly toward Earth. You shine a laser in the forward direction. The light of the laser has a speed c. Naively, and with what we know about velocity addition so far, we would expect the light of the laser to have a speed of $c + (c/2) = 1.5c$ when observed on Earth. This result is what we would predict based on the discussion of relative motion in Chapter 3.

This velocity addition, however, only works for speeds that are small relative to the speed of light. Einstein's second postulate says that the speed of light as seen on Earth is still c. Later in this chapter, we will state a rule for velocity addition that is correct for all speeds. For now, note that c is the maximum possible speed that

any object can have in any reference frame. This statement is astounding and leads to all kinds of interesting and seemingly counterintuitive consequences—all of which have nonetheless been experimentally verified. Therefore, we now know that Einstein's theory is almost certainly correct. We may never think of space and time the same way again!

Self-Test Opportunity 35.1

A light-year is the distance light travels in a year. Calculate that distance in meters.

Beta and Gamma Factors

Because the speed of light plays such an important role in relativity, we introduce two commonly used dimensionless quantities, beta and gamma, that depend only on the (constant) speed of light, c, and the velocity, $\vec{v}$, of an object:

$$\vec{\beta} = \frac{\vec{v}}{c} \tag{35.2}$$

and

$$\gamma = \frac{1}{\sqrt{1-\beta^2}} = \frac{1}{\sqrt{1-(v/c)^2}}. \tag{35.3}$$

We will use the notation $\beta \equiv \left|\vec{\beta}\right|$. Note that for $v \equiv \left|\vec{v}\right| \leq c$, equations 35.2 and 35.3 mean that $\beta \leq 1$ and $\gamma \geq 1$.

It is instructive to plot γ as a function of β (Figure 35.2). For speeds that are small compared to the speed of light, β is very small, approximately equal to zero. In that case, γ is very close to 1. However, as β approaches 1, γ *diverges*—that is, γ grows larger and larger and eventually becomes infinite when $\beta = 1$.

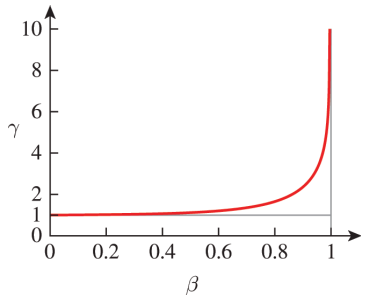

FIGURE 35.2
Dependence of γ on β.

There is a useful approximation that is valid for low speeds. In such cases, $\left|\vec{v}\right|$ is small compared to c, and therefore β is small compared to 1. By using the mathematical series expansion $(1-x)^{-1/2} = 1 + \frac{1}{2}x^2 + \frac{3}{8}x^4 + \cdots$, we can approximate γ as

$$\gamma \approx 1 + \tfrac{1}{2}\beta^2 = 1 + \tfrac{1}{2}\left(\frac{v}{c}\right)^2 \quad (\text{for } \beta \text{ small compared to } 1)$$

Self-Test Opportunity 35.2

At what fraction of the speed of light would the relativistic effect (deviation between the correct relativistic expression and its nonrelativistic approximation) be 5%? At what fraction of the speed of light would the relativistic effect be 50%?

EXAMPLE 35.1 *Apollo* Spacecraft

On its way to the Moon, the *Apollo* spacecraft reached speeds of $4.0 \cdot 10^4\,\text{km/h}$ relative to Earth, almost an order of magnitude (10 times) faster than any jet aircraft.

PROBLEM

What are the values of the relativistic factors β and γ in this case?

SOLUTION

First, convert the speed to SI units:

$$v = 4.0 \cdot 10^4\,\text{km/h} = 4.0 \cdot 10^4\,\text{km/h} \cdot (1000\,\text{m/km})/(360$$

To compute β, simply divide the spacecraft's speed by the speed of light:

$$\beta = \frac{v}{c} = \frac{1.1 \cdot 10^4\,\text{m/s}}{3.0 \cdot 10^8\,\text{m/s}} = 3.7 \cdot 10^{-5}.$$

Now substitute this result into the formula for γ and obtain

$$\gamma = \frac{1}{\sqrt{1-\beta^2}} = \frac{1}{\sqrt{1-\left(3.7 \cdot 10^{-5}\right)^2}} = 1 + 6.9 \cdot 10^{-10} =$$

From Example 35.1, you can see that almost all motion of macroscopic objects involves values of β that are very close to zero and values of γ that are very close to 1. In all such cases, as we will see throughout this chapter, it is safe to neglect the effects of

relativity and calculate the nonrelativistic approximation. However, in many interesting situations, relativity must be kept in mind. This difference is the subject of this chapter.

Light Cones

As a corollary of the two Einstein postulates, we find that nothing can propagate with a speed greater than the speed of light in vacuum. (Strictly speaking, there is the possibility that there exist particles for which the speed of light is not the *upper* but the *lower* limit to their speed. These hypothetical particles, called *tachyons,* will not be discussed any further in this book.) If nothing can propagate with a speed greater than the speed of light in vacuum, then limits exist on how events can influence each other. Two people cannot exchange signals with each other at speeds exceeding the speed of light. Therefore, instantaneous effects of events originating at one point in space on another point in space are impossible. It simply takes time for a signal or a causative influence to propagate through space.

To investigate this result, let's consider the one-dimensional case shown in Figure 35.3. An event occurs at time $t = 0$ at location $x = x_0$ (red dot). A signal that announces this event in space and time can propagate no faster than the speed of light, that is, with a velocity in the interval between $v = -c$ and $v = +c$. The tan-colored triangle in Figure 35.3 shows the region in space and time in which the event can be observed. This region is called the positive **light cone** of the event $(0, x_0)$. The blue point located at time t_1 and position x_1 is able to receive a signal that the original event has happened; however, the green point located at time t_2 and position x_2 is not able to receive such a signal. This implies that the event represented by the red dot cannot possibly have caused the event represented by the green dot in Figure 35.3. The two events, red and green, cannot be causally connected—one cannot have caused the other.

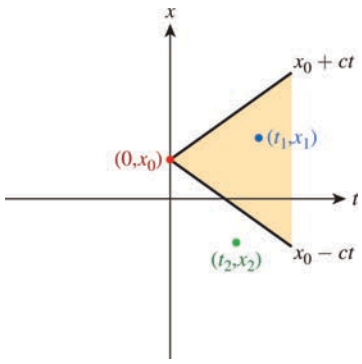

FIGURE 35.3 Light cone of a point in space.

Conversely, there is a region in the past that is able to influence the event at $(0, x_0)$. This region is the negative light cone. Figure 35.4a shows both light cones in the conventional representation with a vertical time axis. The event for which the light cone is displayed is conveniently moved to the origin of the coordinate system. Why is the light cone called a "cone" and not a "triangle"? The answer is shown in Figure 35.4b. For two space coordinates x and y, the condition $v = \sqrt{v_x^2 + v_y^2} = c$ sweeps out a cone in the $(2 + 1)$-dimensional x,y,t space. Only events inside the negative light cone can influence events at the origin, at the apex of the light cone. Conversely, only events inside the positive light cone can be influenced by the event located at the origin.

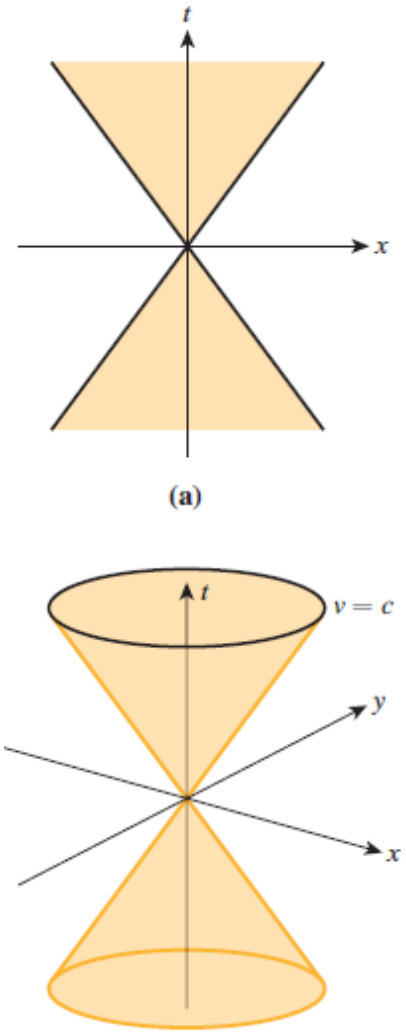

FIGURE 35.4 Conventional representation of the positive and negative light cones, with the time axis pointing vertically up. (a) $(1+1)$-dimensional space-time, (b) $(2+1)$-dimensional space-time.

Often the axes of light-cone diagrams are scaled so that they have the same units. One way to scale the axes is to multiply the

time axis by the speed of light, so that both axes have the units of length. Another method involves dividing the *x*-axis by the speed of light, so that both axes have the units of time. In this way, the speed of light becomes a diagonal line in the light-cone diagram, which is very useful for making quantitative arguments, as can be seen in the following example.

In a light-cone diagram, we can draw world lines. A **world line** is the trajectory of an object in space and time. This kind of plot is often referred to as a *graph in space-time*, reflecting how these two dimensions are intertwined in relativity theory. A typical plot containing several world lines is shown in Figure 35.5. This type of plot represents motion in only one space dimension, *x*, along with time. Let's imagine we have an object initially located at $x = 0$ and $t = 0$ in this plot. If the object is not moving in the *x*-direction, the object traces out a vertical line in this plot (arrow 1). If the object is moving in the positive *x*-direction with a constant speed, its trajectory is represented by a path pointing up and to the right (arrow 2). If the object is moving with a constant speed in the negative *x*-direction, its trajectory is depicted by a path pointing up and to the left (arrow 3). An object traveling with the speed of light in the positive *x*-direction is represented by a trajectory with a 45° angle with respect to the vertical axis (arrow 4). An object traveling with the speed of light in the negative *x*-direction is represented by a trajectory with a -45° angle with respect to the vertical axis (arrow 5).

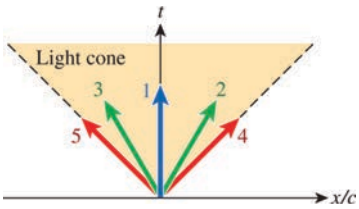

FIGURE 35.5 A graph in space-time showing a positive light cone. Object at rest: blue arrow; objects moving with the speed of light: red arrows; objects moving with a constant speed less than *c*: green arrows.

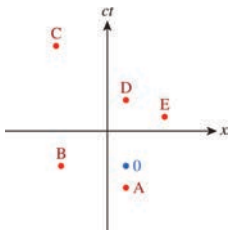
Space-Time Intervals

In Newtonian mechanics, we can easily determine the distance between two points: $\Delta r = \left|\overrightarrow{r_1} - \overrightarrow{r_2}\right| = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2}$. If two events take place at different times, then the time difference between them is $\Delta t = t_2 - t_1$. In view of the discussion of light cones and causality, we introduce the space-time interval s between two events 1 and 2. We define s as follows:

$$s^2 = c^2(\Delta t)^2 - (\Delta r)^2. \qquad \textbf{(35.5)}$$

Concept Check 35.1

An event 0 takes place at some point in space-time, as shown in the figure. Which of the five other events in space-time—A, B, C, D, and/or E—can be influenced by the event 0?



Depending on the sign of s^2, we can distinguish three types of space-time intervals—timelike intervals, lightlike intervals, and spacelike intervals:

$$\left.\begin{array}{lcll} s^2 > 0 & \Rightarrow & c^2\Delta t^2 > \Delta r^2 & \text{timelike} \\ s^2 = 0 & \Rightarrow & c^2\Delta t^2 = \Delta r^2 & \text{lightlike} \\ s^2 < 0 & \Rightarrow & c^2\Delta t^2 < \Delta r^2 & \text{spacelike} \end{array}\right\} \text{space-time interv}$$

Lightlike space-time intervals are on the surface of the light cone, timelike space-time intervals are in the interior of the light cone, and spacelike space-time intervals are on the exterior. In a timelike interval, we can define a proper time interval, $\Delta\tau$, which is the time between two events measured by an observer traveling with a clock in an inertial frame between these events, with the observer's path intersecting the world line of each event as that event occurs. This **proper time** is

$$\Delta\tau = \sqrt{\Delta t^2 - \Delta r^2/c^2}. \qquad \textbf{(35.7)}$$

Note that with the timelike condition that $s^2 > 0$, the proper time is a real number (with a time unit). The existence of timelike (or lightlike) intervals between two events means that the two events can be causally connected.

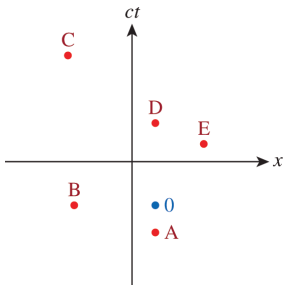
If two events are separated by a spacelike interval, then they cannot be causally connected—that is, neither of the two events can possibly trigger the other one. We can define a proper distance, $\Delta\sigma$, between two events separated by a spacelike interval,

$$\Delta\sigma = \sqrt{\Delta r^2 - c^2\Delta t^2}, \qquad \textbf{(35.8)}$$

which is a real number (with a length unit).

Concept Check 35.2

An event 0 takes place at some point in space-time, as shown in the figure. Which of the five other events in spacetime—A, B, C, D, and/or E—form a timelike space-time interval with the event 0?



35.2 Time Dilation and Length Contraction

In our everyday experience, we consider time and space as being absolute, without restriction or qualification. By “absolute,” we mean that observers in all inertial reference frames measure the same value for the length of any object or for the duration of any event. However, if we follow Einstein’s postulates to their logical conclusions, this is not the case. The concepts of nonabsolute time and space lead to conclusions that sound like science fiction, but they have been verified experimentally.

Time Dilation

One of the most remarkable consequences of the theory of relativity is that time measurement is not independent of the reference frame. Instead, time that elapses between two events in a moving reference frame where events occur at different locations is dilated (made longer) when compared to the time interval in the rest frame (where the events occur at the same location):

$$\Delta t = \gamma \Delta t_0 = \frac{\Delta t_0}{\sqrt{1 - (v/c)^2}}. \qquad \textbf{(35.9)}$$

This **time dilation** means that if a clock advances Δt_0 while at rest, an observer in motion relative to the clock sees the clock advancing by $\Delta t > \Delta t_0$. That time interval Δt depends on the speed v with which the observer is moving relative to the clock! This result is truly revolutionary. However, it has experimentally verifiable consequences, as we will see in Example 35.2.

DERIVATION 35.1 Time Dilation

How can we derive time dilation? We know that relativistic effects involve the speed of light, so let's construct a clock that keeps time by bouncing a vertical light beam off a mirror and detecting the reflection (Figure 35.6a).

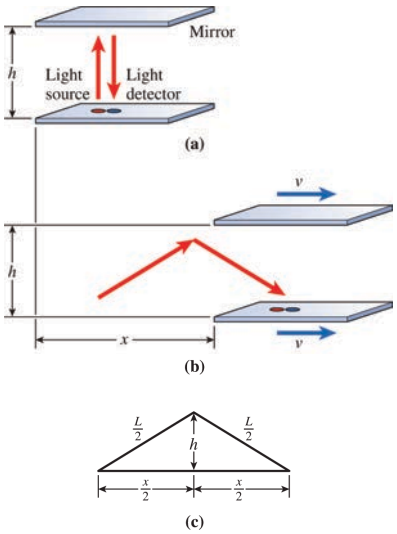


FIGURE 35.6
Measuring time in two different reference frames: (a) The mirror is at rest in this reference frame; (b) the apparatus is moving with velocity v in this reference frame. (c) Triangle formed by the reflected light in the moving reference frame.

If we know the distance h between the mirror and the light source, then the time for the beam to go up and down is

$$\Delta t_0 = \frac{2h}{c},$$

where the subscript zero refers to the fact that the observer of this time interval is not moving relative to the measurement apparatus. (It takes the same time, h/c, for the light beam to go up as for it to go down.)

Now let's have an observer move to the left with a speed v in the horizontal direction. We call this the negative x-direction, so this observer sees the clock moving in the positive x-direction with a speed v (Figure 35.6b). You can see from Figure 35.6c that in this case the observer sees the light beam as having a path length of

$$L = 2\sqrt{h^2 + (x/2)^2}, \qquad \text{(i)}$$

where x is the distance that the clock moves while the light beam is passing through the air. This result is simply a consequence of the Pythagorean Theorem. We have tacitly assumed that h is the same for observers in the two reference frames depicted in Figure 35.6. If h were not the same, then we could distinguish one reference frame from the other, in violation of Einstein's first postulate.

The moving observer would say that $x = v\Delta t$, where Δt refers now to the time interval for the light to be emitted and then detected in this observer's system. We can also use the above equation relating h and Δt_0, $h = c\Delta t_0/2$, to eliminate h.

At this point, the second postulate becomes essential. The light beams can travel only with c, the constant speed of light, which is independent of the velocity of the observer! Thus, we have the relation

$$L = c\Delta t. \qquad \text{(ii)}$$

We substitute for L from equation (ii) into equation (i) and then substitute for h and x to get

$$c\Delta t = 2\sqrt{(c\Delta t_0/2) + (v\Delta t/2)} = \sqrt{(c\Delta t_0)^2 + (v\Delta t)^2}.$$

Solving this equation for Δt, we obtain

$$\Delta t = \frac{\Delta t_0}{\sqrt{1 - (v/c)^2}} = \gamma \Delta t_0.$$

In the clock's rest frame—Figure 35.6a—the time interval is Δt_0; this quantity could represent the time between two clicks of the clock. In the frame in which the clock is moving—Figure 35.6b—the time interval between these two clicks is $\Delta t_0 = \gamma \Delta t_0 > \Delta t_0$. Thus, we say that moving clocks run slow, meaning that the time interval measured is longer when measured in any reference frame in which a clock is moving.

Because the velocity of light is independent of the speed of the observer, we had to admit that the time measured by the two observers is different. This step is remarkably bold.

Just to be clear, there is *nothing* wrong with the clocks, and there's nothing special about a moving clock. Nothing special happens to the clocks due to the high velocities. What is happening is that time itself is slowed down, according to an observer in a different reference frame. This means that everything is slowed down according to this observer, including our motion and our body clocks. We would appear to move in slow motion, and would age slower, compared to the observer in the other reference frame. It is also interesting to note that this effect is reciprocal. That is, observers in two inertial reference frames moving with respect to each other each see the other's clock running slow! But this illustrates the central idea of special relativity—there is no absolute motion; all inertial frames are equally valid for making measurements.

Finally, a remark on notation: In Section 35.1, we introduced the concept of proper time (see equation 35.7). Sometimes you will see the time measured in the rest frame of a clock referred to as *proper time*. The proper time interval used in Derivation 35.1 is Δt_0.

It is one thing to postulate and then mathematically prove the effect of time dilation. It is something else entirely to observe this effect in the laboratory or in nature. Amazingly, this has been done, as discussed in Example 35.2.

EXAMPLE 35.2 Muon Decay

A *muon* is an unstable subatomic particle with a mean lifetime, τ_0, of only 2.2 μs. This lifetime can be observed easily when muons decay at rest in the lab. However, when muons are produced in flight at very high speeds, their mean lifetime becomes time dilated. In 1977, an experiment carried out at the European CERN particle accelerator produced muons with a speed of $v = 0.9994c \Rightarrow \beta = 0.9994$. In this case, we have for γ:

$$\gamma = \frac{1}{\sqrt{1-\beta^2}} = \frac{1}{\sqrt{1-0.9994^2}} = 29.$$

Therefore, the mean lifetime, τ, of the muons is expected to be longer by a factor of $\gamma = 29$ at this speed than if they were at rest:

$$\tau = \gamma\tau_0 = 29(2.2\ \mu\text{s}) = 64\ \mu\text{s}.$$

It is quite straightforward to measure this effect by measuring the time between the production and the decay of the muons. Alternatively, you could move some distance away from the production site and see if the muons still reach you. Without the effect of time dilation, during its lifetime of 2.2 μs before it decayed, a muon with this speed could move a distance of only

$$x = v\tau_0 = (0.9994c)(2.2\ \mu\text{s}) = 660\ \text{m}.$$

However, with the effect of time dilation, the distance traveled becomes

$$x = v\tau = v\gamma\tau_0 = (0.9994c)\ 29(2.2\ \mu\text{s}) = 19\ \text{km}.$$

To do this experiment, you just need to see how far away from the muon's production site you can detect the decay products. The CERN experiment verified the relativity prediction of time dilation. This measurement shows that time dilation is indeed a

real effect. Particles live longer the faster they move. (However, they live the usual time according to clocks in their rest frame.) In fact, giant particle accelerators still in development will collide muons. For these accelerators, muons need to be transported over distances of many kilometers. The fact that these muon colliders are possible at all is due to the effect of time dilation.

Do relativistic effects relate only to subatomic particles and have no relevance for macroscopic objects? No. In 1971, scientists flew four extremely precise atomic clocks around the Earth, once in each direction. They observed that the clocks flying eastward lost 59 ± 10 ns, while the clocks flying westward gained 275 ± 21 ns, compared to a ground-based atomic clock. Thus, the effect of time dilation was confirmed by this experiment with macroscopic clocks. Of course, the effect was incredibly small because the speed of an airliner is small compared with the speed of light. The clocks lost 59 ns and gained 275 ns in 3 days (259, 200 s), a few parts per trillion. The quantitative explanation of this time-dilation experiment also involves general relativity. But this is not the point we want to make here. The main point is that this experiment produced a measurable effect, and not a zero effect, as we would expect in the absence of time dilation. The basic fact that this experiment proves is that time can no longer be considered an absolute quantity.

Concept Check 35.3

A clock on a spaceship shows that a time interval of 1.00 s has expired. If this clock is moving with a speed of 0.860*c* relative to a stationary observer, what time period has expired in the reference frame of the stationary observer?

a) 0.860 s

b) 1.00 s

c) 1.25 s

d) 1.77 s

e) 1.96 s

Length Contraction

Relativity implies not only that time is variant and dilated as a function of speed, but also that length is not invariant. The length L of an object moving with speed v shows a **length contraction** relative to its length in its own rest frame, called its **proper length** L_0. We find that

$$L = \frac{L_0}{\gamma} = L_0\sqrt{1 - (v/c)^2}. \qquad \textbf{(35.10)}$$

DERIVATION 35.2 Length Contraction

Imagine that you want to measure the length of a space shuttle (Figure 35.7) that has a speed v in your reference frame and a proper length L_0. The way to measure the length without using a meter stick is simple: You can hook up a laser beam to a clock fixed in the laboratory. When the tip of the shuttle breaks the laser beam, it starts the clock, and when the end of the shuttle passes that same point and the laser beam is not blocked anymore, the clock stops. This time interval is Δt_0, or the proper time, and thus $L = v\Delta t_0$.

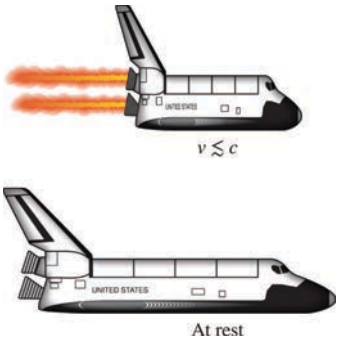

FIGURE 35.7 Illustration of length contraction (not to scale!).

Inside the shuttle, using a clock fixed to the inside, the measured time during which the laser beam is blocked by the shuttle is $\Delta t = \gamma \Delta t_0$ because of time dilation. Thus, an astronaut inside the shuttle observes that a moving clock with speed v emitted light when passing the shuttle's tip and once again (Δt later) when passing the tail and deduces that $L_0 = v\Delta t = v\gamma\Delta t_0$. Thus, we have

$$\frac{L}{L_0} = \frac{v\Delta t_0}{v\gamma\Delta t_0} \quad \text{or} \quad L = \frac{L_0}{\gamma}.$$

Note that for this thought experiment, it is essential that the length measured is *along the direction of motion*. All lengths

perpendicular to the direction of motion remain the same (see Figure 35.7).

Concept Check 35.4

State whether each of the following statements is true or false.

a) For a moving object, its length along the direction of motion is shorter than when it is at rest.

b) When you are stationary, a clock moving past you at a significant fraction of the speed of light seems to run faster than the watch on your wrist.

c) When you are moving with a speed that is a significant fraction of the speed of light and you pass by a stationary observer, you observe that your watch seems to be running faster than the watch of the stationary observer.

As you can see from Derivations 35.1 and 35.2, the phenomena of time dilation and length contraction are quite intimately related. The speed of light being constant for all observers implies time dilation, which has been experimentally confirmed many times. Time dilation, in turn, implies length contraction.

The essential fact to remember about length contraction is that moving objects are shorter. They don't just appear shorter—they *are* shorter as measured by an observer in the frame in which the object is moving. This contraction is another mind-bending consequence of the postulates of special relativity.

EXAMPLE 35.3 Length Contraction of a NASCAR Race Car

You see a NASCAR race car (Figure 35.8) go by at a constant speed of $v = 89.4\,\text{m/s}$ (200 mph). When stopped in the pits, the race car has a length of 5.232 m.

FIGURE 35.8 A NASCAR race car.

U.S. Air Force photo by Master Sgt Michael A. Kaplan

PROBLEM

What is the change in length of the NASCAR race car from your reference frame in the grandstands? Assume that the car is moving perpendicular to your line of sight.

SOLUTION

The length of the race car will be contracted because of its motion. The proper length of the race car is $L_0 = 5.232\,\text{m}$. The length in your reference frame is given by equation 35.10:

$$L = \frac{L_0}{\gamma} = L_0\sqrt{1-(v/c)^2} \approx L_0\left(1-\frac{1}{2}\left(\frac{v}{c}\right)^2\right) = L_0 -$$

where the change in the length of the race car is

$$\Delta L = L_0\frac{1}{2}\left(\frac{v}{c}\right)^2.$$

Here we have applied a series expansion, $\left(1-x^2\right)^{1/2} = 1 - \frac{1}{2}x^2 + \cdots$, as we did in equation 35.4. The car's speed is small compared with the speed of light, so $v/c \ll 1$ and our expansion is well justified. Thus, the race car is shorter by

$$\Delta L = L_0 \frac{1}{2}\left(\frac{v}{c}\right)^2 = \frac{5.232\,\text{m}}{2}\left(\frac{89.4\,\text{m/s}}{3.00 \cdot 10^8\,\text{m/s}}\right) = 2.32 \cdot$$

The car's change in length is smaller than the diameter of a typical atom. So, the length contraction of objects moving at everyday speeds is not noticeable.

Twin Paradox

We have seen that a time interval (say, between clock ticks) depends on the speed of the object (say, a clock) in the frame of an observer, $\Delta t = \gamma \Delta t_0$. Let's perform a little thought experiment:

Astronaut Alice has a twin brother, Bob. At the age of 20, Alice boards a spaceship that flies to a space station 3.25 light-years away from Earth and then returns. The spaceship is a good one and can fly with a speed of 65.0% of the speed of light, resulting in a gamma factor of $\gamma = 1.32$. In Bob's reference frame, the total distance traveled by Alice is $2(3.25 \text{ light-years}) = 6.50$ light-years.

In Alice's reference frame, she travels a distance of $d = 6.50 \text{ light-years}/\gamma = 4.92$ light-years, light-years, because the distance between Earth and the space station is length-contracted in her reference frame. Thus, the time it takes Alice to complete the trip is

$$t = d/v = (4.92c \cdot \text{years})/0.650c = 7.57 \text{ years}.$$

While the entire trip back and forth takes Alice 7.6 years in Alice's reference frame, time dilation means that $7.6\gamma = 10.0$ years pass in Bob's reference frame. Therefore, when Alice steps out of the spaceship after her trip, she will be 27.6 years old, whereas Bob will be 30.0 years old.

Now we can put ourselves into the reference frame of Alice: In Alice's frame, she was at rest and Bob was moving at 65.0% of the speed of light. Therefore, Alice should have aged 1.32 times more than Bob aged. Because Alice knows that she has aged 7.57 years, she expects her brother Bob to be only $20 + 7.57/1.32 = 25.8$ years old when they meet again. Both siblings cannot be younger than each other. This apparent inconsistency is called the *twin paradox*. Which of these two views is right?

The apparent paradox is resolved when we realize that although Bob remains in an inertial reference frame at rest on the Earth for the duration, astronaut Alice lives in two different inertial frames during her round-trip. During the outbound leg, she is moving away from Earth and toward the distant space station. When she reaches the space station, she turns around and travels with a

constant speed back from the space station to Earth. Thus, the symmetry is broken between the two twins.

We can analyze the paths of the two twins in space-time using the techniques of light cones and world lines, plotting time in an inertial rest frame versus the positions of both twins in one direction, the x-direction. We analyze the problem from both the point of view of Bob and the point of view of Alice. We start by analyzing the trip in the rest frame of stay-at-home twin Bob, as shown in Figure 35.9, where the axes are scaled so that the units for both are years.

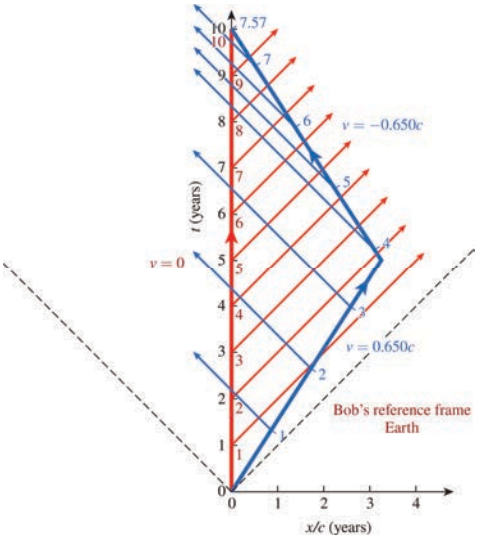

FIGURE 35.9 Plot showing the velocity of the two twins in Bob's reference frame, which is at rest on Earth. The thick, vertical red line represents Bob's trajectory. The two thick blue lines depict Alice's trajectory. Thin red lines labeled by red numbers (corresponding to the years since Alice left) represent Bob's birthday messages. Thin blue lines labeled by blue numbers (also corresponding to the years since Alice left) depict Alice's birthday messages. The dashed lines show the light cone at $t = 0$.

In Figure 35.9, Bob's speed is always zero and he remains at $x = 0$. A red vertical line represents Bob's trajectory. In contrast, Alice is initially moving with a speed of 65.0% of the speed of light ($v = 0.650c$) away from Earth. A blue line labeled $v = 0.650c$ depicts Alice's outbound trajectory. We define the positive x-

direction as pointing from the Earth to the distant space station. Each twin wants to keep in touch with the other. Thus, each twin sends an electronic birthday card to the other twin on their birthday in each one's reference frame. These messages travel with the speed of light. Bob sends his electronic message directly toward the space station, and Alice sends her electronic greeting directly back toward Earth. Bob's messages are shown as red arrows pointing up and to the right. Alice's messages are shown as blue arrows pointing up and to the left. When the message arrows cross the trajectory of one of the twins, that twin receives and enjoys an electronic birthday card.

After 5 years pass in Bob's frame and 3.79 years pass in Alice's frame, Alice reaches the space station and turns for home. Bob is getting a little worried by now because he has received only two birthday cards in 5 years. Alice is not feeling much better, since she has received only one message in 3.79 years. After Alice turns around, she receives eight electronic birthday cards in the next 3.79 years. Bob receives five more greetings in the remaining 5 years. When Alice arrives back home on Earth, she gets a firsthand 30th birthday greeting from Bob, but Alice is not ready to celebrate her 28th birthday yet. Alice's age is 27.6 years. Alice received a total of ten birthday greetings while Bob received only seven.

Now let's analyze the same trip from the inertial rest frame corresponding to Alice's outbound leg (Figure 35.10) to show that we can get the same answer from Alice's point of view. In this reference frame, Bob and Earth are both traveling in the negative x-direction with a velocity $v = -0.650c$. During the outbound portion of the trip, Alice's velocity is zero in her reference frame. The space station is traveling toward Alice with a speed of 65.0% of the speed of light, so the distance of 3.25 light-years is covered in 3.79 years because of length contraction. Note that this part of the two diagrams in Figure 35.9 and Figure 35.10 is completely symmetric.

When the space station reaches Alice, the symmetry in the two representations of Figures 35.9 and 35.10 is broken. Alice begins to

travel with a speed fast enough to catch up with Earth in the negative x-direction. To establish a relative speed of 65.0% of the speed of light with respect to Earth, Alice must travel with a speed of 91.4% of the speed of light. (This relativistic addition of velocities is discussed in Section 35.3.)

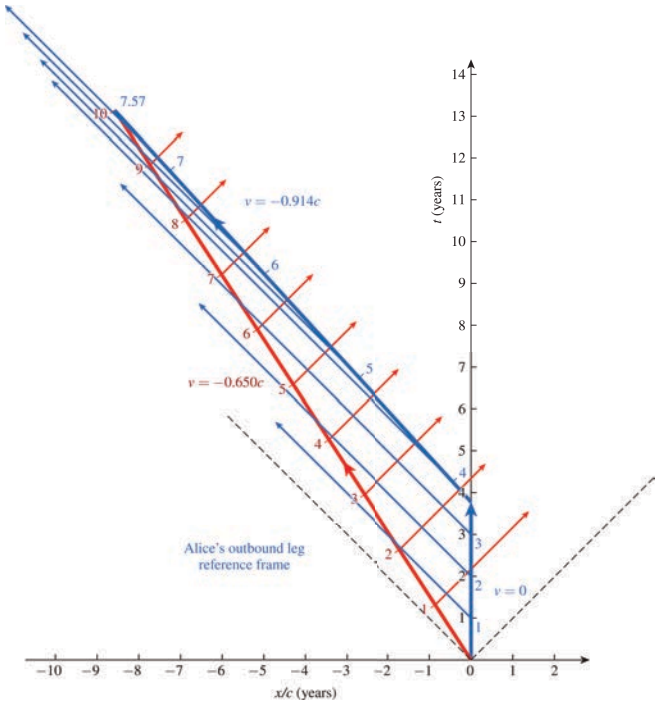

FIGURE 35.10 Plot showing the velocity of the two twins in the reference frame of Alice's outbound leg. The thick red line represents Bob's trajectory. The two thick blue lines depict Alice's trajectory. Thin red lines labeled by red numbers (corresponding to the years since Alice left) represent Bob's birthday messages. Thin blue lines labeled by blue numbers (corresponding to the years since Alice left) depict Alice's birthday messages. The dashed lines represent the light cone at $t = 0$.

Again Bob receives two birthday greetings in the first 5 years in his reference frame, while Alice again receives one birthday greeting before she starts moving toward Earth. As Alice streaks for Earth at a speed of 0.914*c*, she receives eight birthday greetings, while Bob again receives five. When the twins are reunited on Earth, Bob is 30.0 years old and Alice is 27.6 years old. This result using Alice's outbound reference frame is the same as the one we obtained using Bob's reference frame. Thus, the twin paradox is resolved.

Concept Check 35.5

The nearest star to us other than the Sun is Proxima Centauri, which is 4.22 light-years away. Suppose a spaceship could travel at a speed of 90.0% of the speed of light. If you were in that spaceship, how long would it take you to travel from the Sun to Proxima Centauri, from your point of view?

a) 2.04 years

b) 2.29 years

c) 3.42 years

d) 3.80 years

e) 4.22 years

Note that we analyzed the twin paradox in terms of special relativity only. You might worry about the parts of Alice's journey that involved acceleration. Alice had to accelerate to 65.0% of the speed of light to begin her journey to the space station, and then she had to slow down, stop, and reaccelerate to a speed of 65.0% of the speed of light to return to Earth. Even at a constant acceleration of three times the acceleration of gravity, it would take almost 3 months to reach a speed of 65.0% of the speed of light from rest and the same amount of time to stop, starting at a speed of 65.0% of the speed of light. However, we could postulate various

scenarios to remove these objections or at least minimize their importance. For example, we could simply make the trip longer, making the acceleration phase negligible. Acceleration is necessary to explain the twin paradox because Alice must reverse her course to return to Earth, changing her inertial reference frame. However, the effects of general relativity are not needed to explain the twin paradox.

Relativistic Frequency Shift

If time is not invariant, then quantities that depend explicitly on time may also be expected to change as a function of an object's velocity. The frequency f is one such quantity.

In Chapter 16, we discussed the Doppler effect for sound waves—the change in sound's frequency due to the relative motion between observer, source, and medium. We have seen, however, that light does not need a medium in which to propagate. Therefore, the **relativistic frequency shift** is only remotely connected to the Doppler effect. (However, it is often informally referred to as *the relativistic Doppler effect* or the *Doppler effect for electromagnetic radiation*.) If v is the relative velocity between source and observer and the relative motion occurs in a radial direction (source and observer are moving either directly toward each other or directly away from each other), then the formula for the observed frequency, f, of light with a given frequency f_0 is

$$f = f_0\sqrt{\frac{c \mp v}{c \pm v}}, \qquad \textbf{(35.11)}$$

where the upper signs (– in the numerator and + in the denominator) are used for motion away from each other and the lower signs (+ in the numerator and – in the denominator) for motion toward each other. (A transverse Doppler shift also occurs, purely due to time-dilation effects, but we will not consider this effect here.)

Because the relationship $c = \lambda f$ between speed, wavelength, and frequency is still valid, we get for the wavelength:

$$\lambda = \lambda_0\sqrt{\frac{c \pm v}{c \mp v}}. \qquad \textbf{(35.12)}$$

When looking out through our telescopes into the universe, we find that just about all galaxies send light toward us that is **red-**

shifted, meaning $\lambda > \lambda_0$ (red is the visible color with the longest wavelength). This means that these galaxies have $v > 0$; that is, they are moving away from us. (If an object is moving toward us, then $\lambda < \lambda_0$ and the light is said to be **blue-shifted.**) In addition, astoundingly, the farther away galaxies are from us, the more they are red-shifted. This observation is clear evidence for an ever-expanding universe.

Often astronomers quote a **red-shift parameter,** also referred to as just the *red-shift*. This quantity is defined as the ratio of the shift in the wavelength of light divided by the wavelength of that light as observed when the source is at rest:

$$z = \frac{\Delta\lambda}{\lambda_0} = \frac{\lambda - \lambda_0}{\lambda_0} = \sqrt{\frac{c \pm v}{c \mp v}} - 1. \qquad \textbf{(35.13)}$$

Concept Check 35.6

Which of the following statements about the red-shift parameter is (are) true?

a) The red-shift is always positive.

b) The red-shift depends on the wavelength of the light.

c) The red-shift depends on the frequency of the light.

d) The red-shift is always less than 1.

e) The red-shift depends on how fast the light is moving.

SOLVED PROBLEM 35.1 Galactic Red-Shift

In March 2021, the most distant galaxy from Earth, GN-x11, was shown to have a red-shift of $z = 10.957$. using the Keck I telescope at the Maunakea Observatory in Hawaii.

PROBLEM

With what speed is the galaxy GN-x11 moving away from us?

SOLUTION

THINK

The red-shift is a function of the speed v with which the galaxy moves away from us. We can solve equation 35.13 for the speed in terms of the red-shift.

SKETCH

Figure 35.11 shows a sketch of the galaxy moving away from Earth (not to scale).

FIGURE 35.11 A galaxy moving away from Earth (not to scale).

RESEARCH

We start with equation 35.13, relating the red-shift, z, to the speed v with which the galaxy is moving away from us:

$$z = \sqrt{\frac{c+v}{c-v}} - 1.$$

We can rearrange this equation to get

$$\begin{aligned}(z+1)^2 &= \frac{c+v}{c-v} \\ c(z+1)^2 - v(z+1)^2 &= c+v.\end{aligned}$$

Gathering the multiplicative factors of v on one side and those of c on the other side, we get

$$v + v(z+1)^2 = c(z+1)^2 - c.$$

SIMPLIFY

We can now write an expression for the speed of the galaxy moving away from us in terms of the speed of light:

$$\frac{v}{c} = \frac{(z+1)^2 - 1}{(z+1)^2 + 1}.$$

CALCULATE

Putting in the numerical values gives us

$$\frac{v}{c} = \frac{(10.957+1)^2 - 1}{(10.957+1)^2 + 1} = 0.986108202.$$

ROUND

We report our result to five significant figures:

$$\frac{v}{c} = 0.98611.$$

DOUBLE-CHECK

A galaxy moving away from us with a velocity of 98.611% of the speed of light seems reasonable (at least it does not exceed the speed of light). It makes sense that the most distant galaxy from us would be moving away from us at a very high speed.

35.3 Lorentz Transformation

In studying time dilation and length contraction, we have seen how time and space intervals can be transformed from one inertial reference frame to another. These transformations of time and space can be combined in going from one reference frame into another that moves with speed v relative to the first one.

To be specific, suppose we have two reference frames, F (with coordinate system x, y, z and time t) and F' (with coordinate system x', y', z' and time t'), which are at the same point $x = x', y = y', z = z'$ (this arrangement can always be accomplished by a simple shift in the location of the origin of the coordinate systems) at the same time $t = t' = 0$, and moving with velocity v relative to each other along the x-axis. We want to know how to describe an event in frame F' (which is some occurrence, like a firecracker explosion) that has coordinates x, y, z and is happening at time t as observed in frame F, using coordinates x', y', z' and time t' (Figure 35.12).

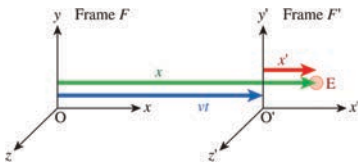

FIGURE 35.12 The Lorentz transformation connects two reference frames moving at a constant velocity v relative to one another.

Nonrelativistically, this transformation is given by

$$\begin{aligned} x' &= x - vt \\ y' &= y \\ z' &= z \\ t' &= t. \end{aligned} \tag{35.14}$$

This transformation is known as the **Galilean transformation,** which we encountered in Chapter 3 when discussing motion in two and three dimensions. These equations are correct as long as v is small compared to c. Before we considered time dilation, the last one of these equations would have seemed utterly trivial. Now this is no longer the case.

The transformation that is valid for all velocities of magnitude v is called the **Lorentz transformation,** first given by the Dutch physicist Hendrik Lorentz (1853–1928):

$$\begin{aligned} x' &= \gamma(x - vt) \\ y' &= y \\ z' &= z \\ t' &= \gamma\big(t - vx/c^2\big). \end{aligned} \tag{35.15}$$

We can also construct the inverse transformation:

$$\begin{aligned} x &= \gamma(x' + vt') \\ y &= y' \\ z &= z' \\ t &= \gamma\big(t' + vx'/c^2\big). \end{aligned} \tag{35.16}$$

In the limit of small speeds ($\gamma = 1, \beta = v/c = 0$), the Galilean transformation follows from the Lorentz transformation as a special case, as can be easily seen. However, for speeds that are not

small compared to the speed of light, the Lorentz transformation includes the effects of both time dilation and length contraction.

DERIVATION 35.3 Lorentz Transformation

There is an ongoing discussion on what constitutes the "simplest" derivation of the Lorentz transformation. Here we follow the paper by J.-M. Lévy, who published this derivation in the *American Journal of Physics,* Vol. 75, No. 7 (2007), pp. 615–618. In this derivation, we make use of the fact that we have already derived the effect of length contraction (Derivation 35.2).

Let's look at Figure 35.12. Assume that $y = y' = 0$, $z = z' = 0$ and consider the event E in frame F (with coordinate system x, y, z and time t). The green arrow of length x marks the position vector of the event E relative to the origin O of frame F. We can use simple vector addition and find that the green arrow, $\overrightarrow{\mathrm{OE}}$, is the vector sum

$$\overrightarrow{\mathrm{OE}} = \overrightarrow{\mathrm{OO'}} + \overrightarrow{\mathrm{O'E}}, \qquad \text{(i)}$$

where $\overrightarrow{\mathrm{OO'}}$ is the displacement vector of the origin of frame F' relative to the origin of F, and $\overrightarrow{\mathrm{O'E}}$ is the displacement vector from the origin of F' to event E. This vector addition equation (i) is valid independent of the frame in which we are evaluating our results, and now all we need to do is to express equation (i) in both frames.

First, let's evaluate equation (i) in frame F, where the length of the vector $\overrightarrow{\mathrm{OE}}$ is simply x and the length of the vector $\overrightarrow{\mathrm{OO'}}$ is vt. Because x' is measured in frame F', expressing it in frame F results in length contraction; that is, in frame F, the length of the vector $\overrightarrow{\mathrm{O'E}}$ can be expressed as x'/γ. This means that in frame F we obtain the following for equation (i):

$$x = vt + x'/\gamma. \qquad \text{(ii)}$$

Now let's perform the same task in frame F' (with coordinate system x', y', z' and time t'). In this frame, we find that the length of $\overrightarrow{\mathrm{O'E}}$ is x' and the length of $\overrightarrow{\mathrm{OO'}}$ is vt' But frame F is moving relative to the rest frame, F', and therefore, in frame F', x is length-contracted. Thus, the length of $\overrightarrow{\mathrm{OE}}$ is x/γ in frame F'. Consequently, in F', we evaluate equation (i) as

$$x/\gamma = vt' + x'. \qquad \text{(iii)}$$

Now all that is left are some algebraic manipulations. First, we subtract vt from both sides of equation (ii) and then multiply both sides by γ, resulting in

$$\gamma(x - vt) = x', \qquad \text{(iv)}$$

which is the first equation of the Lorentz transformation (equation 35.15). Multiplying both sides of equation (iii) by γ gives us the first equation of the inverse Lorentz transformation (equation 35.16),

$$x = \gamma\big(x' + vt'\big). \qquad \text{(v)}$$

If we insert the expression for x' from equation (iv) into (v), we find

$$x = \gamma(\gamma(x - vt) + vt') = \gamma^2(x - vt) + \gamma vt' \Rightarrow$$
$$x/\gamma^2 = x - vt + vt'/\gamma \Rightarrow$$
$$-\left(1 - \gamma^{-2}\right)x = -vt + vt'/\gamma.$$

Since $\gamma = 1/\sqrt{1 - v^2/c^2}$, it follows that $\gamma^2 = 1/\left(1 - v^2/c^2\right)$ and therefore $1 - \gamma^{-2} = v^2/c^2$. This leads to

$$-xv^2/c^2 = -vt + vt'/\gamma$$
$$-xv/c^2 = -t + t'/\gamma$$
$$\gamma\left(t - xv/c^2\right) = t',$$

which we recognize as the last equation in the Lorentz transformation (equation 35.15).

Self-Test Opportunity 35.3

By inserting the expression for *x* from equation (v) in Derivation 35.3 into equation (iv), one is able to derive the equation $t = \gamma\left(t' + vx'/c^2\right)$. Can you show this?

Concept Check 35.7

Which of the following are invariants under the nonrelativistic Galilean transformation of equation 35.14?

a) *x*

b) *y*

c) *z*

d) *t*

Invariants

Under a Lorentz transformation between inertial frames, the coordinate along the direction of relative motion of the two inertial frames (chosen to be the *x*-coordinate here) changes, as does the time. The two coordinates perpendicular to the velocity vector of the relative motion (chosen to be the *y*- and *z*-coordinates here) remain the same in both frames. They are **invariants** under the Lorentz transformation.

What other, if any, kinematical invariants can one construct? At this point, we will not attempt to be exhaustive but will focus on one, which was introduced earlier. This invariant is the space-time interval of equation 35.5, $s^2 = c^2\Delta t^2 - \Delta r^2$.

DERIVATION 35.4 Lorentz-Invariance of Space-Time Intervals

We need to show that the space-time interval is the same in different inertial frames, that is, that $s^2 = s'^2$. Since we have an expression for s^2 in terms of the coordinates and we know how the coordinates transform under a Lorentz transformation, we can construct our proof:

$$\begin{aligned} s'^2 &= c^2\Delta t'^2 - \Delta r'^2 \\ &= c^2\Delta t'^2 - \Delta x'^2 - \Delta y'^2 - \Delta z'^2 \\ &= c^2\gamma^2\left(\Delta t - v\Delta x/c^2\right)^2 - \gamma^2(\Delta x - v\Delta t)^2 - \Delta y^2 - \\ &= c^2\gamma^2\left(\Delta t^2 - 2v\Delta x\Delta t/c^2 + v^2\Delta x^2/c^4\right) - \gamma^2\left(\Delta x^2 - \right. \end{aligned}$$

In the second step, we simply replaced $\Delta r'^2$ by the sum of the squares of the components. In the third step, we applied the Lorentz transformation to each coordinate interval, and in the fourth step, we evaluated the squared terms. Now we can carry out the multiplications and then cancel the underlined terms:

$$\begin{aligned} s'^2 &= c^2\gamma^2\Delta t^2 \underline{-2v\gamma^2\Delta x\Delta t} + v^2\gamma^2\Delta x^2/c^2 - \gamma^2\Delta x^2 \\ &= c^2\gamma^2\Delta t^2 + v^2\gamma^2\Delta x^2/c^2 - \gamma^2\Delta x^2 - v^2\gamma^2\Delta t^2 - \\ &= c^2\Delta t^2\left(\gamma^2 - v^2\gamma^2/c^2\right) - \Delta x^2\left(\gamma^2 - v^2\gamma^2/c^2\right) - \end{aligned}$$

Now we need to evaluate the expression in parentheses in the last line of equation (i):

$$\gamma^2 - v^2\gamma^2/c^2 = \frac{1}{1 - v^2/c^2} - \frac{v^2/c^2}{1 - v^2/c^2} = \frac{1 - v^2/c^2}{1 - v^2/c^2} =$$

Using this identity, we find for the space-time interval:

$$\begin{aligned} s'^2 &= c^2\Delta t^2 \underbrace{\left(\gamma^2 - v^2\gamma^2/c^2\right)}_{1} - \Delta x^2 \underbrace{\left(\gamma^2 - v^2\gamma^2/c^2\right)}_{1} - \Delta \\ &= c^2\Delta t^2 - \Delta x^2 - \Delta y^2 - \Delta z^2 \\ &= c^2\Delta t^2 - \Delta r^2 \\ &= s^2. \end{aligned}$$

We find indeed that $s^2 = s'^2$, meaning that the space-time interval is invariant under Lorentz transformation.

Other invariants are introduced below.

Relativistic Velocity Transformation

Let's return to the problem we touched on in Section 35.1. Suppose you are flying in a rocket through space with a speed of $c/2$ directly toward Earth, and you shine a laser in the forward direction. Naively, you might expect that the light of the laser would have a speed of $c + (c/2) = 1.5c$ when observed on Earth. This observation would follow from the velocity-addition formula in Chapter 3, $\overrightarrow{v}_{\text{pg}} = \overrightarrow{v}_{\text{ps}} + \overrightarrow{v}_{\text{sg}}$, where the subscripts p, g, and s refer to the projectile (light, in this case), the ground, and the spaceship. However, according to Einstein, the light of the laser has a speed c in either the rocket's or the Earth's reference frame.

Because the result using the nonrelativistic velocity-addition formula contradicts the postulate that no speed is greater than c, we clearly need a new formula to add velocities correctly. We will restrict the use of **relativistic velocity addition** to one-dimensional motion of the two frames relative to each other in the positive or negative x-directions. If the velocity of an object has a value of $\overrightarrow{u} = (u_x, u_y, u_z)$ in frame F, and if frame F' moves with velocity $\overrightarrow{v} = (v, 0, 0)$ relative to frame F, then the velocity $\overrightarrow{u} = (u_x, u_y, u_z)$ of that object in frame F' has the value given by

$$\begin{aligned} u'_x &= \frac{u_x - v}{1 - \dfrac{vu_x}{c^2}} \\ u'_y &= \frac{u_y/\gamma}{1 - \dfrac{vu_x}{c^2}} \\ u'_z &= \frac{u_z/\gamma}{1 - \dfrac{vu_x}{c^2}}. \end{aligned} \qquad \textbf{(35.17)}$$

The inverse transformation from frame F' to frame F is given by

$$
\begin{aligned}
u_x &= \frac{u'_x + v}{1 + \dfrac{vu'_x}{c^2}} \\
u_y &= \frac{u'_y/\gamma}{1 - \dfrac{vu'_x}{c^2}} \\
u_z &= \frac{u'_z/\gamma}{1 - \dfrac{vu'_x}{c^2}}.
\end{aligned}
\qquad \textbf{(35.18)}
$$

We have restricted all motion to the positive and negative x-directions, just as was done to arrive at the formula for the Lorentz transformation. However, $\overrightarrow{u}$, $\overrightarrow{u'}$, and $\overrightarrow{v}$ are all vectors and can have positive and negative values, depending on the particular situation to which these transformation equations are applied. In addition, these formulas can also be used to add and subtract two velocities appropriately.

DERIVATION 35.5 Velocity Transformation

To see how a velocity transforms from one frame to another, we can start with the Lorentz transformation, which tells us how spatial and time coordinates transform. Then we can take the time derivative of the x-coordinate, which gives us the velocity component in the direction of the relative motion of the two frames with respect to each other (we call this velocity u, because we have already used the symbol v for the velocity of the frames relative to each other):

$$u'_x = \frac{dx'}{dt'} = \frac{\gamma(dx - vdt)}{\gamma(dt - vdx/c^2)}.$$

All we have done up to this point is to express the differentials dx' and dt' in the frame F, with the aid of the Lorentz transformation of equations 35.15. Now we cancel out the factor γ in the numerator and denominator and find

$$u'_x = \frac{dx - vdt}{dt - vdx/c^2} = \frac{\dfrac{dx}{dt} - v}{1 - \dfrac{v}{c^2}\dfrac{dx}{dt}}.$$

Substituting from $u_x = dx/dt$, we then get the velocity transformation for the longitudinal component (the component along the direction of the relative motion between the two frames):

$$u'_x = \frac{u_x - v}{1 - \dfrac{vu_x}{c^2}}.$$

Now we can conduct a similar exercise for the transverse components, that is, the components of the velocity vector perpendicular to the direction of relative motion between the

two frames. We show this explicitly for the y-direction, but the z-direction is found using the same arguments. Again we take the derivative and Lorentz-transform the differentials, recognizing that $dy' = dy$:

$$u'_y = \frac{dy'}{dt'} = \frac{dy}{\gamma(dt - vdx/c^2)}.$$

Dividing the numerator and denominator by dt then leads to the desired result:

$$u'_y = \frac{\dfrac{dy}{dt}}{\gamma\left(1 - \dfrac{v}{c^2}\dfrac{dx}{dt}\right)} \underset{\leftarrow}{=} \frac{u_y/\gamma}{1 - \dfrac{vu_x}{c^2}}.$$

Self-Test Opportunity 35.4

Start with $u_x = dx/dt$, use the inverse Lorentz transformation, and show that you arrive at

$$u_x = \frac{u'_x + v}{1 + \dfrac{vu'_x}{c^2}}.$$

Note that in the limit when the speeds are small compared to the speed of light, $|v| \ll c$ and $|u| \ll c$, the term vu_x/c^2 in the denominator of the velocity transformation equation becomes small compared to 1, and γ approaches 1, so equations 35.17 and 35.18 approach the nonrelativistic limit of $u'_x = u_x - v$ and $u_x = u'_x + v$, $u'_y = u_y$, and $u'_z = u_z$.

Back to our example: Now you can see that $u' = c$ "plus" $v = c/2$ does not yield 1.5c, but instead

$$u = \frac{u' + c/2}{1 + \dfrac{u'c/2}{c^2}} = \frac{c + c/2}{1 + \dfrac{cc/2}{c^2}} = c.$$

Therefore this analysis works out just right: The speed of light is the same in every reference frame! Thus, equations 35.17 and 35.18 have the proper nonrelativistic limit and at the same time satisfy the postulates of special relativity.

SOLVED PROBLEM 35.2 Particles in an Accelerator

Suppose you have an electron and an alpha particle (nucleus of a helium atom) moving through a piece of beam pipe inside a particle accelerator. The particles are traveling in the same direction. The speed of the electron is 0.830*c*, and the speed of the alpha particle is 0.750*c*, both measured by a stationary observer in the lab.

PROBLEM

What is the speed of the alpha particle as observed from the electron, in terms of the speed of light?

SOLUTION

THINK

The electron is overtaking the alpha particle, because it is faster, as measured by the stationary observer in the lab. One could be tempted to make constructions of the kind $\vec{v}_1 - \vec{v}_2$. However, since we now have the relativistic velocity transformation, it is far easier to cast this problem in this way. Assume that all given velocities occur in the positive x-direction. All we need to do is to be careful which velocities we identify as v, u_x, and u'_x. We can then use equation 35.17 or equation 35.18 to find our answer.

SKETCH

Figure 35.13 is a sketch of the electron passing the alpha particle.

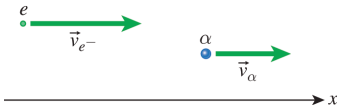

FIGURE 35.13
Electron moving past an alpha particle.

RESEARCH

We have two reference frames, our original frame F with origin on Earth and frame F' with origin on the electron, moving with constant velocity v relative to the lab.

Finding the velocity u'_x of the alpha particle in the frame of the electron involves the relativistic transformation of velocities, where the velocity u_x of the alpha particle in the lab's frame is already known. We can then use equation 35.17 to accomplish our goal of finding

$$u'_x = \frac{u_x - v}{1 - \dfrac{vu_x}{c^2}}.$$

SIMPLIFY

There is not much to simplify in this case. Most of the work here was in defining which quantity is measured in which frame and identifying the correct relative velocity of the frames.

CALCULATE

Putting in the numerical values gives us

$$u'_x = \frac{u_x - v}{1 - \dfrac{vu_x}{c^2}} = \frac{0.750c - 0.830c}{1 - \dfrac{(0.830c)(0.750c)}{c^2}} = -0.2119205$$

ROUND

We report the result to three significant figures:

$$u'_x = -0.212c.$$

DOUBLE-CHECK

The negative sign for the velocity of the alpha particle as seen by the electron makes sense because the alpha particle would be seen to be approaching the electron in the negative x-direction. If we calculate the relative velocity between the electron and the alpha particle nonrelativistically, we obtain

$$v_{\text{rel}} = v_{\text{alpha}} - v_{\text{electron}} = 0.750c - 0.830c = -0.080c.$$

Looking at our solution, we can see that the nonrelativistic velocity difference is modified by a factor of $\left|1/\left(1 - u_x v/c^2\right)\right|$. As the velocities of the electron and the alpha particle become a significant fraction of the speed of light, this factor will become larger than 1, and the magnitude of the relativistic velocity difference will be larger than the magnitude of the nonrelativistic difference. Thus, our result seems reasonable.

Concept Check 35.8

We have just seen that the real sum of two positive velocities consistent with relativity is less than the sum resulting from nonrelativistic velocity addition. What about velocity differences? Assume that two velocity vectors, $\vec{v}_1$ and $\vec{v}_2$, both point in the positive x-direction. Call the relative velocity between the two $\vec{v}_r$. Which of the following is correct?

a) $\left|\vec{v}_r\right|_{\text{nonrelativistic}} < \left|\vec{v}_r\right|_{\text{relativistic}}$

b) $\left|\vec{v}_r\right|_{\text{nonrelativistic}} = \left|\vec{v}_r\right|_{\text{relativistic}}$

c) $\left|\vec{v}_r\right|_{\text{nonrelativistic}} > \left|\vec{v}_r\right|_{\text{relativistic}}$

d) Either (a) or (c) is correct, depending on which of the two velocities, $\vec{v}_1$ or $\vec{v}_2$, is larger.

SOLVED PROBLEM 35.3 Same Velocity

For some purposes, particle physicists need to have beams of electrons that have exactly the same velocity as beams of protons. For a proton, $m_p c^2 = 938\,\text{MeV}$. For an electron, $m_e c^2 = 0.511\,\text{MeV}$.

PROBLEM

If you have a proton beam with kinetic energy 2.50 GeV, what is the required kinetic energy for a beam of electrons with the same velocity?

Page 1098

SOLUTION

THINK

Particles with the same velocity v have the same value of γ. We can write expressions for the electron and the proton relating γ, the total energy, and the rest mass, solve them for γ, and equate them. The total energy of a particle is equal to the rest mass plus the kinetic energy. We can then solve for the required kinetic energy of the electron.

SKETCH

This is one of the rare times when a sketch is not needed.

RESEARCH

We can relate the energy E of a particle and γ through

$$E = \gamma m c^2.$$

We can therefore write the energy for an electron as $E_e = \gamma m_e c^2$. and the energy for a proton as $E_p = \gamma m_p c^2$. We can then equate γ for the electron and the proton:

$$\gamma = \frac{E_\mathrm{e}}{m_\mathrm{e}c^2} = \frac{E_\mathrm{p}}{m_\mathrm{p}c^2}.$$

The energy of the electron can be written as the sum of kinetic energy and rest energy, $E_\mathrm{e} = K_\mathrm{e} + m_\mathrm{e}c^2$. In the same way, we write for the proton $E_\mathrm{p} = K_\mathrm{p} + m_\mathrm{p}c^2$.

SIMPLIFY

We can combine the preceding equations to get

$$\frac{K_\mathrm{e} + m_\mathrm{e}c^2}{m_\mathrm{e}c^2} = \frac{K_\mathrm{p} + m_\mathrm{p}c^2}{m_\mathrm{p}c^2}.$$

Solving this for the kinetic energy of the electron, we obtain

$$K_\mathrm{e} = m_\mathrm{e}c^2\left(\frac{K_\mathrm{p} + m_\mathrm{p}c^2}{m_\mathrm{p}c^2}\right) - m_\mathrm{e}c^2.$$

CALCULATE

Putting in the numerical values gives us

$$K_\mathrm{e} = (0.511\ \mathrm{MeV})\left(\frac{2500\ \mathrm{MeV} + 938\ \mathrm{MeV}}{938\ \mathrm{MeV}}\right) - (0.511\ \mathrm{M}$$

ROUND

We report our result with three significant figures:

$$K_\mathrm{e} = 1.36\ \mathrm{MeV}.$$

DOUBLE-CHECK

We can double-check our result by calculating γ for the electron and the proton. For the electron, we have

$$\gamma = \frac{E_\mathrm{e}}{m_\mathrm{e}c^2} = \frac{1.36\ \mathrm{MeV} + 0.511\ \mathrm{MeV}}{0.511\ \mathrm{MeV}} = 3.66.$$

For the proton,

$$\gamma = \frac{E_\mathrm{p}}{m_\mathrm{p}c^2} = \frac{2.50\ \mathrm{GeV} + 938\ \mathrm{MeV}}{938\mathrm{MeV}} = 3.67,$$

which agrees with our calculated value for the electron within rounding error. Thus, our result seems reasonable.

35.4 Relativistic Momentum and Energy

Length, time, and velocity are not the only concepts that need revision within the theory of special relativity. Energy and momentum need revising as well. Again we are guided by the principle that physical laws should be invariant under the transformation from one frame to another and the realization that for speeds small compared to the speed of light we should again recover the nonrelativistic relationships derived earlier in the mechanics chapters.

Momentum

In Newtonian mechanics (see Chapter 7) momentum is defined as the product of velocity and mass: $\vec{p} = m\vec{v}$. Because we have now seen that an object's speed cannot exceed c, either the definition of momentum has to be changed or a maximum momentum is possible for a given particle. It turns out that the first possibility is the correct one.

The definition of momentum that is consistent with the theory of special relativity is

$$\vec{p} = \gamma m\vec{u}, \qquad \textbf{(35.19)}$$

where m is the **rest mass** of the particle (its mass as measured in a frame where it is at rest), $\vec{u}$ is the velocity of the particle in some frame, $\gamma = \dfrac{1}{\sqrt{1 - u^2/c^2}}$, and $\vec{p}$ is the momentum of the particle in that frame. Equation 35.19 is valid only for particles having mass $m > 0$. We discuss massless particles later in this section. (Unfortunately, many older textbooks use the notion of *relativistic mass, γ m*. This notion has been almost universally rejected. Mass is now considered invariant—that is, independent of the speed at which an object moves in a particular reference frame.)

In Figure 35.14, the two formulas for the momentum are compared. Blue shows the correct formula, and red the nonrelativistic approximation. The velocity is shown in terms of c, and the momentum in terms of mc. Up to speeds of approximately $c/2$, the two formulas give pretty much the same result, but then the correct relativistic momentum goes to infinity as v approaches c.

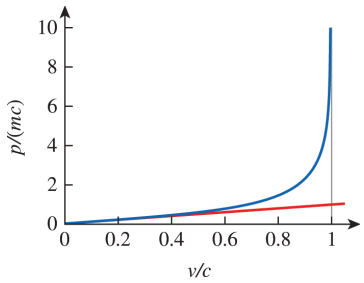

FIGURE 35.14
Momentum as a function of speed. The blue line plots the exact formula; the red line, the nonrelativistic approximation.

Newton's Second Law does not have to be modified in the relativistic limit. It remains

$$\vec{F}_{\text{net}} = \frac{d}{dt}\vec{p}, \tag{35.20}$$

where $\vec{p}$ is the relativistic momentum.

Energy

If momentum needs a change of definition, energy can also be expected to be in need of revision.

In our nonrelativistic considerations, we found that the total energy of a particle in the absence of an external potential is just its kinetic energy, $K = \frac{1}{2}mv^2$. In the relativistic case, we find that we have to consider the contribution of the mass to the energy of a particle. Einstein found that the energy of a particle with mass m at rest is

$$E_0 = mc^2. \qquad \textbf{(35.21)}$$

(Arguably the most famous formula in all of science!)

If the particle is in motion, then the energy increases by the same factor γ by which time is dilated for a moving particle. The general case for the energy is then

$$E = \gamma E_0 = \gamma mc^2. \qquad \textbf{(35.22)}$$

The correct formula for the kinetic energy is obtained by subtracting the "rest energy" from the total energy:

$$K = E - E_0 = (\gamma - 1)E_0 = (\gamma - 1)mc^2. \qquad \textbf{(35.23)}$$

The nonrelativistic formula for kinetic energy works at speeds that are small compared to the speed of light. So, how can we recover the nonrelativistic approximation $K = \frac{1}{2}mv^2$ from the general relativistic formula?

This result is actually quite straightforward, because for small speeds we already found that $\gamma = 1 + \frac{1}{2}\beta^2 = 1 + \frac{1}{2}v^2/c^2$. We can insert this expression for γ into the kinetic energy formula (equation 35.23) and get

$$K_{\text{small } v} = (\gamma - 1)mc^2 \approx \left(1 + \tfrac{1}{2}v^2/c^2 - 1\right)mc^2 = \tfrac{1}{2}mv^2.($$

DERIVATION 35.6 Energy

Let's go back to the work–kinetic energy theorem (see Chapter 5) and calculate the consequences of using the Lorentz transformation. For simplicity we use a one-dimensional case with motion along the x-direction only. By definition, work is the integral of the force:

$$W = \int_{x_0}^{x} F dx = \int_{x_0}^{x} \frac{dp}{dt} dx.$$

Here we want to assume that x_0 is the coordinate at $t = 0$ and that the particle has zero speed and therefore zero kinetic energy at $t = 0$. We can calculate dp/dt by using equation 35.19 and taking the time derivative:

$$\frac{dp}{dt} = \frac{d}{dt}(\gamma m v) = \frac{d}{dt}\left(\frac{mv}{\sqrt{1 - v^2/c^2}}\right) = \frac{m}{\sqrt{1 - v^2/c^2}} \frac{d}{d}$$
$$= \left(\frac{m(1 - v^2/c^2)}{(1 - v^2/c^2)^{3/2}} + \frac{mv^2/c^2}{(1 - v^2/c^2)^{3/2}}\right)\frac{dv}{dt} = \frac{1}{(1 - v^2}$$

where we have used the product and chain rules of differentiation. We can insert this result into the above integral for the work. By using the substitution of variables $dx = v dt$, we then find

$$W = \int_0^t \frac{m}{(1 - v^2/c^2)^{3/2}} \frac{dv}{dt} v \, dt = \int_0^v \frac{mv dv}{(1 - v^2/c^2)^{3/2}}.$$

Evaluating this integral, we arrive at

$$W = \frac{mc^2}{\sqrt{1 - v^2/c^2}}\bigg|_0^v = \frac{mc^2}{\sqrt{1 - v^2/c^2}} - mc^2 = (\gamma - 1)mc$$

Since the work–kinetic energy theorem states that $W = \Delta K$, and since in this case we started with a kinetic energy of zero, this leads us to

$$K = (\gamma - 1)mc^2,$$

which is equation 35.23. We also see from the evaluation of the integral that the term mc^2 arises from the contribution of $v = 0$ and can thus be identified as the rest energy of equation 35.21.

Momentum-Energy Relationship

We found that the nonrelativistic kinetic energy and momentum of an object are related via $K = p^2/2m$. Therefore, it is appropriate to ask what the correct general relationship between energy and momentum is. With $E = \gamma mc^2$ and $\overrightarrow{p} = \gamma m\overrightarrow{v}$ as our starting point, we find

$$E^2 = p^2c^2 + m^2c^4. \tag{35.25}$$

DERIVATION 35.7 Energy-Momentum Relation

We start with our equations for momentum and energy and square each of them:

$$\vec{p} = \gamma m \vec{v} \Rightarrow p^2 = \gamma^2 m^2 v^2,$$
$$E = \gamma m c^2 \Rightarrow E^2 = \gamma^2 m^2 c^4.$$

The square of the relativistic factor γ appears in both equations. Expressed in terms of v and c, it is

$$\gamma^2 = \frac{1}{1-\beta^2} = \frac{1}{1-v^2/c^2} = \frac{c^2}{c^2-v^2}.$$

Now we can evaluate the expression for the square of the energy, obtaining

$$E^2 = \frac{c^2}{c^2-v^2} m^2 c^4 = \frac{c^2-v^2+v^2}{c^2-v^2} m^2 c^4 = m^2 c^4 + \frac{v^2}{c^2-}$$
$$= m^2 c^4 + \frac{c^2}{c^2-v^2} m^2 v^2 c^2 = m^2 c^4 + \gamma^2 m^2 v^2 c^2$$
$$= m^2 c^4 - + p^2 c^2.$$

In the second step of this computation, we simply added and subtracted v^2 in the numerator, then realized that we could split the numerator in such a way that the factor $c^2 - v^2$ would cancel the denominator. In the next step, we rearranged the factors in the second term of the sum so that we could factor out γ again, and finally recognized that $\gamma^2 m^2 v^2 = p^2$, which gives us our desired result.

The energy-momentum relationship of equation 35.25 is often presented in the form of its square root,

$$E = \sqrt{p^2c^2 + m^2c^4}. \qquad \textbf{(35.26)}$$

Note that equation 35.25 can also be rewritten in the form

$$E^2 - p^2c^2 = m^2c^4. \qquad \textbf{(35.27)}$$

The mass m of a particle is a scalar invariant, and the speed c in vacuum is also invariant, so it follows from this simple rearrangement that $E^2 - p^2c^2$ is an invariant, just like the space-time interval $s^2 = c^2\Delta t^2 - \Delta r^2$ is an invariant.

A special case of equation 35.27 is relevant for particles with zero mass. (Photons, the particle representation for all radiation, including visible light, are examples of massless particles.) If a particle has $m = 0$, then the energy-momentum relationship simplifies considerably, and the momentum becomes proportional to the energy:

$$E = pc \quad (\text{for } m = 0). \qquad \textbf{(35.28)}$$

Speed, Energy, and Momentum

For particles with $m > 0$, dividing the absolute value of the momentum, $p = \gamma m v$, by the energy, $E = \gamma m c^2$, gives

$$\frac{p}{E} = \frac{\gamma m v}{\gamma m c^2} = \frac{v}{c^2} \Rightarrow v = \frac{pc^2}{E},$$

or, equivalently,

$$\beta = \frac{v}{c} = \frac{pc}{E}. \qquad \textbf{(35.29)}$$

This formula is often very useful for determining the relativistic factor β from the known energy and momentum of a particle. However, it also provides another energy-momentum relationship that is useful in practice:

$$\beta = \frac{pc}{E} \Rightarrow p = \frac{\beta E}{c} \quad \text{or} \quad E = \frac{pc}{\beta}. \qquad \textbf{(35.30)}$$

EXAMPLE 35.4 Electron at 0.99*c*

We have seen that in some applications it is advantageous to use the energy unit electron-volt (eV), $1\text{ eV} = 1.602 \cdot 10^{-19}\text{J}$. The rest energy of an electron is $E_0 = 5.11 \cdot 10^5\text{ eV} = 0.511\text{ MeV}$, and its rest mass is $m = 0.511\text{ MeV}/c^2$.

PROBLEM

If an electron has a speed that is 99.0% of that of light, what are its total energy, kinetic energy, and momentum?

SOLUTION

First, we calculate γ for this case:

$$\gamma = \frac{1}{\sqrt{1-\beta^2}} = \frac{1}{\sqrt{1-(0.990)^2}} = 7.09.$$

The total energy of the electron is given by

$$E = \gamma E_0 = 7.09(0.511\text{ MeV}) = 3.62\text{ MeV}.$$

The kinetic energy is therefore

$$K = (\gamma - 1)E_0 = 6.09(0.511\text{ MeV}) = 3.11\text{ MeV}.$$

The momentum of this electron is then

$$p = \frac{\beta E}{c} = \frac{(0.990)(3.62\text{ MeV})}{c} = 3.58\text{ MeV/c}.$$

Interestingly, we can accelerate electrons to 99% of the speed of light with quite small accelerators, which can fit in labs of typical physics buildings. However, going above 0.99*c* becomes very expensive. To get electrons to 99.9999999% of the speed of light requires a giant particle accelerator. The SLAC linear accelerator at Stanford, over 3 km long, is one such machine.

The equation $E = mc^2$ implies that energy and mass are related and can be interconverted. In chemistry class, you may have heard the expression “conservation of mass,” which means that in chemical reactions between different molecules, the number of atoms of each kind has to remain the same. However, this is merely an accounting device, and not a strict conservation law. The conservation laws of energy and momentum still hold in relativistic kinematics, but the total mass in a reaction is *not* conserved exactly. This fact is particularly evident in decays of particles, and Example 35.5 examines one such case.

EXAMPLE 35.5 Kaon Decay

The neutral kaon is a particle that can decay into a positive pion and a negative pion:

$$K^0 \rightarrow \pi^+ + \pi^-.$$

Particles will be discussed in much greater detail in Chapter 39, but the kinematics of particle decays can be understood just from the principles of relativity.

PROBLEM

What is the kinetic energy of each of the two pions after the decay of the kaon? The mass of the neutral kaon is $497.65\,\mathrm{MeV}/c^2$, and the masses of the positive and negative pions are each $139.57\,\mathrm{MeV}/c^2$. Assume that the neutral kaon is at rest before the decay occurs.

SOLUTION

Momentum and energy are conserved in this decay. The momentum before and after the decay of the kaon is zero. Thus,

$$\vec{p}_{\pi^+} + \vec{p}_{\pi^-} = 0.$$

We see that the magnitudes of the momenta of the two pions are the same. Because the masses of the two pions are also the same, their kinetic energies after the decay must be the same:

$$K_{\pi^+} = K_{\pi^-} = K,$$

where K is the kinetic energy of each pion after the decay. The total energy of the kaon before the decay is

$$E = m_{K^0}c^2,$$

because the kaon is at rest. After the decay, the total energy is

$$E = E_{\pi^+} + E_{\pi^-} = \left(m_{\pi^+}c^2 + K_{\pi^+}\right) + \left(m_{\pi^-}c^2 + K_{\pi^-}\right).$$

Energy conservation means that the total energy before and after the decay is the same:

$$m_{K^0}c^2 = \left(m_{\pi^+}c^2 + K_{\pi^+}\right) + \left(m_{\pi^-}c^2 + K_{\pi^-}\right).$$

We can rearrange this equation to get

$$m_{K^0}c^2 - m_{\pi^+}c^2 - m_{\pi^-}c^2 = K_{\pi^+} + K_{\pi^-} = 2K,$$

remembering that the kinetic energies of the π^+ and the π^- are the same. Solving for the kinetic energy of each pion gives us

$$K = \frac{m_{K^0}c^2 - m_{\pi^+}c^2 - m_{\pi^-}c^2}{2}.$$

Putting in the values of the masses given in the problem statement leads us to the result:

$$K = \tfrac{1}{2}(497.65\,\text{MeV} - 139.57\,\text{MeV} - 139.57\,\text{MeV}) = 10$$

Note that the entire kinetic energy of the two pions, which are the decay products from the kaon at rest, comes from the mass difference between the mass of the kaon and the sum of the masses of the two pions.

The conversion of mass into energy is used in nuclear fission reactions, where heavy atomic nuclei are split into smaller parts, liberating a large amount of kinetic energy in the process, which in turn is converted into heat and ultimately electrical energy. This is the basis for the nuclear power industry and will be covered in much greater detail in Chapter 40 on nuclear physics. There we will also discuss nuclear fusion, which is ultimately based on the same mass-energy relation, and which powers most stars and will hopefully soon be used in commercially available fusion reactors for electrical power generation.

Lorentz Transformation of Momentum and Energy

Derivation 35.3 showed that the position vector $\vec{r}$ and the time t in some frame F can be expressed in some other frame F' as the position vector $\vec{r}'$ and the time t' via a Lorentz transformation. What about momentum and energy?

In equation 35.19, the momentum vector is defined as $\vec{p} = \gamma m\vec{u}$. From this followed equation 35.22 for the energy, $E = \gamma mc^2$. Velocities can be transformed from one frame to another using equation 35.17 via the relationship $u'_x = (u_x - v)/\left(1 - vu_x/c^2\right)$. Therefore, the Lorentz transformation of momentum and energy can be written as

$$\begin{aligned} p'_x &= \gamma\left(p_x - vE/c^2\right) \\ p'_y &= p_y \\ p'_z &= p_z \\ E' &= \gamma(E - vp_x). \end{aligned} \qquad \textbf{(35.31)}$$

We leave the proof of this relationship to an end-of-chapter exercise. With the aid of this Lorentz transformation, one can show that $E^2 - p^2c^2 = E'^2 - p'^2c^2$, that is, that $E^2 - p^2c^2$ is a Lorentz invariant. This proof is analogous to Derivation 35.4 and is also left as an end-of-chapter exercise.

Two-Body Collisions

Lorentz transformations and Lorentz invariants help in dealing with very common problems in relativistic kinematics, those of two-body collisions. We have just stated that $E^2 - p^2c^2$ is a Lorentz invariant. This definition can be extended to the energies and momentum vectors of two particles, as observed in a certain frame (Figure 35.15). (We use subscripts 1 and 2 to identify the individual particles.) It is common to introduce the quantity S (pronounced simply as *ess*) as

$$S \equiv (E_1 + E_2)^2 - \left(\overrightarrow{p_1} + \overrightarrow{p_2}\right)^2 c^2, \qquad \textbf{(35.32)}$$

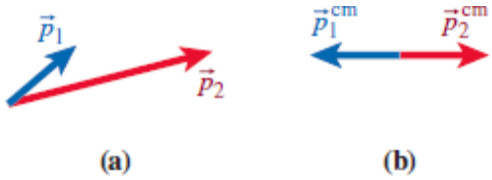

FIGURE 35.15
Momentum vectors of two particles in two different inertial frames. (a) Arbitrary frame; (b) center-of-mass frame.

where E_1 and $\overrightarrow{p_1}$ are the total energy and momentum of particle 1, and E_2 and $\overrightarrow{p_2}$ are the total energy and momentum of particle 2. Since $E^2 - p^2c^2$ is a Lorentz invariant, so is S. Thus, we are free to transform our observed quantities into a frame in which they are easiest to evaluate. A convenient frame is the center-of-mass frame. We denote the quantities in the center-of-mass frame with a superscript cm. In Chapter 8, we found that in this frame, the two momentum vectors of the two particles are exactly equal in

magnitude and opposite in direction: $\overrightarrow{p_1^{\text{cm}}} = -\overrightarrow{p_2^{\text{cm}}}$. Evaluating S in this frame, we see that

$$S = (E_1^{\text{cm}} + E_2^{\text{cm}})^2 - \underbrace{\left(\overrightarrow{p_1^{\text{cm}}} + \overrightarrow{p_2^{\text{cm}}}\right)^2}_{0} c^2 = (E_1^{\text{cm}} + E_2^{\text{cm}})^2.$$

This shows the physical meaning of S: The square root of S is equal to the sum of the energies of the two particles. That is, it is the total available energy in the center-of-mass frame:

$$\sqrt{S} = E_1^{\text{cm}} + E_2^{\text{cm}}. \qquad \textbf{(35.33)}$$

Thus, $\sqrt{S}$ provides information on the maximum energy that can be used for physical processes in two-body collisions. Because the energy of each of the two particles can also be written as the sum of kinetic energy plus mass energy, equation 35.33 can also be written as

$$\sqrt{S} = K_1^{\text{cm}} + m_1 c^2 + K_2^{\text{cm}} + m_2 c^2.$$

For practical considerations, the other of the two most interesting inertial frames, besides the center-of-mass frame, is the laboratory frame. The following example shows a useful relationship between the laboratory and the center-of-mass frames.

EXAMPLE 35.6 Colliders vs. Fixed-Target Accelerators

Suppose you want to create collisions between two protons in order to produce new particles. Two kinds of accelerators can accomplish this. In one, you can have one proton at rest and shoot the other one at it with some kinetic energy. This is the method used in a fixed-target accelerator. A more complicated way to generate collisions is to accelerate the two protons to the same kinetic energy and run them into each other from opposite directions. This technique requires much greater precision, but has a huge payoff if large center-of-mass energies are needed.

PROBLEM

The Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory can produce proton beams with a kinetic energy of 250 GeV, traveling in opposite directions. What kinetic energy would a proton beam produced by a fixed-target accelerator need to have to reach the same center-of-mass energy?

SOLUTION

The rest mass of the proton is $m_\mathrm{p} = 0.938\ \mathrm{GeV}/c^2$. It is small compared to the kinetic energies in this problem, but if we do not neglect it, we will arrive at a formula that is applicable for all beam energies.

In the center-of-mass frame, the total available energy is ($m_1 = m_2 = m_p$ and $K_1^\mathrm{cm} = K_2^\mathrm{cm} \equiv K^\mathrm{cm}$):

$$S = \left(2K^\mathrm{cm} + 2m_\mathrm{p}c^2\right)^2. \qquad \text{(i)}$$

In the lab frame, which is used by the fixed-target accelerator, we can start with equation 35.32, which is of course valid in all

inertial frames, and evaluate

$$\begin{aligned} S &= \left(E_1^{\text{lab}} + E_2^{\text{lab}}\right)^2 - \left(\overrightarrow{p_1}^{\text{lab}} + \overrightarrow{p_2}^{\text{lab}}\right)^2 c^2 \\ &= \left(E_1^{\text{lab}}\right)^2 + 2E_1^{\text{lab}}E_2^{\text{lab}} + \left(E_2^{\text{lab}}\right)^2 - \left(\overrightarrow{p_1}^{\text{lab}}\right)^2 c^2 - 2\left(\overrightarrow{p_1}^{\text{lab}}\right. \\ &= \left[\left(E_1^{\text{lab}}\right)^2 - \left(\overrightarrow{p_1}^{\text{lab}}\right)^2 c^2\right] + \left[\left(E_2^{\text{lab}}\right)^2 - \left(\overrightarrow{p_2}^{\text{lab}}\right)^2 c^2\right] + 2 \end{aligned}$$

The terms in the square brackets are the squared invariant mass energies of the proton in each case; substituting for the terms in the square brackets from equation 35.27 gives

$$S = 2m_{\text{p}}^2 c^4 + 2E_1^{\text{lab}}E_2^{\text{lab}} - 2\left(\overrightarrow{p_1}^{\text{lab}} \cdot \overrightarrow{p_2}^{\text{lab}}\right)c^2. \quad \text{(ii)}$$

One of the protons, say proton 1, is at rest $\left(\overrightarrow{p_1}^{\text{lab}} = 0,\ E_1^{\text{cm}} = m_{\text{p}}c^2\right)$. This eliminates the scalar product in equation (ii). For the other proton, we can write the total energy as the sum of kinetic energy and mass energy and then obtain

$$S = 2m_{\text{p}}^2 c^4 + 2m_{\text{p}}c^2\left(K^{\text{lab}} + m_{\text{p}}c^2\right) = 4m_{\text{p}}^2 c^4 + 2m_{\text{p}}c$$

Because S is invariant, we can set equations (i) and (iii) equal and find

$$\begin{aligned} 4m_{\text{p}}^2 c^4 + 2m_{\text{p}}c^2 K^{\text{lab}} &= \left(2K^{\text{cm}} + 2m_{\text{p}}c^2\right)^2 \\ &= 4\left(K^{\text{cm}}\right)^2 + 8K^{\text{cm}}m_{\text{p}}c^2 + 4m_{\text{p}}^2 c^4. \end{aligned}$$

We solve this for the kinetic energy in the lab frame and find

$$K^{\text{lab}} = 4K^{\text{cm}} + \frac{2(K^{\text{cm}})^2}{m_{\text{p}}c^2}.$$

Clearly, for beam kinetic energies that are small compared to the proton's mass energy, the linear term in this expression dominates. (The linear term is exactly what a nonrelativistic calculation would have found; see Chapter 8.) But for large kinetic energies, the quadratic term dominates, as shown in Figure 35.16. Knowing that the cost of an accelerator increases with the kinetic energy, we can clearly see that only colliders can be used to attain the very high center-of-mass energies needed for cutting-edge particle and nuclear physics experiments.

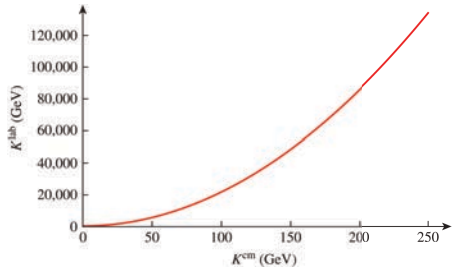

FIGURE 35.16
Equivalent fixed-target beam kinetic energy as a function of the center-of-mass kinetic energy in proton-proton collisions.

Finally, here is the numerical answer: If we insert 250 GeV (the value for proton beams at RHIC) as the center-of-mass kinetic energy for each of the two beams, we find that a fixed-target accelerator would need to attain a beam energy of over 134,000 GeV (134 TeV).

35.5 General Relativity

So far, we have talked about only special relativity. The theory of general relativity encompasses all of special relativity but, in addition, provides a theory of gravity. We have seen one theory of gravity that has been used rather successfully since the time of Newton. In the Newtonian theory of gravity, the gravitational force acting on a mass m due to another mass M is given as

$$F_{\mathrm{g}} = \frac{GmM}{r^2} = ma, \qquad \textbf{(35.34)}$$

where we have used Newton's Second Law to relate the force to m and the acceleration a. The mass m appears twice in this equation, but there is one very fine difference. The mass that appears on the right side is called the *inertial mass*. This mass is the mass that undergoes the acceleration. However, the quantity that has a role in the force of gravity is also a mass, the *gravitational mass*. Even in our most sensitive experimental tests, we find that inertial mass and gravitational mass are exactly equal, within experimental uncertainty.

The Newtonian theory of gravity served us extremely well. It was in almost complete agreement with all experimental observations. However, some small problems occurred in precision observations, such as a discrepancy in the exact orbit of the planet Mercury, that could not be explained with the Newtonian theory of gravity.

Albert Einstein again had the decisive insight, in 1907: *"If a person falls freely, he will not feel his own weight"* (Figure 35.17). This observation means that you cannot distinguish whether you are in an accelerating reference frame or subject to a gravitational force. This idea led to the famous **Equivalence Principle:**

> All local freely falling nonrotating laboratories are equivalent for the performance of all physical experiments.

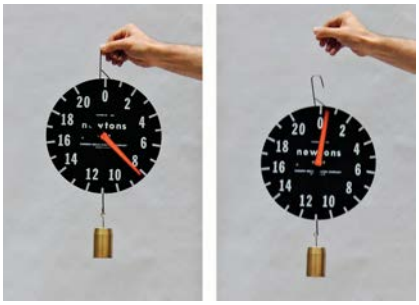

FIGURE 35.17
Einstein's observation: A free-falling object becomes weightless.

W. Bauer and G. D. Westfall

From this principle, we can prove that space and time are locally curved due to the presence of masses and, in turn, that *curved space-time* affects the motion of masses, determining how they move.

This concept may seem difficult to visualize, but an example might help. Consider a flat rubber sheet that symbolizes space in two dimensions. If you put a bowling ball onto this rubber sheet, it will deform the sheet in the way shown in Figure 35.18a. Any mass that now comes rolling along the surface of the rubber sheet experiences the curvature of the sheet and thus moves as if attracted to the bowling ball. From the viewpoint of general relativity, however, this scenario is a free motion along the shortest path in curved space-time. In Figure 35.18b, a second mass comes along, which causes its own deformation of space that results in a mutual attraction, but the principle remains the same.

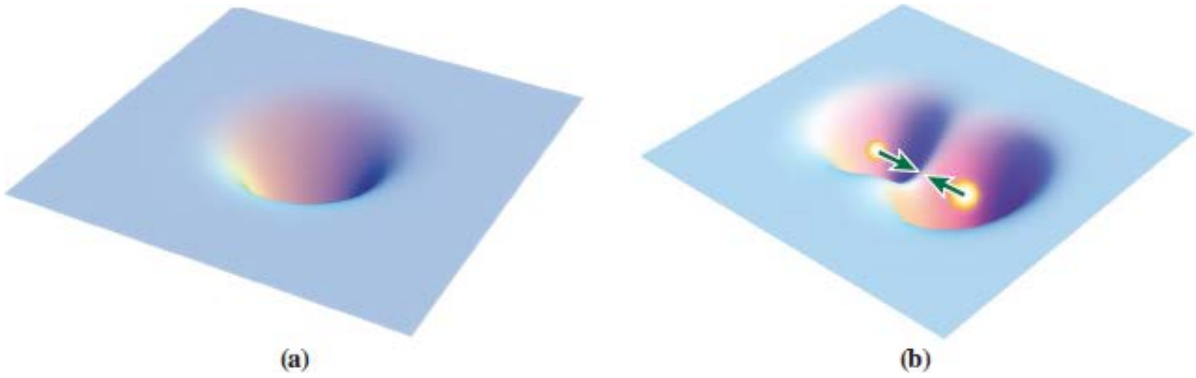

FIGURE 35.18 The deformation of space due to the presence of a massive object. (a) One object deforms space around it; (b) two objects attract each other as a result of their deformation of space.

One of the most striking predictions of general relativity concerns the motion of light. Because light does not have mass, the Newtonian law of gravity would suggest that gravity cannot affect the motion of light. The theory of general relativity, however, holds that light moves through curved space-time along the shortest path and thus should be deflected by the presence of large masses.

Observations by British astronomer Sir Arthur Eddington (1882–1944) during a solar eclipse in 1919 confirmed this spectacular prediction. Figure 35.19 shows the photograph taken by Eddington's team during the solar eclipse.

FIGURE 35.19
Photograph taken by Eddington's team of a solar eclipse on May 29, 1919, on the island of Principe, near Africa. The horizontal bars mark the apparent positions of the distant star.

NASA/Aubrey Gemignani

To visualize what was happening, we again use our rubber sheet analogy. Light from a distant star that passes near the Sun is deflected, as shown in Figure 35.20. The mass of the Sun acts like a lens. The consequence is that an observer sees two stars, or even arcs, instead of just one star. Eddington measured the undeflected direction of the distant star 6 months later by photographing stars at night when the Sun was not near the path of their light. The observed displacement was about $\frac{1}{5}$ the diameter of the image of the distant star. General relativity predicted that the angular separation of the observed image and the actual direction of the star would be 1.74", in good agreement with the observed angular separation. These measurements could be carried out only during a solar eclipse; otherwise, the light from the Sun would simply overpower the light from the stars. The systematic accuracy of

these results has been criticized, but subsequent measurements in several solar eclipses have verified them.

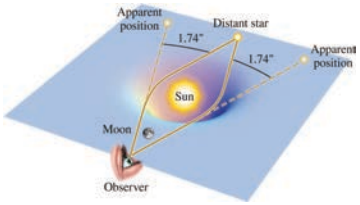

FIGURE 35.20
Light from a distant star is bent around the Sun. The angle is greatly exaggerated for clarity. Such apparent stars are visible close to the Sun only during a solar eclipse.

Recent observations with the Hubble Space Telescope have demonstrated gravitational lensing by massive dark objects (Figure 35.21). Figure 35.21a shows the light from a distant galaxy following a curved path around an unseen, massive dark object. This effect can produce two or more images of the distant galaxy, as illustrated, or it can produce arcs of light originating from the distant galaxy. Several arcs resulting from the gravitational lensing by a massive dark object are visible in Figure 35.21b.

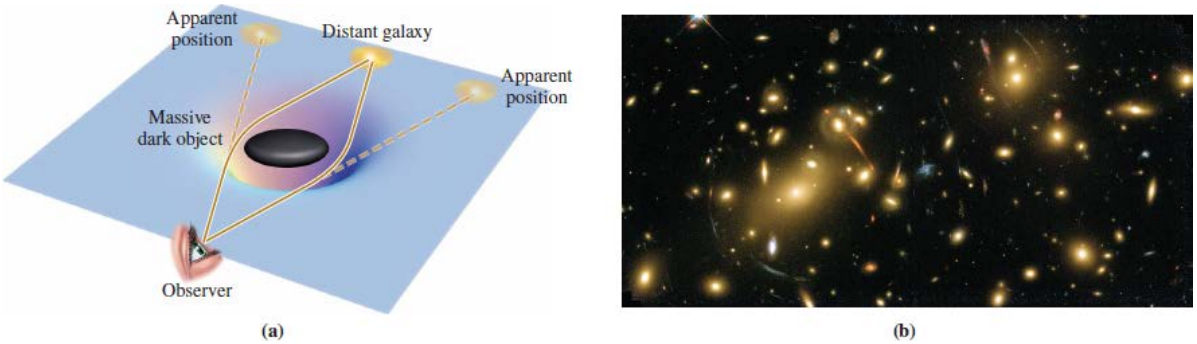

FIGURE 35.21 (a) Gravitational lensing of a distant galaxy by a massive dark object; (b) arcs due to gravitational lensing around the galaxy cluster Abell 2218.

Black Holes

When light comes close enough to an object of sufficient mass, the light cannot escape from the curvature in space-time generated by that object. What we mean by “close enough” is defined by the **Schwarzschild radius:**

$$R_{\mathrm{S}} = \frac{2GM}{c^2}. \qquad \textbf{(35.35)}$$

Every mass has a Schwarzschild radius that can be easily calculated. This formula can be arrived at by setting the escape speed found in Chapter 12, $v_{\mathrm{esc}} = \sqrt{\frac{2GM}{R}}$, equal to the speed of light and rearranging. If this radius lies within the interior of the object, nothing remarkable happens. For example, the Schwarzschild radius of Earth (representing the mass of Earth with a point mass of the same magnitude) is

$$R_{\mathrm{S,E}} = \frac{2GM_E}{c^2} = \frac{2\left(6.67 \cdot 10^{-11}\mathrm{Nm^2/kg^2}\right)\left(6.0 \cdot 10^{24}\mathrm{kg}\right)}{\left(3.0 \cdot 10^{8}\mathrm{m/s}\right)^2} =$$

This radius is less than $\frac{1}{2}$ inch and obviously much less than the radius of Earth. The Schwarzschild radius has physical meaning only if the mass M for which it is entirely contained inside the radius.

However, at the end of their lives, stars that had original masses larger than about 15 solar masses collapse to such high densities that their radii are less than their Schwarzschild radii. No information on such an object can escape from it to the outside. We call such an object a **black hole.** (If we could compact the entire Earth to a sphere with less than $\frac{1}{2}$ inch radius, it would turn into a

black hole.) Supermassive black holes with masses equal to millions of solar masses are at the centers of many galaxies, including our own. Example 12.4 pointed out the existence of a very massive black hole in the center of the Milky Way and showed that the mass of this black hole is approximately $3.7 \cdot 10^6$ times the mass of our Sun.

Concept Check 35.9

What is the Schwarzschild radius of a black hole with a mass of 14.6 solar masses $\left(m_{\text{sun}} = 1.99 \cdot 10^{30}\ \text{kg}\right)$?

a) 43.2 cm

b) 55.1 m

c) 1.55 km

d) 43.1 km

e) $4.55 \cdot 10^4$ km

Gravitational Waves

One particularly intriguing prediction of general relativity, the existence of gravitational waves, has been confirmed by the observation of gravitational waves with LIGO (the Laser Interferometer Gravitational-Wave Observatory). LIGO consists of two observatories, one in Hanford, Washington, and the other in Livingston, Louisiana, located 3002 km apart. In 2015, LIGO observed gravity waves emitted from a binary black hole merger. The two black holes spiraled in around each other until they merged into a single black hole. The mass of one of the black holes was 36 times the mass of the Sun and the mass of the second black hole was 29 times the mass of the Sun. The black hole pair was 1.3 billion light-years from Earth. The observed signals in Hanford and Livingston are shown in Figures 35.22a and 35.22b with time on the x-axis and strain on the y-axis. Strain is the fractional amount by which distances are distorted by the gravitational waves passing through LIGO. Figures 35.22c and 35.22d show the general relativity predictions for the binary black hole system for Hanford and Livingston, respectively. That these predictions match the measurements demonstrates that general relativity can explain the emission of gravitational waves.

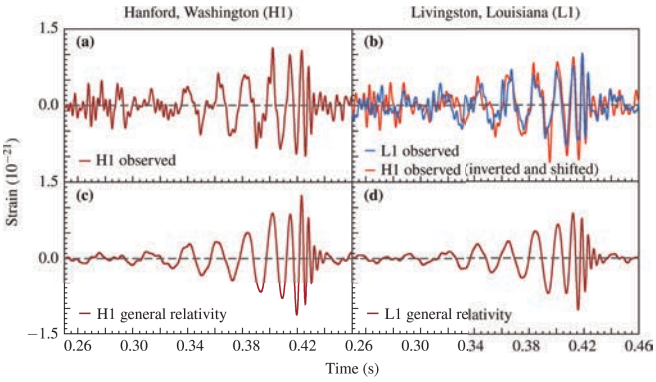

FIGURE 35.22 Results for the first observation of gravitational waves from the two LIDO observatories. (a) The signal from Hanford; (b) the signal from Livingston with the signal from Hanford inverted and shifted; (c) the prediction using general relativity for Hanford; (d) the prediction using general relativity for Livingston.

Data from Physical Review Letters 116, 061102 (2016). https://dcc.ligo.org/LIGO-G1600204-v6/public

Figure 35.22b shows the comparison between the signals from Hanford and Livingston. The results from Hanford have been inverted to account for the different orientation of the two detectors, and the data were shifted in time to take account for the 6.9 millseconds that gravitational waves would take to travel between the two sites. The fact that these measurements match closely confirms that the two observatories measured the same event. This work led to the 2017 Nobel Prize in Physics being awarded to Rainer Weiss, Barry C. Barish, and Kip S. Thorne.

An even more sensitive gravitational wave observatory is on the drawing board. Tentatively named LISA (Laser Interferometer Space Antenna), it will consist of three spacecraft arranged in an equilateral triangle of side length 5 million km (Figure 35.23). A recent test of the concepts and techniques forming the basis of

LISA called LISA Pathfinder was completed successfully in 2017. Launch of LISA is planned for 2034.

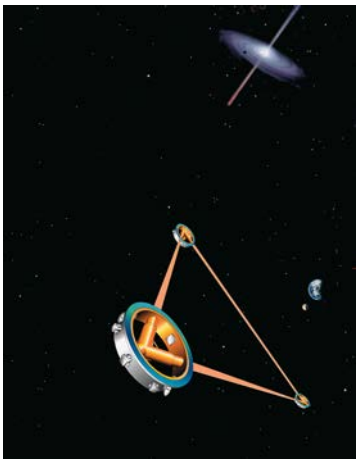

FIGURE 35.23
Artist's concept of LISA (Laser Interferometer Space Antenna), which has been proposed as the next generation of gravitational wave detector.

NASA/JPL/Caltech

An early indication of a source of gravitational wave emission was provided by binary pulsars, which consist of two neutron stars (extremely small dense stars with diameters of about 20 km) orbiting each other at a very close distance, with one of the pair being a pulsar emitting pulses of electromagnetic radiation at very precise time intervals, usually in the range of milliseconds to seconds. These binary pulsars emit very intense gravitational waves. Since the total energy of the system is conserved, a binary pulsar's orbital period decreases over time. This effect was first observed in 1974 by Russell Hulse and his thesis advisor, Joseph Taylor, who shared the 1993 Nobel Prize in Physics for their discovery. They were also able to show that the loss in pulsar

period length is consistent with the predictions of general relativity.

An intriguing experiment called NANOGrav (North American Nanohertz Observatory for Gravitational Waves) is using millisecond pulsers distributed throughout the Milky Way galaxy to detect gravitational waves. These pulsars emit pulses of radio waves with a very precise period. When gravitational waves pass through the galaxy, space and time shrink and stretch causing variations in the period of the pulsars observed on Earth. By carefully observing the correlations of the periods of these pulsars, gravitational waves can be detected using the entire galaxy as a laboratory (Figure 35.24). This type of detection is sensitive to spiraling pairs of supermassive black holes with masses millions of times larger than the mass of the Sun, which complements the sensitivity of LIGO. NANOGrav researchers recently have used 45 pulsars with well-known periods over a span of 3 years to search for evidence of gravitational waves. Further plans include boosting sensitivity by observing longer periods of time, adding additional well-characterized pulsars, and cooperating with the International Pulsar Timing Array (IPTA).

35.6 Relativity in Our Daily Lives: GPS

While you may argue that most relativistic effects are important only in outer space, at impossibly large speeds, or at the beginning of our universe, relativity touches all of our lives through one technology. This application is the **Global Positioning System (GPS),** which consists of 24 satellites that orbit the Earth (Figure 35.25), at an altitude of about 20,000 km above ground, with a period of one half of a sidereal day [1 sidereal day = the time for the Earth to complete one full rotation so that the stars have the same position again in the night sky $= 86,164.09074\,\text{s} \approx (1 - 1/365.2425)(86,400\,\text{s})$; see also Example 9.3].

FIGURE 35.25 GPS satellite in orbit.

Andrey Armyagov/Shutterstock

GPS operates by having clocks on all satellites synchronized to a very high precision. The modern atomic clocks on board these satellites have fractional time stability to typically 1 part in 10^{13}. By sending synchronized timing signals, the satellites enable users with a GPS receiver to determine their own location in space and time. Typically, a receiver can detect signals from at least four satellites simultaneously. For each satellite, the receiver's position

in space, $\overline{r}_r$, and time, t_r, relative to that of satellite i can be determined from the equation

$$\left|\overrightarrow{r_r} - \overrightarrow{r_i}\right| = c\,|t_r - t_i|. \qquad \textbf{(35.36)}$$

Because the positions in time and space of each satellite are known, equation 35.36 is an equation with four unknown quantities: the three spatial coordinates and the time on the clock of the receiver. Detecting signals from four satellites gives the receiver four equations with four unknown quantities. This system of equations provides solutions with an astonishing accuracy of about 1 m.

For these equations to hold, we must rely on the second postulate of special relativity. However, other relativistic effects also need to be included. The satellites move with speeds of approximately 4 km/s relative to Earth, and time-dilation effects cause frequency shifts in the clocks of 1 part in 10^{10} (satellite atomic clocks slow by about 7 μs/day compared to ground-based clocks), which is about 1000 times too large to be ignored. In addition, gravitational corrections due to general relativity are at least of the same magnitude. Therefore, correct application of the theory of relativity is essential for the proper functioning of the Global Positioning System.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- Light always moves at the same speed, independent of the velocity of the source and the observer: $c = 2.99792458 \cdot 10^8\ \mathrm{m/s}$.
- The two postulates of special relativity are
  (1) The laws of physics are the same in every inertial reference frame, independent of the motion of the reference frame.
  (2) The speed of light, *c*, is the same in every inertial reference frame.
- The dimensionless quantities $\beta \leq 1$ and $\gamma \geq 1$ are defined as follows:

$$\beta = \left|\overrightarrow{v}/c\right| \quad \text{and} \quad \gamma = \frac{1}{\sqrt{1-\beta^2}} = \frac{1}{\sqrt{1-(v/c)^2}}.$$

- Time is dilated as a function of the speed of the observer, according to

$$\Delta t = \gamma \Delta t_0 = \frac{\Delta t_0}{\sqrt{1-(v/c)^2}},$$

  where Δt_0 is the time measured in the rest frame.
- Length in the direction of motion is contracted as a function of the speed of the observer, according to

$$L = \frac{L_0}{\gamma} = L_0\sqrt{1-(v/c)^2},$$

  where L_0 is the proper length, measured in its rest frame.

- The relativistic frequency shift for light from a moving source is

$$f = f_0 \sqrt{\frac{c \mp v}{c \pm v}},$$

and the corresponding wavelength correction is

$$\lambda = \lambda_0 \sqrt{\frac{c \pm v}{c \mp v}}.$$

The red-shift parameter is defined as

$$z = \frac{\Delta\lambda}{\lambda} = \sqrt{\frac{c \pm v}{c \mp v}} - 1.$$

- The Lorentz transformation for space and time coordinates is

$$x' = \gamma(x - vt); \quad y' = y; \quad z' = z; \quad t' = \gamma\left(t - vx/c^2\right).$$

- The relativistic velocity transformation is

$$u' = \frac{u - v}{1 - vu/c^2},$$

and the inverse transformation is

$$u = \frac{u' + v}{1 + vu'/c^2},$$

where all velocities are in the same direction.

- The rest energy of a particle is $E_0 = mc^2$.
- The relativistic expression for momentum is $\overrightarrow{p} = \gamma m \overrightarrow{v}$, and that for energy is $E = \gamma E_0 = \gamma mc^2$.

- The relationship between energy and momentum is given by $E^2 = p^2c^2 + m^2c^4$.
- The Lorentz transformation for momentum and energy is

$$p'_x = \gamma\left(p_x - vE/c^2\right); \quad p'_y = p_y; \quad p'_z = p_z; \quad E' = \gamma(l$$

- The Lorentz invariant,

$$S \equiv (E_1 + E_2)^2 - \left(\overrightarrow{p_1} + \overrightarrow{p_2}\right)^2 c^2,$$

  is the square of the total available energy in the center-of-mass frame.
- The Equivalence Principle of the theory of general relativity states that all local freely falling nonrotating laboratories are equivalent for the performance of all physical experiments.
- The Schwarzschild radius of a massive object is given by

$$R_\mathrm{S} = \frac{2GM}{c^2}.$$

ANSWERS TO SELF-TEST OPPORTUNITIES

35.1 1 light-year $= (3.00 \cdot 10^8\ \text{m/s})(365.25\ \text{days/year})$
$(24\ \text{hours/day})(3600\ \text{s/hour}) = 9.47 \cdot 10^{15}\text{m}$

35.2

5% effect:

Exact: $\beta = \sqrt{1-\gamma^{-2}} = \sqrt{1-(1.05)^{-2}} = 0.31 = 31\%$ of c

Approximation: $\beta \approx \sqrt{2(\gamma-1)} = \sqrt{2(1.05-1)} = 0.32 = 33\%$ of c 50% effect:

Extract: $\beta = \sqrt{1-\gamma^{-2}} = \sqrt{1-(1.50)^{-2}} = 0.75 = 75\%$ of c

35.3

$$
\begin{aligned}
&\gamma\{\gamma(x'+vt')-vt\} = \gamma^2(x'+vt')-\gamma vt = x' \Rightarrow (\text{divided b}\\
&x'+vt'-vt/\gamma = x'/\gamma^2 \Rightarrow (\text{subtract } x')\\
&vt'-vt/\gamma = x'\left(\gamma^{-2}-1\right) = -x'v^2/c^2 \Rightarrow (\text{divided by } v)\\
&t'-t/\gamma = -x'v/c^2 \Rightarrow (\text{rearrange})\\
&t'+x'v/c^2 = t/\gamma \Rightarrow (\text{multiply with } \gamma)\\
&t = \gamma\left(t'+x'v/c^2\right).
\end{aligned}
$$

35.4

$$u_x = \frac{dx}{dt} = \frac{\gamma(dx'+vdt')}{\gamma(dt'+vdx'/c^2)}u' = \frac{\dfrac{dx'}{dt'}+v}{1+\dfrac{v}{c^2}\dfrac{dx'}{dt'}} = \frac{{u'}_x+v}{1+\dfrac{v{u'}_x}{c^2}}.$$

PROBLEM-SOLVING GUIDELINES

1. The first step in attacking any relativity problem is to identify the information. What are the events involved in the problem? What are the reference frames? What is the proper time, and what is the proper length? Review Section 35.2 and be sure you know how to recognize the proper time and proper length.

2. Given the subtleties of relativity theory, checking answers is very important. Check that time has dilated and length has contracted for a reference frame that is moving relative to a stationary frame.

3. For the Lorentz transformation equations, be sure to identify the two reference frames, as well as the direction of the velocity between them and the velocity of any motion within each frame.

MULTIPLE-CHOICE QUESTIONS

35.1 The most important fact we learned about the aether is that

a) no experimental evidence of its effects was ever found.

b) its existence was proven experimentally.

c) it transmits light in all directions equally.

d) it transmits light faster in the longitudinal direction.

e) it transmits light slower in the longitudinal direction.

35.2 If spaceship A is traveling at 70% of the speed of light relative to an observer at rest, and spaceship B is traveling at 90% of the speed of light relative to an observer at rest, which of the following have the greatest velocity as measured by an observer in spaceship B?

a) a cannonball shot from A to B at 50% of the speed of light as measured in A's reference frame

b) a ball thrown from B to A at 50% of the speed of light as measured in B's reference frame

c) a particle beam shot from a stationary observer to B at 70% of the speed of light as measured in the stationary reference frame

d) a beam of light shot from A to B, traveling at the speed of light in A's reference frame

e) All of the above have the same velocity as measured in B's reference frame.

35.3 A particle of rest mass m_0 travels at a speed $v = 0.20c$. How fast must the particle travel in order for its momentum to increase to twice its original value?

a) $0.40c$

b) $0.10c$

c) $0.38c$

d) $0.42c$

e) $0.99c$

35.4 Which quantity is invariant—that is, has the same value—in all reference frames?

a) time interval, Δt

b) space interval, Δx

c) velocity, v

d) space-time interval, $c^2(\Delta t)^2 - (\Delta x)^2$

35.5 Two twins, A and B, are in deep space on similar rockets traveling in opposite directions with a relative speed of $c/4$. After a while, twin A turns around and travels back toward twin B again, so that their relative speed is $c/4$. When they meet again, is one twin younger, and if so, which twin is younger?

a) Twin A is younger.

b) Twin B is younger.

c) The twins are the same age.

d) Each twin thinks the other is younger.

35.6 A proton has a momentum of 3.0 GeV/c. With what velocity is it moving relative to a stationary observer?

a) $0.31c$

b) $0.33c$

c) $0.91c$

d) $0.95c$

e) $3.2c$

35.7 A square of area $100\ \mathrm{m}^2$ that is at rest in a reference frame is moving with a speed $\left(\sqrt{3/2}\right)c$. Which of the following statements is incorrect?

a) $\beta = \sqrt{3/2}$

b) $\gamma = 2$

c) To an observer at rest, it looks like a square with an area less than $100\ \mathrm{m}^2$.

d) The length along the direction of motion is contracted by a factor of $\frac{1}{2}$.

35.8 Consider a particle moving with a speed less than $0.5c$. If the speed of the particle is doubled, by what factor will the momentum increase?

a) less than 2

b) 2

c) greater than 2

35.9 Three groups of experimenters measure the average decay time for a specific type of radioactive particle. Group 1 accelerates the particles to $0.5c$, moving from left to right, and then measures the decay time in the beam, obtaining a result of 20 ms. Group 2 accelerates the particles to $-0.5c$, from right to left, and then measures the decay time in the beam. Group 3 keeps the particles at rest in a container and measures their decay time. Which of the following is true about these measurements?

a) Group 2 measures a decay time of 20 ms.

b) Group 2 measures a decay time less than 20 ms.

c) Group 3 measures a decay time of 20 ms.

d) Both (a) and (c) are true.

e) Both (b) and (c) are true.

35.10 A person in a spaceship holds a meter stick parallel to the motion of the ship as it passes by the Earth with $\gamma = 2$. What length does an observer at rest on the Earth measure for the meter stick?

a) 2 m

b) 1 m

c) 0.5 m

d) 0.0 m

e) none of the above

35.11 A person in a spaceship holds a meter stick as the ship moves parallel to the Earth's surface with $\gamma = 2$. What does the *person in the ship* notice if she rotates the stick from parallel to perpendicular to the ship's motion?

a) The stick becomes shorter.

b) The stick becomes longer.

c) The length of the stick stays the same.

35.12 A person in a spaceship holds a meter stick as the ship moves parallel to the Earth's surface with $\gamma = 2$. What does an *observer on the Earth* notice as the person in the spaceship rotates the stick from parallel to perpendicular to the ship's motion?

a) The stick becomes shorter.

b) The stick becomes longer.

c) The length of the stick stays the same.

35.13 As the velocity of an object increases, so does its energy. What does this imply?

a) At very low velocities, the object's energy is equal to its mass times c^2.

b) In order for an object with mass m to reach the speed of light, infinite energy is required.

c) Only objects with $m = 0$ can travel at the speed of light.

d) all of the above

e) none of the above

35.14 In the LHC at CERN in Geneva, Switzerland, two beams of protons are accelerated to $E = 7\ \text{TeV}$. The proton's rest mass is approximately $m = 1\ \text{GeV}/c^2$. When the two proton beams collide, what is the rest mass of the heaviest particle that can possibly be created?

a) $1\,\mathrm{GeV}/c^2$

b) $2\,\mathrm{GeV}/c^2$

c) $7\,\mathrm{TeV}/c^2$

d) $14\,\mathrm{TeV}/c^2$

CONCEPTUAL QUESTIONS

35.15 In mechanics, one often uses the model of a perfectly rigid body to determine the motion of physical objects (see, for example, Chapter 10 on rotation). Explain how this model contradicts Einstein's special theory of relativity.

35.16 Use light cones and world lines to help solve the following problem. Eddie and Martin are throwing water balloons very fast at a target. At $t = -13\ \mu s$, the target is at $x = 0$, Eddie is at $x = -2\ km$, and Martin is at $x = 5\ km$; all three remain in these positions for all time. The target is hit at $t = 0$. Who made the successful shot? Prove this using the light cone for the target. When the target is hit, it sends out a radio signal. When does Martin know the target has been hit? When does Eddie know the target has been hit? Use the world lines to show this. Before starting to draw the diagrams, consider this: If your x position is measured in kilometers and you are plotting t versus x/c, what unit must t be in?

35.17 A gravitational lens should produce a halo effect and not arcs. Given that the light travels not only to the right and left of the intervening massive object but also to the top and bottom, why do we typically see only arcs?

35.18 Suppose you are explaining the theory of relativity to a friend, and you tell him that nothing can go faster than 300,000 km/s. He says that is obviously false: Suppose a spaceship traveling past you at 200,000 km/s, which is perfectly possible according to what you are saying, fires a torpedo straight ahead whose speed is 200,000 km/s relative to the spaceship, which is also perfectly possible; then, he says, the torpedo's speed is 400,000 km/s. How would you answer him?

35.19 Consider a positively charged particle moving at constant speed parallel to a current-carrying wire, in the direction of the current. As you know (after studying Chapters 27 and 28), the

particle is attracted to the wire by the magnetic force due to the current. Now suppose another observer moves along with the particle, so according to him the particle is at rest. Of course, a particle at rest feels no magnetic force. Does that observer see the particle attracted to the wire or not? How can that be? (Either answer seems to lead to a contradiction: If the particle is attracted, it must be by an electric force because there is no magnetic force, but there is no electric field from a neutral wire; if the particle is not attracted, the observer sees that the particle is, in fact, moving toward the wire.)

35.20 At rest, a rocket has an overall length of L. A garage at rest (built for the rocket by the lowest bidder) is only $L/2$ in length. Luckily, the garage has both a front door and a back door, so that when the rocket flies at a speed of $v = 0.866c$, it fits entirely into the garage. However, according to the rocket pilot, the rocket has length L and the garage has length $L/4$. How does the rocket pilot observe that the rocket does not fit into the garage?

35.21 A rod at rest on Earth makes an angle of 10° with the x-axis. If the rod is moved along the x-axis, what happens to this angle, as viewed by an observer on the ground?

35.22 An astronaut in a spaceship flying toward Earth's Equator at half the speed of light observes Earth to be an oblong solid, wider and taller than it appears deep, rotating around its long axis. A second astronaut flying toward Earth's North Pole at half the speed of light observes Earth to be a similar shape but rotating about its short axis. Why does this not present a contradiction?

35.23 Consider two clocks carried by observers in a reference frame moving at speed v in the positive x-direction relative to Earth's rest frame. Assume that the two reference frames have parallel axes and that their origins coincide when clocks at that point in both frames read zero. Suppose the clocks are separated by a distance l in the x'-direction in their own reference frame; for instance, $x' = 0$ for one clock and $x' = l$ for the other, with $y' = z' = 0$ for both. Determine the readings t' on both clocks as functions of the time coordinate t in Earth's reference frame.

35.24 Prove that in all cases, adding two sub-light-speed velocities relativistically will always yield a sub-light-speed velocity. Consider motion in one spatial dimension only.

35.25 A famous result in Newtonian dynamics is that if a particle in motion collides elastically with an identical particle at rest, the two particles emerge from the collision on perpendicular trajectories. Does the same hold in the special theory of relativity? Suppose a particle of rest mass m and total energy E collides with an identical particle at rest, and the two particles emerge from the collision with new velocities. Are those velocities necessarily perpendicular? Explain.

35.26 Suppose you are watching a spaceship orbiting Earth at 80% of the speed of light. What is the length of the ship as viewed from the center of the orbit?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 35.1

35.27 Find the speed of light in *feet per nanosecond,* to three significant figures.

35.28 Find the value of g, the gravitational acceleration at Earth's surface, in light-years per year per year, to three significant figures.

35.29 Michelson and Morley used an interferometer to show that the speed of light is constant, regardless of Earth's motion through any purported luminiferous aether. An analogy can be made with the different times it takes a rowboat to travel two different round-trip paths in a river that flows at a constant velocity (u) downstream. Let one path be for a distance D directly across the river, then back again; and let the other path be the same distance D directly upstream, then back again. Assume that the rowboat travels at a constant speed v (with respect to the water) for both trips. Neglect the time it takes for the rowboat to turn around. Find the ratio of the cross-stream time to the upstream-downstream time, as a function of the given constants.

35.30 What is the value of γ for a particle moving at a speed of $0.800c$?

Section 35.2

35.31 An astronaut on a spaceship traveling at a speed of 0.50c is holding a meter stick parallel to the direction of motion.

a) What is the length of the meter stick as measured by another astronaut on the spaceship?

b) If an observer on Earth could observe the meter stick, what would be the length of the meter stick as measured by that observer?

35.32 A spacecraft travels along a straight line from Earth to the Moon, a distance of $3.84 \cdot 10^8$ m. Its speed measured on Earth is 0.50c.

a) How long does the trip take, according to a clock on Earth?

b) How long does the trip take, according to a clock on the spacecraft?

c) Determine the distance between Earth and the Moon if it were measured by a person on the spacecraft.

35.33 A 30.-year-old says goodbye to her 10.-year-old son and leaves on an interstellar trip. When she returns to Earth, both she and her son are 40. years old. What was the speed of the spaceship?

35.34 If a muon is moving at 90.0% of the speed of light, how does its measured lifetime compare to its lifetime of $2.2 \cdot 10^{-6}$ s when it is in the rest frame of a laboratory?

35.35 A fire truck 10.0 m long needs to fit into a garage 8.00 m long (at least temporarily). How fast must the fire truck be going to fit entirely inside the garage, at least temporarily? How long does it take for the truck to get inside the garage, from

a) the garage's point of view?

b) the fire truck's point of view?

35.36 In Jules Verne's classic *Around the World in Eighty Days,* Phileas Fogg travels around the world in, according to his calculation, 81 days. Because he crossed the International Date Line, he actually made it only 80 days. How fast would he have to

go in order to have time dilation make 80 days seem like 81? (Of course, at this speed, it would take a lot less than 1 day to get around the world....)

• **35.37** Suppose NASA discovers a planet just like Earth orbiting a star just like the Sun. This planet is 35 light-years away from our Solar System. NASA quickly plans to send astronauts to this planet, but with the condition that the astronauts not age more than 25 years during the journey.

a) At what speed must the spaceship travel, in Earth's reference frame, so that the astronauts age 25 years during their journey?

b) According to the astronauts, what will be the distance of their trip?

• **35.38** Consider a meter stick at rest in a reference frame F. It lies in the x,y-plane and makes an angle of 37° with the x-axis. The reference frame F then moves with a constant velocity v parallel to the x-axis of another reference frame F'

a) What is the velocity of the meter stick measured in F' at an angle 45° to the x-axis?

b) What is the length of the meter stick in F' under these conditions?

••**35.39** A spaceship shaped like an isosceles triangle has a width of 20.0 m and a length of 50.0 m. What is the angle between the base of the ship and the side of the ship as measured by a stationary observer if the ship is moving past the observer at a speed of $0.400c$? Plot this angle as a function of the speed of the ship.

35.40 How fast must you be traveling relative to a blue light (480 nm) for it to appear red (660 nm)?

35.41 In your physics class, you have just learned about the relativistic frequency shift, and you decide to amaze your friends at a party. You tell them that once you drove through a stoplight and when you were pulled over, you did not get ticketed because you explained to the police officer that the relativistic Doppler shift made the red light of wavelength 650 nm appear green to you, with

a wavelength of 520 nm. If your story were true, how fast would you have been traveling?

35.42 A meteor made of pure kryptonite (yes, we know that there really isn't such a thing as kryptonite …) is moving toward Earth. If the meteor eventually hits Earth, the impact will cause severe damage, threatening life as we know it. If a laser hits the meteor with light of wavelength 560 nm, the meteor will blow up. The only laser on Earth powerful enough to hit the meteor produces light with a 532-nm wavelength. Scientists decide to launch the laser in a spacecraft and use special relativity to get the right wavelength. The meteor is moving very slowly, so there is no correction for relative velocities. At what speed does the spaceship need to move so that the laser light will have the right wavelength, and should it travel toward or away from the meteor?

35.43 Radar-based speed detection works by sending an electromagnetic wave out from a source and examining the Doppler shift of the reflected wave. Suppose a wave of frequency 10.6 GHz is sent toward a car moving away from the source at a speed of 32.0 km/h. What is the difference between the frequency of the wave emitted by the source and the frequency of the wave an observer in the car would detect?

• **35.44** A He-Ne laser onboard a spaceship moving toward a remote space station emits a beam of red light directed toward the space station. The wavelength of the light in the beam, as measured by a wavelength meter on the spaceship, is 632.8 nm. If the astronauts on the space station see the beam as a blue beam of light with a measured wavelength of 514.5 nm, what is the relative speed of the spaceship with respect to the space station? What is the red-shift parameter, z, in this case?

Section 35.3

35.45 Sam sees two events as simultaneous:

(i) Event *A* occurs at the point (0,0,0) at the instant 0:00:00 universal time.

(ii) Event *B* occurs at the point (500. m,0,0) at the same moment.

Tim, moving past Sam with a velocity of $0.999c\hat{x}$, also observes the two events.

a) Which event occurs first in Tim's reference frame?

b) How long after the first event does the second event happen in Tim's reference frame?

35.46 Use relativistic velocity addition to reconfirm that the speed of light with respect to any inertial reference frame is *c*. Assume one-dimensional motion along a common *x*-axis.

35.47 You are driving down a straight highway at a speed of $v = 50.0\ \text{m/s}$ relative to the ground. An oncoming car travels with the same speed in the opposite direction. What relative speed do you observe for the oncoming car?

35.48 A rocket ship approaching Earth at 0.90*c* fires a missile toward Earth with a speed of 0.50*c*, relative to the rocket ship. As viewed from Earth, how fast is the missile approaching Earth?

35.49 In the twin paradox example (in Section 35.2), Alice boards a spaceship that flies to a space station 3.25 light-years away and then returns with a speed of 0.65*c*.

a) Calculate the total distance Alice traveled during the trip, as measured by Alice.

b) Using the total distance from part (a), calculate the total time duration for the trip, as measured by Alice.

• **35.50** In the twin paradox example, Alice boards a spaceship that flies to a space station 3.25 light-years away and then returns with a speed of 0.650*c*. View the trip in terms of Alice's reference frame.

a) Show that Alice must travel with a speed of 0.914*c* to establish a relative speed of 0.650*c* with respect to Earth when she is

returning to Earth.

b) Calculate the time duration for Alice's return flight to Earth at the speed of 0.914*c*.

••35.51 Robert, standing at the rear end of a railroad car of length 100. m, shoots an arrow toward the front end of the car. He measures the velocity of the arrow as 0.300*c*. Jenny, who was standing on the platform, saw all of this as the train passed her with a velocity of 0.750*c*. Determine the following as observed by Jenny:

a) the length of the car

b) the velocity of the arrow

c) the time taken by arrow to cover the length of the car

d) the distance covered by the arrow

••35.52 Consider motion in one spatial dimension. For any velocity v, define the parameter θ via the relation $v = c \tanh \theta$, where c is the speed of light in vacuum. This quantity is called the *velocity parameter* or the *rapidity* corresponding to velocity v.

a) Prove that for two velocities, which add via a Lorentz transformation, the corresponding velocity parameters simply add algebraically, that is, like Galilean velocities.

b) Consider two reference frames in motion at speed v in the x-direction relative to one another, with axes parallel and origins coinciding when clocks at the origin in both frames read zero. Write the Lorentz transformation between the two coordinate systems entirely in terms of the velocity parameter corresponding to v and the coordinates.

Section 35.4

35.53 What is the speed of a particle whose momentum is $p = mc$?

35.54 An electron's rest mass is $0.511\ \text{MeV}/c^2$.

a) How fast must an electron be moving if its energy is to be 10 times its rest energy?

b) What is the momentum of the electron at this speed?

35.55 The Relativistic Heavy Ion Collider (RHIC) can produce colliding beams of gold nuclei with beam kinetic energy of $A \cdot 100.$ GeV in the center-of-mass frame, where A is the number of nucleons in a gold nucleus (197). You can approximate the mass energy of a nucleon as 1.00 GeV. What is the equivalent beam kinetic energy for a fixed-target accelerator? (See Example 35.6.)

35.56 How much work is required to accelerate a proton from rest up to a speed of $0.997c$?

35.57 In proton accelerators used to treat cancer patients, protons are accelerated to $0.61c$. Determine the energy of each proton, expressing your answer in mega-electron-volts (MeV).

• **35.58** In some proton accelerators, proton beams are directed toward each other to produce head-on collisions. Suppose that in such an accelerator, protons move with a speed relative to the lab reference frame of $0.9972c$.

a) Calculate the speed of approach of one proton with respect to another one with which it is about to collide head on. Express your answer as a multiple of c, using six significant figures.

b) What is the kinetic energy of each proton (in units of MeV) in the laboratory reference frame?

c) What is the kinetic energy of one of the colliding protons (in units of MeV) in the rest frame of the other proton?

••**35.59** The hot filament of the electron gun in a cathode ray tube releases electrons with nearly zero kinetic energy. The electrons are next accelerated under a potential difference of 5.00 kV, before being steered toward the phosphor on the screen of the tube.

a) Calculate the kinetic energy acquired by an electron under this accelerating potential difference.

b) Is the electron moving at relativistic speed?

c) What are the electron's total energy and momentum? (Give both values, relativistic and nonrelativistic, for both quantities.)

35.60 Consider a one-dimensional collision at relativistic speeds between two particles with masses m_1 and m_2. Particle 1 is initially moving with a speed of $0.700c$ and collides with particle 2, which is initially at rest. After the collision, particle 1 recoils with a speed of $0.500c$, while particle 2 starts moving with a speed of $0.200c$. What is the ratio m_2/m_1?

• **35.61** In an elementary-particle experiment, a particle of mass m is fired, with momentum mc, at a target particle of mass $2\sqrt{2}m$. The two particles form a single new particle (in a completely inelastic collision). Find the following:

a) the speed of the projectile before the collision

b) the mass of the new particle

c) the speed of the new particle after the collision

• **35.62** Show that momentum and energy transform from one inertial frame to another as $p'_x = \gamma\left(p_x - vE/c^2\right)$; $p'_y = p_y$; $p'_z = p_z$; $E' = \gamma(E - vp_x)$. (*Hint:* Look at Derivation 35.4 for the space-time Lorentz transformation.)

••**35.63** Show that $E^2 - p^2c^2 = E'^2 - p'^2c^2$, that is, that $E^2 - p^2c^2$ is a Lorentz invariant. (*Hint:* Look at Derivation 35.4, which shows that the space-time interval is a Lorentz invariant.)

Sections 35.5 and 35.6

35.64 The deviation of the space-time geometry near the Earth from the flat space-time of the special theory of relativity can be gauged by the ratio Φ/c^2, where Φ is the Newtonian gravitational potential at the Earth's surface. Find the value of this quantity.

35.65 Calculate the Schwarzschild radius of a black hole with the mass of

a) the Sun.

b) a proton. How does this result compare with the size scale of 10^{-15} m usually associated with a proton?

35.66 Assuming that the speed of GPS satellites is approximately 4.00 km/s relative to Earth, calculate how much slower per day the atomic clocks on the satellites run, compared to stationary atomic clocks on Earth.

35.67 What is the Schwarzschild radius of the black hole at the center of our Milky Way? (*Hint:* The mass of this black hole was determined in Example 12.4.)

Additional Exercises

35.68 In order to fit a 50.0-foot-long stretch limousine into a 35.0-foot-long garage, how fast would the limousine driver have to be moving, in the garage's reference frame? Comment on what happens to the garage in the limousine's reference frame.

35.69 Using relativistic expressions, compare the momentum of two electrons, one moving at $2.00 \cdot 10^8 \text{m/s}$ and the other moving at $2.00 \cdot 10^3 \text{m/s}$. What is the percent difference between nonrelativistic momentum values and these values?

35.70 Rocket A passes Earth at a speed of 0.75 *c*. At the same time, rocket B passes Earth moving with a speed of 0.95 *c* relative to Earth in the same direction. How fast is B moving relative to A when it passes A?

35.71 Determine the difference in kinetic energy of an electron traveling at 0.9900 *c* and one traveling at 0.9999 *c*, first using standard Newtonian mechanics and then using special relativity.

35.72 Right before take-off, a passenger on a plane flying from town A to town B synchronizes his clock with the clock of his friend who is waiting for him in town B. The plane flies with a constant velocity of 240 m/s. The moment the plane touches the ground, the two friends check their clocks simultaneously. The clock of the passenger on the plane shows that it took exactly 3.00 h to travel from A to B. Ignoring any effects of acceleration:

a) Will the clock of the friend waiting in B show a shorter or a longer time interval?

b) What is the difference between the readings of the two clocks?

35.73 The explosive yield of the atomic bomb dropped on Hiroshima near the end of World War II was approximately 15.0 kilotons of TNT. One kiloton corresponds to about $4.8 \cdot 10^{12}$ J of energy. Find the amount of mass that was converted into energy in this bomb.

35.74 At what speed will the length of a meter stick appear to be 90.0 cm?

35.75 What is the relative speed between two objects approaching each other head on, if each is traveling at speed of 0.600*c* as measured by an observer on Earth?

35.76 An old song contains these lines: "While driving in my Cadillac, what to my surprise; a little Nash Rambler was following me, about one-third my size." The singer of that song assumes that the Nash Rambler is driving at a similar velocity. Suppose, though, rather than actually being one-third the Cadillac's size, the proper length of the Rambler is the same as that of the Cadillac. What would be the velocity of the Rambler relative to the Cadillac for the song's observation to be accurate?

35.77 You shouldn't invoke time dilation due to your relative motion with respect to the rest of the world as an excuse for being late to class. While it is true that relative to those at rest in the classroom, your time while you are in motion runs more slowly, the difference is negligible. Suppose over a weekend you drove from your college in the Midwest to New York City and back, a round-trip of 2200. mi, driving for 20.0 h in each direction. By what amount, at most, would your watch differ from your professor's watch?

35.78 A spaceship is traveling at two-thirds of the speed of light directly toward a stationary asteroid. If the spaceship turns on its headlights, what will be the speed of the light traveling from the spaceship to the asteroid as observed by

a) someone on the spaceship?

b) someone on the asteroid?

35.79 Two stationary space stations are separated by a distance of 100. light-years, as measured by someone on one of the space stations. A spaceship traveling at 0.950*c* relative to the space stations passes by one of them heading directly toward the other one. How long will it take to reach the other space station, as measured by someone on the spaceship? How much time will have passed for a traveler on the spaceship as it travels from one space

station to the other, as measured by someone on one of the space stations? Round the answers to the nearest year.

35.80 An electron is accelerated from rest through a potential of $1.0 \cdot 10^6$ V. What is its final speed?

35.81 In the age of interstellar travel, an expedition is mounted to an interesting star 2000.0 light-years from Earth. To make it possible to get volunteers for the expedition, the planners guarantee that the round-trip to the star will take no more than 10.000% of a normal human lifetime. (At the time, the normal human lifetime is 400.00 years.) What is the minimum speed with which the ship carrying the expedition must travel?

••**35.82** What is the energy of a particle with speed of 0.800*c* and a momentum of $1.00 \cdot 10^{20}$ N s?

••**35.83** In a high-speed football game, a running back traveling at 55.0% of the speed of light relative to the field throws the ball to a receiver running in the same direction at 65.0% of the speed of light relative to the field. The speed of the ball relative to the running back is 80.0% of the speed of light.

a) How fast does the receiver perceive the speed of the ball to be?

b) If the running back shines a flashlight at the receiver, how fast will the photons appear to be traveling to the receiver?

• **35.84** You have been presented with a source of electrons, ^{14}C, having kinetic energy equal to 0.305 times the rest energy. Suppose you have a pair of detectors that can detect the passage of the electrons without disturbing them. You wish to show that the relativistic expression for momentum is correct and the nonrelativistic expression is incorrect. If a 2.0-m-long baseline between your detectors is used, what timing accuracy is needed to show that the relativistic expression for momentum is correct?

• **35.85** A spacecraft travels a distance of $1.00 \cdot 10^{-3}$ light-years in 20.0 h, as measured by an observer stationed on Earth. How long does the journey take as measured by the captain of the spacecraft?

• **35.86** More significant than the kinematic features of the special theory of relativity are the dynamical processes it describes that Newtonian dynamics does not. Suppose a hypothetical particle

with rest mass 1.000 GeV/c^2 and kinetic energy 1.000 GeV collides with an identical particle at rest. Amazingly, the two particles fuse to form a single new particle. Total energy and momentum are both conserved in the collision.

a) Find the momentum and speed of the first particle.

b) Find the rest mass and speed of the new particle.

••35.87 Although it deals with inertial reference frames, the special theory of relativity describes accelerating objects without difficulty. Of course, uniform acceleration no longer means $dv/dt = g$, where g is a constant, since that would have v exceeding c in a finite time. Rather, it means that the acceleration *experienced* by the moving body is constant: In each increment of the body's own proper time, $d\tau$ the body experiences a velocity increment $dv = g d\tau$ as measured in the inertial frame in which the body is momentarily at rest. (As it accelerates, the body encounters a sequence of such frames, each moving with respect to the others.) Given this interpretation:

a) Write a differential equation for the velocity v of the body, moving in one spatial dimension, as measured in the inertial frame in which the body was initially at rest (the "ground frame"). You can simplify your equation by remembering that squares and higher powers of differentials can be neglected.

b) Solve the equation from part (a) for $v(t)$, where both v and t are measured in the ground frame.

c) Verify that $v(t)$ behaves appropriately for small and large values of t.

d) Calculate the position of the body, $x(t)$, as measured in the ground frame. For convenience, assume that the body is at rest at ground-frame time $t = 0$ and at ground-frame position $x = c^2/g$.

e) Identify the trajectory of the body on a space-time diagram (a *Minkowski diagram,* for Hermann Minkowski) with coordinates x and ct, as measured in the ground frame.

f) For $g = 9.81\ \text{m/s}^2$, calculate how much time it takes the body to accelerate from rest to 70.7% of c, measured in the ground

frame, and how much ground-frame distance the body covers in this time.

MULTI-VERSION EXERCISES

35.88 A gold nucleus of rest mass 183.473 GeV/c^2 is accelerated from 0.5785c to 0.8433c. How much work is done on the gold nucleus in this process?

35.89 A gold nucleus of rest mass 183.473 GeV/c^2 is accelerated from 0.4243c to some final speed. In this process, 140.779 GeV of work is done on the gold nucleus. What is the final speed of the gold nucleus as a fraction of c?

35.90 A gold nucleus of rest mass 183.473 GeV/c^2 is accelerated from some initial speed to a final speed of 0.8475c. In this process, 137.782 GeV of work is done on the gold nucleus. What was the initial speed of the gold nucleus as a fraction of c?

35.91 Two identical nuclei, each with rest mass 50.30 GeV/c^2, are accelerated in a collider to a kinetic energy of 503.01 GeV and made to collide head on. If one of the two nuclei were instead kept at rest, what would the kinetic energy of the other nucleus have to be for the collision to achieve the same center-of-mass energy?

35.92 Two identical nuclei are accelerated in a collider to a kinetic energy of 621.38 GeV and made to collide head on. If one of the two nuclei were instead kept at rest, the kinetic energy of the other nucleus would have to be 15,161.70 GeV for the collision to achieve the same center-of-mass energy. What is the rest mass of each of the nuclei?

35.93 A nucleus with rest mass 23.94 GeV/c^2 is at rest in the lab. An identical nucleus is accelerated to a kinetic energy of 10,868.96 GeV and made to collide with the first nucleus. If instead the two nuclei were made to collide head on in a collider, what would the kinetic energy of each nucleus have to be for the collision to achieve the same center-of-mass energy?

Photovoltaic cells convert light into electricity. Solar farms like that shown in Figure 36.1 use these cells, and so do the sensors in elevator and garage doors. In order to understand how these devices convert light into moving electrons, we need to look at another aspect of light, which will lead us into the quantum world. When light interacts with material objects, it often reveals a particle-like nature: Tiny wave packets called *photons* interact with individual atoms or molecules or biological cells. The photoelectric effect is impressive physical proof that light can have particle characteristics, and we will study it in the present chapter. Einstein provided the explanation for the photoelectric effect in 1905; a century later, we apply this effect to harness the power of solar radiation and help satisfy humanity's ever-increasing need for electrical power.

FIGURE 36.1 A section of the carport solar array at Michigan State University, the largest in North America. This solar array was completed in 2017, covers 5000 parking spaces, and delivers 15,000 MWh of electricity per year.

W. Bauer and G. D. Westfall

Does the existence of photons mean that light is not a wave after all? We will see in this chapter that the difference between a

wave and a particle is not clear-cut. At very small scales, waves can act like particles, and particles can act like waves. This discovery led to revolutionary changes in our understanding of physics, as far-reaching as the changes in space and time described by the theory of relativity. The remaining chapters of this book are devoted to the new ideas that arose from the discovery of photons —known as quantum physics.

WHAT WE WILL LEARN

- On the basis of the quantum hypothesis, it is possible to derive Planck' Radiation Law for the power radiated in a given frequency interval. The quantum approach avoids the ultraviolet catastrophe that makes the classical explanation unphysical at short wavelengths (high frequencies), and it contains the classical radiation laws as limits.
- What we normally think of as a wave, such as light, has particle characteristics. The photoelectric effect is explained with the quantum hypothesis by saying that light consists of elementary quanta called *photons*. The energy of a photon is equal to its frequency times Planck's constant.
- The Compton effect is the scattering of a high-energy photon (X-ray) off an electron. The observations for the scattering of X-rays are explained by kinematics, which assumes that the photon has particle characteristics.
- What we normally think of as matter also has wave characteristics. The de Broglie wavelength of a particle is defined as Planck's constant divided by the magnitude of the particle's momentum; it is the fundamental wavelength associated with a matter wave.
- The Heisenberg Uncertainty Relation stipulates that the product of the uncertainty in momentum and the uncertainty in position, measured simultaneously, has an absolute lower bound. An energy-time uncertainty relation has the same lower bound as that for momentum and position.
- Elementary quantum particles have an intrinsic property called *spin*, which has the dimension of angular momentum. Spin is quantized. Particles are divided into two categories: fermions with spins that are half-integer multiples of Planck's constant divided by 2π, and bosons with spins that are integer multiples of Planck's constant divided by 2π.
- The Pauli Exclusion Principle states that no two fermions can occupy the same quantum state at the same time. This

means that in any given atom, no two fermions can have exactly identical quantum numbers, which are numbers that characterize the quantum state of the particle. Bosons can condense at a low temperature in such a way that most of them occupy the same quantum state.

36.1 The Nature of Matter, Space, and Time

By now you have probably accepted the notion that matter consists of constituents called *atoms*. Originally atoms were thought to be indivisible, hence the name *atom,* which derives from the Greek word $\alpha\tau o\mu o\varsigma$ ("individual, indivisible"). We will see that atoms actually do have substructure. Each atom consists of a "cloud" of electrons surrounding a nucleus, which in turn consists of neutrons and protons. It is currently thought that electrons have no substructure, but protons and neutrons are known to be composed of three quarks, held together by gluons (see Section 21.2). These quarks and gluons are also thought to be elementary—that is, they are thought to lack substructure. How physicists have arrived at these deductions and conclusions is the subject of Chapters 37–40. For now, however, it suffices to point out that matter is granular—it consists of extremely small, indivisible pieces.

What about time and space—are they granular, too? In Chapter 35 on relativity, we learned some rather surprising results about the connection between time and space. However, we have not yet considered the question of whether time or space can be subdivided into infinitesimally small quantities. Calculus assumes that time is continuous, not granular, because limits of $\Delta t \to 0$ are used to arrive at the definitions of velocity and acceleration. Energy and momentum are related to each other in ways similar to the ways space and time are related. This immediately raises the question of whether energy and momentum are continuous quantities, or if some smallest granule of energy and some elementary quantity of momentum exist. For example, a spinning ball has rotational kinetic energy. By increasing its angular speed, we also increase its kinetic energy. But can we make the increment infinitesimally small, or is there some smallest quantum of energy that we are forced to add?

Let's start this investigation by taking another look at light. Light can be considered an electromagnetic wave, as shown in

Chapter 31. In our studies of light, we first explored geometric optics in Chapters 32 and 33, examining image formation with mirrors, lenses, and other optical instruments. In those chapters, we assumed that light consists of rays that move along straight lines. When we looked in Chapter 34 at interference and diffraction, we were forced to invoke the wave character of light. In that chapter, we found that the wave character of light comes into play only when we explore spatial dimensions on the order of the wavelength of light and that geometric optics provides very good approximations for spatial dimensions that are very large compared to the wavelength.

Page 1119

Does our previous description of light as an electromagnetic wave suffice to describe all the phenomena we can observe? The answer is no, as we will see in this chapter.

36.2 Blackbody Radiation

When we talked about thermal radiation in Chapter 18, we introduced the idealized concept of a blackbody. This idealization can be realized to good accuracy by looking at the radiation coming from a small hole in a large cavity kept at a temperature *T*. If we look at the visible light that emerges from such a hole at room temperature, the hole appears black because all the light that enters the cavity through the hole is scattered and ultimately absorbed by the walls. However, at much higher temperatures, the hole begins to glow in the visible part of the electromagnetic spectrum. Everyday examples of visible light approximating blackbody radiation include the dull red color of the cooking elements of electric stoves, the bright light from the filament of an incandescent light bulb, the light from the Sun, and the red glow of volcanic lava (Figure 36.2).

FIGURE 36.2
Volcanic lava emits light and is a very good approximation of a blackbody radiator.

Sami Sarkis/Getty Images

Let's first briefly review what was known about blackbody radiation from classical wave physics and from empirical observations. The *Stefan-Boltzmann Radiation Law* for the total intensity I (energy radiated per unit time and unit area) of this blackbody radiation is

$$I = \int_0^\infty \epsilon(\lambda) d\lambda = \sigma T^4. \qquad \textbf{(36.1)}$$

Here $\epsilon(\lambda)$ is the **spectral emittance** (often called the *spectral radiance*) as a function of wavelength. It is the power radiated per unit area and wavelength and has the SI units of $\mathrm{W\,m^{-3}}$. The integral extends over all possible wavelengths from zero to infinity, and σ is the Stefan-Boltzmann constant,

$$\sigma = 5.670374419 \cdot 10^{-8}\ \mathrm{W\,m^{-2}\ K^{-4}}.$$

The Stefan-Boltzmann constant is defined exactly based on other fundamental constants that have exactly defined values. The most important feature of the Stefan-Boltzmann Radiation Law (equation 36.1) is that the total intensity of the radiation increases with the fourth power of the temperature.

In 1896, German physicist Wilhelm Wien (1864–1928) empirically derived **Wien's Law** to describe the spectral emittance of a blackbody:

$$\epsilon_{\mathrm{Wien}}(\lambda) = \frac{a}{\lambda^5} e^{-b/\lambda T} \quad (\text{approximation for small } \lambda), \tag{36.2}$$

where a and b are constants. Wien's Law succeeded in describing the spectral emittance of blackbodies for short wavelengths but was less successful in describing the spectral emittance for long wavelengths. The **Wien Displacement Law** summarizes another important experimental finding about the spectral emittance. It states that the spectral emittance peaks at a certain wavelength, λ_{m}, and that this wavelength depends on the temperature:

$$\lambda_{\mathrm{m}} T = \text{constant} = 2.90 \cdot 10^{-3}\ \mathrm{K\ m}. \tag{36.3}$$

Using the representation of light as an electromagnetic wave, the English physicists Lord Rayleigh and Sir James Jeans managed to derive an expression for the spectral emittance of blackbody radiation:

$$\epsilon_{\mathrm{RJ}}(\lambda) = \frac{2\pi c k_{\mathrm{B}} T}{\lambda^4} \quad (\text{approximation for large } \lambda). \tag{36.4}$$

Here c is the speed of light and k_{B} is Boltzmann's constant, defined exactly as

$$k_{\mathrm{B}} = 1.380649 \cdot 10^{-23}\,\mathrm{J/K}.$$

This solution, however, had one glaring fault: As $\lambda \to 0$, the expression on the right side of equation 36.4 diverges. This problem later became known as the *ultraviolet catastrophe* (recall that ultraviolet radiation has small wavelengths). If equation 36.4 were correct for all wavelengths, then the integral in equation 36.1 would diverge and the intensity radiated by a blackbody would become infinite at any temperature. Clearly, this is impossible! However, for large wavelengths, the result obtained by Rayleigh and Jeans fits the experimental observations.

In order to provide a formula for the spectral emittance that fits the observations at all wavelengths, the German physicist Max Planck took a radical step in 1900. He proposed that the energy contained in light and all other electromagnetic radiation interacts with solid objects in discrete bundles. He hypothesized that the energy of a bundle is proportional to the frequency of the radiation:

$$E = hf, \tag{36.5}$$

where *h* is **Planck's constant** and has the exact value

$$h = 6.62607015 \cdot 10^{-34}\ \mathrm{J\ s}. \tag{36.6}$$

We have already introduced the energy unit the electron-volt, $1\,\mathrm{eV} = 1.602176634.10^{-19}\,\mathrm{J}$, and Planck's constant can also be expressed in terms of that unit: $h = 4.135667696 \cdot 10^{-15}\,\mathrm{eV\ s}$.

As you will see later in this chapter, many formulas in quantum physics involve Planck's constant divided by 2π. Because this is a relatively common occurrence, it is customary to use the notation $\hbar$ to denote this ratio:

$$\hbar \equiv \frac{h}{2\pi} = 1.05457187 \cdot 10^{-34}\ \text{J s} = 6.582119569 \cdot 10^{-16}\ \text{e}$$

The wavelength and frequency of light are still related to the speed via $c = \lambda f$, so we can also write, instead of equation 36.5,

$$E = hf = \frac{hc}{\lambda}. \tag{36.8}$$

Planck's Radiation Law, which Planck based on the quantized-energy hypothesis, is

$$I_T(f) = \frac{2h}{c^2} \frac{f^3}{e^{hf/k_\text{B}T} - 1}. \tag{36.9}$$

Here $I_T(f)df$ is the power (amount of energy per unit time) radiated in the frequency range between f and $f + df$ by a blackbody at temperature T per unit surface area of the blackbody opening and per unit solid angle. The name for $I_T(f)$ is the *specific intensity*, or the **spectral brightness,** and its SI units are $\text{W m}^{-2}\,\text{sr}^{-1}\,\text{Hz}^{-1}$. We will revisit Planck's result later in this chapter in order to understand the dependence of the spectral brightness on frequency and temperature.

Note that the spectral brightness does not depend on direction. The spectral brightness, $I_T(f)$, can be integrated over the entire hemisphere of all possible directions to give the spectral emittance, $\epsilon_T(f)$:

$$\begin{aligned}
\epsilon_T(f) &= \int_\Omega I_T(f)\cos\theta\, d\Omega = \int_0^{\pi/2}\left(\int_0^{2\pi} I_T(f)\, d\phi\right)\sin\theta\cos\theta \\
&= I_T(f)\int_0^{2\pi} d\phi \int_0^{\pi/2} \sin\theta\cos\theta\, d\,\theta \\
&= I_T(f)2\pi\tfrac{1}{2} \\
&= \pi I_T(f).
\end{aligned}$$

Thus, we see that the spectral emittance is larger than the spectral brightness by exactly the factor π:

$$\epsilon_T(f) = \pi I_T(f). \qquad \textbf{(36.10)}$$

The factor cos θ in the first integral is the projection of the normal vector to the hole, $\widehat{n}$, in the direction of the radiation, so cos θ represents the effective reduction of the unit emission area as a function of the polar angle. The integral over the solid angle of the hemisphere is a double integral over the angle Φ from 0 to $\pi/2$ and the angle ϕ from 0 to 2π (Figure 36.3).

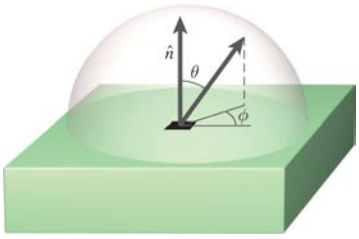

FIGURE 36.3
Blackbody radiating through the small black hole in all directions of the hemisphere.

These integrals are easily evaluated, as shown, because $I_T(f)$ does not depend on the angles. Combining equation 36.10 with equation 36.9, we obtain

$$\epsilon_T(f) = \frac{2\pi h}{c^2} \frac{f^3}{e^{hf/k_B T} - 1}. \qquad \textbf{(36.11)}$$

The spectral emittance, $\epsilon_T(f)$, has the SI units of $\mathrm{W\ m^{-2}\ Hz^{-1}}$.

We can also write the spectral brightness and the spectral emittance as functions of the wavelength instead of the frequency. To do this, we use $c = \lambda f$;

$$I_T(\lambda) = I_T(f) \left| \frac{df}{d\lambda} \right| = I_T(f) \left| \frac{d}{d\lambda} \left(\frac{c}{\lambda} \right) \right| = I_T(f) \frac{c}{\lambda^2}.$$

Therefore, the spectral brightness as a function of wavelength is given as

$$I_T(\lambda) = \frac{2hc^2}{\lambda^5 \left(e^{hc/\lambda k_B T} - 1 \right)}. \qquad \textbf{(36.12)}$$

Its SI units are $\mathrm{W\,m^{-2}\,sr^{-1}}$. The spectral emittance can be obtained as a function of wavelength by integrating the spectral brightness over all emission angles, resulting in a multiplicative factor of π and giving

$$\epsilon(\lambda) = \frac{2\pi hc^2}{\lambda^5\left(e^{hc/\lambda k_\mathrm{B}T} - 1\right)}, \qquad \textbf{(36.13)}$$

which has SI units of $\mathrm{W\,m^{-3}}$. All four versions of Planck's Law (equations 36.9, 36.11, 36.12, and 36.13) are equally valid. Care must be taken, however, when talking about the spectral brightness or the spectral emittance. They differ by a factor of π, as shown, because the spectral emittance is the integral of the spectral brightness over all emission angles in the hemisphere.

Figure 36.4 displays plots of the Planck Radiation Law for the spectral emittance as a function of wavelength for three temperatures. The top curve is calculated for a temperature of 5800 K, approximately the surface temperature of the Sun. The spectral emittance has a maximum near a wavelength of 500 nm (green-blue), in accordance with the result of equation 36.3, the Wien Displacement Law. The other two curves are for 5400 K, peaking at 540 nm (yellow-green), and 5000 K, peaking at 580 nm (orange). Overlaid on the graph are the colors of the visible spectrum.

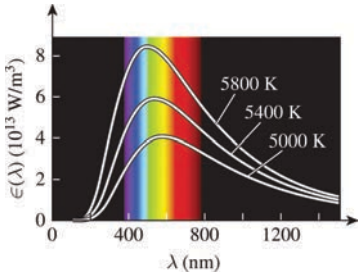

FIGURE 36.4
Planck spectral emittance as a function of wavelength for three temperatures: 5800 K, 5400 K, and 5000 K, from top to bottom.

DERIVATION 36.1 Radiation Laws

Let's show that Wien's Law, the Rayleigh-Jeans Law, the Stefan-Boltzmann Radiation Law, and the Wien Displacement Law can be derived from Planck's Radiation Law (equation 36.13).

Wien's Law: For small values of λ, the argument of the exponential function in Planck's Radiation Law becomes large, which allows us to write

$$\frac{1}{e^{hc/\lambda k_B T} - 1} \approx e^{-hc/\lambda k_B T}.$$

We then obtain an expression for Wien's Law as a limiting case of Planck's Law:

$$\epsilon(\lambda) = \frac{2\pi hc^2}{\lambda^5\left(e^{hc/\lambda k_B T} - 1\right)} \approx \frac{2\pi hc^2}{\lambda^5} e^{-hc/\lambda k_B T},$$

which has the same dependence on wavelength as equation 36.2, with the constants now defined as $a = 2\pi hc^2$ and $b = hc/k_B$.

Rayleigh-Jeans Law: For large values of λ, the argument of the exponential function in Planck's Radiation Law becomes small. We can expand the exponential function for small arguments as $e^x \approx 1 + x$. In this case, we then have $e^{hc/\lambda k_B T} - 1 \approx hc/\lambda k_B T$, and we find for large values of the wavelength:

$$\epsilon(\lambda) = \frac{2\pi hc^2}{\lambda^5\left(e^{hc/\lambda k_B T} - 1\right)} \approx \frac{2\pi hc^2}{\lambda^5(hc/\lambda k_B T)} = \frac{2\pi c k_B T}{\lambda^4},$$

which is the Rayleigh-Jeans Law as given in equation 36.4.

Wien Displacement Law: For this law, we need to find the wavelength for which $\epsilon(\lambda)$ reaches a maximum; that is, we need to take the derivative with respect to the wavelength and find the root. The derivative is

$$\begin{aligned}\frac{d\epsilon(\lambda)}{d\lambda} &= \frac{d}{d\lambda}\left(\frac{2\pi hc^2}{\lambda^5\left(e^{hc/\lambda k_{\mathrm{B}}T}-1\right)}\right) \\ &= -\frac{10\pi hc^2}{\lambda^6\left(e^{hc/\lambda k_{\mathrm{B}}T}-1\right)} + \frac{2\pi h^2c^3e^{hc/\lambda k_{\mathrm{B}}T}}{\lambda^7\left(e^{hc/\lambda k_{\mathrm{B}}T}-1\right)^2 k_{\mathrm{B}}T} \\ &= \frac{2\pi hc^2}{\lambda^7\left(e^{hc/\lambda k_{\mathrm{B}}T}-1\right)^2 k_{\mathrm{B}}T}\left(-5\lambda k_{\mathrm{B}}T\left(e^{hc/\lambda k_{\mathrm{B}}T}-1\right.\right.\end{aligned}$$

Except for the uninteresting case where $T \to \infty$, this expression can be zero only if the numerator is zero. Therefore, we need to solve

$$-5\lambda_{\mathrm{m}}k_{\mathrm{B}}T\left(e^{hc/\lambda_{\mathrm{m}}k_{\mathrm{B}}T}-1\right) + hce^{hc/\lambda_{\mathrm{m}}k_{\mathrm{B}}T} = 0,$$

where λ_{m} is the value of the wavelength for which the Planck Radiation Law has its maximum. If we substitute from $u = hc/\lambda_{\mathrm{m}}k_{\mathrm{B}}T$, then this equation reduces to

$$5(e^u - 1) = ue^u \Rightarrow 5 - 5e^{-u} = u.$$

This equation can be solved by simple iteration, by using a spreadsheet, for example. The trivial root is $u = 0$, but we are not interested in this solution, which corresponds to an infinite wavelength. Therefore, we start our iteration at the value 1 and find $5 - 5e^{-1} = 3.1606$. Then we insert this new value, finding $5 - 5e^{-3.1606} = 4.7880$, and so on. We reach convergence very quickly and obtain

$$u = \frac{hc}{\lambda_{\mathrm{m}}k_{\mathrm{B}}T} = 4.9651 \Rightarrow \lambda_{\mathrm{m}}T = \frac{hc}{k_{\mathrm{B}}4.9651}.$$

Using the values of the constants *h, c,* and k_{B}, we then find

$$\lambda_{\mathrm{m}} T = 2.898 \cdot 10^{-3}\ \mathrm{K\ m},$$

which is in complete agreement with the experimentally found value given by equation 36.3.

Stefan-Boltzmann Law: To obtain the total intensity radiated, *I,* we need to integrate Planck's Radiation Law over the wavelength, from zero to infinity. We find

$$I = \int_0^\infty \epsilon(\lambda)\, d\lambda = \int_0^\infty \frac{2\pi h c^2}{\lambda^5 \left(e^{hc/\lambda k_{\mathrm{B}} T} - 1\right)} d\lambda = \frac{2 k_{\mathrm{B}}^4 \pi^5}{15 h^3 c^2} T^4 =$$

Inserting the values for Planck's constant, Boltzmann's constant, and the speed of light, we can verify that the Stefan-Boltzmann constant is indeed given by

$$\sigma = \frac{2 k_{\mathrm{B}}^4 \pi^5}{15 h^3 c^2} = 5.6704 \cdot 10^{-8} \mathrm{W\ m^{-2} K^{-4}}.$$

Thus, we see that the radiation law derived by Planck contains the previously known radiation laws as special cases, as illustrated in Figure 36.5.

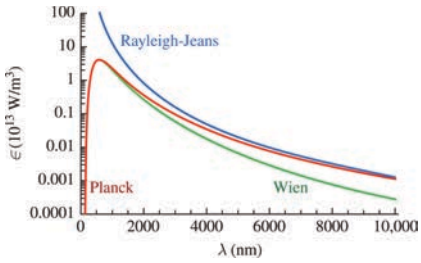

FIGURE 36.5
Comparison of Planck's Radiation Law, the Rayleigh-Jeans Law, and Wien's Law (using the constants from Derivation 36.1) for $T = 5000\ \mathrm{K}$.

Concept Check 36.1

The visible spectrum of light extends from approximately 380 nm (violet-blue) to 780 nm (red). What is the corresponding range of photon energies in units of electron-volts?

a) 1.59 eV to 3.26 eV

b) $2.54 \cdot 10^{-19}$ eV to $5.23 \cdot 10^{-19}$ eV

c) $0.38 \cdot 10^{15}$ eV to $0.78 \cdot 10^{15}$ eV

d) 190 eV to 390 eV

Planck's Law is consistent with Wien's Law for short wavelengths and agrees with the Rayleigh-Jeans Law at long wavelengths. This success earned immediate acceptance for Planck's Radiation Law for blackbodies, even though it was based on the radical assumption of quantized energy states. In particular, one can see from Derivation 36.1 how the quantum hypothesis resolves and avoids the classical ultraviolet catastrophe discussed earlier (see equation 36.4): For a given frequency *f*, the energy *hf* is needed to create a photon. As the frequency increases, it becomes

less and less likely that the system can supply the energy needed for the creation of a photon. This leads to a cutoff at high frequencies and thus at low wavelengths, in agreement with observations. Thus, the observed avoidance of the ultraviolet catastrophe is a direct consequence of the quantum nature of light.

Page 1123

The most stunning example of a blackbody spectrum is obtained from the cosmic background radiation. This radiation is a remnant of the Big Bang and is astonishingly uniform in the entire universe. The COBE satellite in 1990 and more recently the WMAP and Planck satellites have substantiated this in amazing detail. As indicated in Figure 36.6, the COBE mission found that the cosmic background radiation is that of a perfect blackbody at a temperature of $2.725 \pm 0.001\,\mathrm{K}$; that is, the entire universe is a perfect blackbody radiator. George Smoot and John Mather, the leaders of the COBE team, received the 2006 Nobel Prize in Physics for the achievements of that mission. (A more detailed discussion of the cosmic background radiation is presented in Chapter 39.)

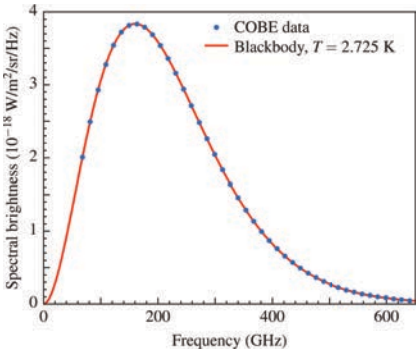

FIGURE 36.6 The spectral brightness of the cosmic background radiation as a function of frequency. The blue squares indicate data obtained by the COBE satellite, while the red curve is the Planck spectrum with a temperature of 2.725 K.

Just as blackbody radiation was used to measure the temperature of the universe, it can be used to measure the temperature of objects without physically touching them. If an object is hot enough, it will radiate photons in the visible range, as mentioned earlier in this section. For example, the temperature of molten iron in a steel factory can be measured by analyzing the photons radiated from the red-hot iron. Objects close to room temperature radiate photons mainly in the infrared range. Modern infrared thermometers can measure a person's temperature by observing the infrared radiation from the person's eardrum. Infrared thermometers are also used to measure the temperatures of food and electrical components.

36.3 Photoelectric Effect

Planck's hypothesis about the existence of some smallest possible discrete energy quanta was originally viewed as a computational construction, not as a real revolution in physics. This view changed, however, in 1905, with Einstein's explanation of the photoelectric effect. Einstein solved the puzzle of the photoelectric effect by proposing that light behaves as if it consists of localized bundles, or *quanta*, of energy-light. The photoelectric effect was originally discovered by Heinrich Hertz in 1886 and definitively demonstrated in 1916 by Robert A. Millikan, who quantitatively verified all of Einstein's predictions. Einstein's explanation of the photoelectric effect earned him the 1921 Nobel Prize in Physics. The quantized nature of light was conclusively demonstrated in 1923 by Arthur Holly Compton, as we will see in Section 36.4. The American chemist Gilbert Lewis (1875–1946) coined the term **photon** in 1926 to refer to these quanta of energy-light. For the remainder of this chapter, photons will be considered to be the quanta of light and all electromagnetic radiation.

In the **photoelectric effect,** light knocks electrons out of the surface of a suitable metal, creating an electric current. To see a practical application of the photoelectric effect, we have to look no further than the door of an elevator. How does the door sense that someone is standing in the opening? The answer is a photosensor, which usually consists of a light source and a light receptor utilizing the photoelectric effect. If an object, such as a person, is located between the light source and the receptor, the receptor no longer receives light and triggers electric switches to keep the elevator door open. Similarly, automatic garage-door openers are required to use a photosensor to avoid crushing a person on the way down.

A series of experiments can be performed to examine the photoelectric effect. Figure 36.7 shows the basic setup. On the left side is a light source, which could be a light bulb as shown or a light-emitting diode (which is utilized in many photocircuits) or just plain sunlight. On the right side is a photosensor, consisting of

a piece of metal (photocathode, rectangular shape) and a metal plate (anode, black line) housed in an evacuated glass container. A metal often used for the photocathode is cesium. The photosensor is part of a circuit with a voltage source and an ammeter. Between the light source and the photosensor is a filter that passes only one color of light (blue in this case). Experiments yield the following observations:

- With voltage set at $V = 0$ and a blue filter, a current is detectable in the ammeter. This indicates that electrons are crossing the gap between the photocathode and the anode. If the intensity of the light is increased, the measured current rises as well, indicating that more electrons move across the gap.
- With a red filter, no current is detectable in the ammeter. This finding does not change as a function of the light intensity.
- With a blue filter and a positive value of *V,* the current flowing through the ammeter rises. As voltage is changed to increasingly more negative values, the current measured in the ammeter is gradually reduced and then stops at some threshold value of the voltage.

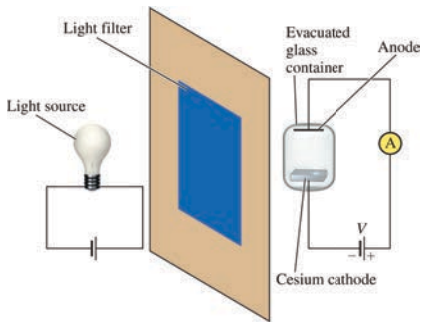

FIGURE 36.7
Schematic circuit diagram for the photoelectric effect.

From these experiments, one can conclude that electrons must get released from the surface of the metal by the light striking it. These electrons must have a kinetic energy, and the maximum of this kinetic energy can be measured by applying a negative voltage to the anode. The electrons need to overcome this voltage to cross the gap from the photocathode to the anode. If the electrons (charge $q = -e$) start with a maximum kinetic energy of $K_{\max}$ from the surface of the cathode and just reach the anode with zero kinetic energy after overcoming a potential of $V = -V_0$, then, from the work-energy theorem, we find

$$W = \Delta K + \Delta U = (0 - K_{\max}) + [(-e)(-V_0) - 0] = -K$$
$$eV_0 = K_{\max} = \tfrac{1}{2}mv_{\max}^2.$$

(The nonrelativistic approximation $\frac{1}{2}mv^2$ for the kinetic energy of the electrons can be used here, because the electrons are moving slowly in this case.) The potential V_0 is called the *stopping potential,* and for a given material it depends on the color of the light, which implies that it has a frequency dependence. Careful measurements reveal a linear dependence of V_0 on the frequency f. In addition, below a certain frequency, the stopping potential becomes zero. Light with a lower frequency is not able to give the electrons in the photocathode enough energy to escape from its surface.

The key conceptual problems of the photoelectric effect from the viewpoint of classical wave physics can be summarized as follows:

- Classically, a beam of light of any frequency can eject electrons from a metal, as long as the light has enough intensity. However, observations show that the incident light beam must have a frequency greater than the minimum value, $f_{\min}$, regardless of its intensity. Einstein's explanation was that the energy of the energy-light quantum (the photon) is proportional to the frequency, $E = hf$.

- Classically, the maximum kinetic energy of the ejected electrons should increase with increasing intensity of the light beam. However, observations show that increasing the intensity of the light beam increases the number of electrons ejected per second, not their energy; only increasing the frequency of the light increases the energy of the ejected electrons.

The physical picture of the photoelectric effect is that a photon with an energy determined by equation 36.5 hits an electron at the surface of the metal and ejects it from the material, provided that the electron gains sufficient energy to overcome its attraction to the material.

For a given material, a minimum energy is required to free an electron from the surface. This minimum energy, called the **work function, ϕ**, is a constant for a given material. The maximum kinetic energy that an electron can have after colliding with a photon and being freed from the metal surface is then $K_{\max} = hf - \phi$. Because $K_{\max}$ cannot be negative, this equation tells us that there is a minimum (threshold) light frequency necessary for the photoelectric effect to occur:

$$f_{\min} = \phi/h, \qquad \textbf{(36.15)}$$

which is consistent with the experimental results. Table 36.1 shows work functions and corresponding threshold frequencies and cutoff wavelengths for various metals. Using the connection between the maximum kinetic energy and the stopping potential in equation 36.14, we then find for the frequency dependence of the stopping potential in the photoelectric effect:

$$eV_0 = hf - \phi. \qquad \textbf{(36.16)}$$

Table 36.1 Work Functions and Corresponding Minimum Frequencies and Maximum Wavelengths for Common Elements

Element	$\phi(\text{eV})$	$f_{\text{min}}\left(10^{15}\text{Hz}\right)$	$\lambda_{\text{max}}(\text{nm})$

Work Functions and Corresponding Minimum Frequencies and Maximum Wavelengths for Common Elements			
Element	$\phi(\mathrm{eV})$	$f_{\min}\left(10^{15}\mathrm{Hz}\right)$	$\lambda_{\max}(\mathrm{nm})$
Uranium	3.6	0.87	344
Zinc	4.3	1.04	288

EXAMPLE 36.1 Work Function

Suppose you are using a circuit like that in Figure 36.7 and you have a photosensor with an unknown material for the photocathode. When using light of wavelength 250 nm (ultraviolet), you find that you have to apply a stopping potential of 2.86 V to eliminate the current. When using light of wavelength 392 nm (blue-violet), you measure a value of 1.00 V for the stopping potential, and using a wavelength of 540 nm (orange), you measure a stopping potential of 0.170 V.

PROBLEM

What is the value of the work function for this material?

SOLUTION

It is perhaps easiest to solve this problem in graphical form. Equation 36.16 shows that the stopping potential, the work function, and the frequency have a linear relationship, and because linear relationships can be drawn as straight lines, it is best to convert the given wavelengths into corresponding frequencies by using $f = c/\lambda$. We then plot the stopping potential, V_0, as a function of frequency for the three given data points (Figure 36.8). When we fit a straight line through these data points, the line gives us a value of -2.1 V at $f = 0$. Using equation 36.16, we then find for the work function:

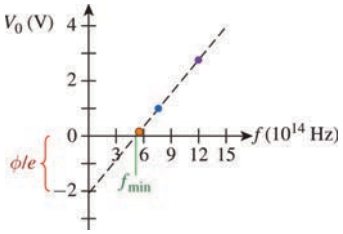

FIGURE 36.8
Applied stopping potential as a function of the frequency of light for a particular photosensor material.

$$eV_0(f = 0) = -\phi \Rightarrow \phi = -e\,V_0(f = 0) = -e(-2.1\ \text{V}) =$$

Looking at Table 36.1, we can see that the material used in this photosensor is probably cesium, which has the lowest work function of all the metals listed.

Self-Test Opportunity 36.1

Assuming that the work function in Example 36.1 indeed has a value of 2 eV, find the maximum kinetic energy that emitted electrons can have for the three given cases of light of different wavelengths incident on the photosensor.

Chapter 35, on relativity, showed that the momentum and the energy of any particle are related by $E^2 = P^2c^2 + m^2c^4$. A photon has zero mass, so its energy and momentum are related by $E = pc$. (When the symbol p is used with no arrow, it stands for the magnitude of the momentum; however, we may refer to p simply

as the momentum.) For the momentum of a photon, we can then write, from equation 36.8:

$$p = \frac{E}{c} = \frac{hf}{c} = \frac{h}{\lambda}. \qquad \textbf{(36.17)}$$

Thus, we see that a photon's momentum and energy are both proportional to the frequency and inversely proportional to the wavelength of the corresponding electromagnetic radiation. A photon acts like a particle, even though it is described by a frequency. Light acts like a wave even though it consists of particles called photons. This **wave-particle duality** of light is conceptually hard to grasp, and it kept physicists and philosophers busy for the first part of the 20th century.

Several practical problems are associated with detecting single photons of visible light. First, as you found in Concept Check 36.1, each photon has energy only in the range between 1.6 and 3.3 eV. Expressed in SI units, this is in the range between $2.6 \cdot 10^{-19}$ and $5.3 \cdot 10^{-19}$ J—a very small amount of energy. Even the best photocathodes have a quantum efficiency of only 30% or less for a photon in this energy range, meaning that at most only 30% of the photons hitting the photocathode actually manage to knock out an electron. Second, one liberated electron (or photoelectron) represents only a very tiny charge and thus only a very tiny current. To register an easily measurable current, many electrons need to be generated from each photoelectron. Many practical devices accomplish this with photomultiplier tubes.

A **photomultiplier tube** makes use of the fact that an electron that hits a metal surface with a kinetic energy on the order of 100 eV usually knocks out several electrons in the process. Therefore, a photocathode and an anode are combined in an evacuated glass tube with several intermediate plates, called *dynodes*. Each dynode is kept at a potential difference of several

hundred volts relative to its neighbors (Figure 36.9). Commercially available photomultiplier tubes have chains of up to $n = 14$ dynodes, and each dynode produces a statistical average of η electrons for each electron that hits it, where η can have values of up to 3.5. The total gain of such a photomultiplier tube is then η^n. For $n = 14$ and $\eta = 3.4$, for example, this gain factor is $2.76 \cdot 10^7$ —that is, almost 28 million electrons are produced at the anode for each photoelectron knocked out of the photocathode by a single photon.

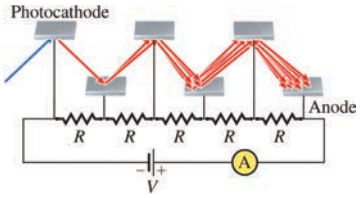

FIGURE 36.9
Schematic diagram of a photomultiplier tube. The blue arrow represents a single photon, and the red arrows represent electrons.

Another application of the detection of photons is night-vision devices. A schematic diagram of a night-vision device is shown in Figure 36.10b. In a night-vision device, an entire image of an object is focused on the photocathode by the objective lens. The incident photons cause the photocathode to release electrons. A potential difference of around 1000 V accelerates these electrons into a microchannel plate that contains an array of millions of channels that function like miniature photomultiplier tubes, multiplying the number of electrons by a factor of around 10^4. A second potential difference of around 1000 V between the microchannel plate and a phosphor screen accelerates the multiplied electrons so that they hit the screen and cause the emission of green light where they strike the screen, forming an intensified image. This light is then focused by the eyepiece to produce an image like the one shown in Figure 36.10c. This type of night-vision device works by amplifying

low light levels. There is another type of night-vision device that uses infrared light emitted by warm objects to observe those objects in the dark.

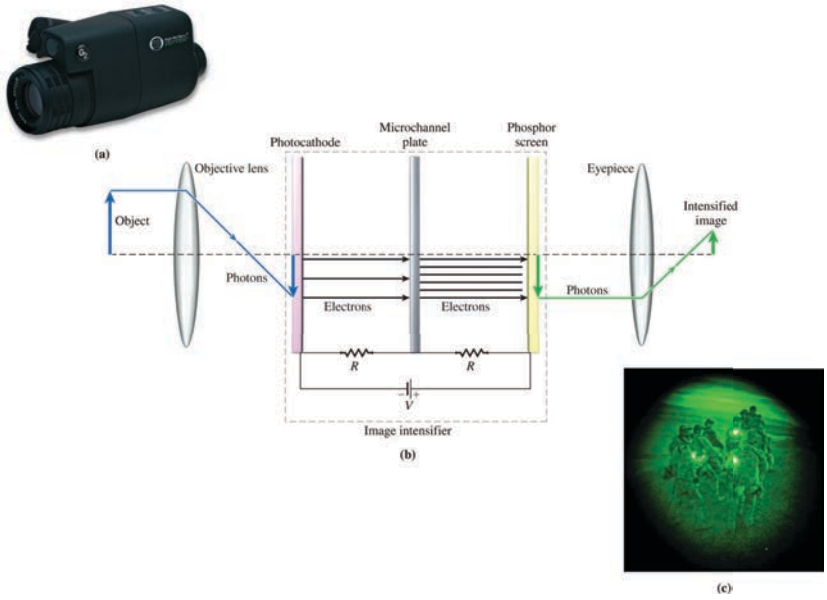

FIGURE 36.10 A night-vision device produces an intensified image of an object in low-light conditions. (a) Photo of a night-vision device; (b) schematic diagram; (c) image produced with a night-vision device.

Concept Check 36.2

You have a source of light with a given intensity and wavelength. You reduce the wavelength while leaving the intensity the same. Which of the following statements is true?

a) More photons per second will be emitted from the light source.

b) Fewer photons per second will be emitted from the light source.

c) The number of photons emitted per second will remain the same, but the energy of each one will be reduced.

d) The number of photons emitted per second will remain the same, but the energy of each one will be increased.

e) The number of photons emitted per second will remain the same, but each one will move slower.

Other methods are also used to detect single photons and convert them into an electric signal. Most notable among these are charge-coupled devices (CCDs) and complementary metal oxide semiconductor devices (CMOS), which form the basis of every digital camera and video recorder. However, an understanding of the physics underlying a CCD or a CMOS requires knowledge of semiconductors.

EXAMPLE 36.2 Photons from a Laser Pointer

Any object that you see emits photons that travel from the object to your retinas, where the photons trigger electric signals that are sent to your brain. Let's look at a light source to begin to understand the numbers of photons involved.

PROBLEM

What is the approximate number of photons emitted per second by a 5.00-mW green laser pointer?

SOLUTION

Green laser pointers usually operate at a wavelength of 532 nm. A wavelength of 532 nm corresponds to a frequency of

$$f = \frac{c}{\lambda} = \frac{2.998 \cdot 10^{8}\ \text{m/s}}{5.32 \cdot 10^{-7}\ \text{m}} = 5.635 \cdot 10^{14}\text{Hz}.$$

With Planck's hypothesis, $E = hf$, we can calculate the energy contained in a single photon emitted by the green laser pointer:

$$E = hf = \left(6.626 \cdot 10^{-34}\ \text{J s}\right)\left(5.635 \cdot 10^{14}\text{s}^{-1}\right) = 3.73 \cdot 10$$

Because the laser pointer is rated at 5.00 mW, it emits 5.00 mJ of energy each second. The number of photons emitted in each second is therefore

$$n = \frac{5.00 \cdot 10^{-3}\ \text{J}}{3.73 \cdot 10^{-19}\ \text{J}} = 1.34 \cdot 10^{16}.$$

In other words, this little handheld laser pointer emits over 13 million billion photons each second!

DISCUSSION

The energy of a single photon emitted from this green laser pointer can be expressed in units of eV s as well:

$$E = hf = \left(4.13567 \cdot 10^{-15}\text{eV s}\right)\left(5.635 \cdot 10^{14}\text{s}^{-1}\right) = 2.33$$

Now you may begin to grasp the usefulness of the electron-volt as the energy unit for dealing with atomic and quantum phenomena. The typical energy scale for processes in this realm is the electron-volt.

Self-Test Opportunity 36.2

Calculate the number of photons in the visible spectrum emitted each second by the Sun. To solve this problem, you need to know that the Sun's radiation has an intensity of $1370\,\text{W/m}^2$ on Earth, which is at a distance of 148 million km from the Sun. From this information, you can calculate the total power output of the Sun. Then, by examining Figure 36.4, you can see that approximately $\frac{1}{4}$ of the photons in the Sun's radiation are in the visible spectrum.

36.4 Compton Scattering

The discussion of the electromagnetic spectrum in Chapter 31 characterized X-rays as those electromagnetic waves with frequencies approximately 100 to 100,000 times higher than visible light. Viewing the electromagnetic spectrum as consisting of photons, we see that X-ray photons have energies of hundreds to hundreds of thousands of electron-volts. X-rays can be produced by accelerating electrons until they have several thousand electron-volts (several keV) of kinetic energy and then shooting them into a metal foil. The deceleration of the electrons in the foil creates the X-rays. These X-rays are called **Bremsstrahlung,** which is the German word for "deceleration radiation." (Another process also occurs in which atoms become excited and then emit X-rays of certain energies; this process is discussed in Chapter 38.) Classical electromagnetic theory can make certain predictions for electromagnetic radiation produced with accelerated charges, but a complete understanding really requires a theory called **quantum electrodynamics,** developed in the 1950s by American physicists Julian Schwinger (1918–1994) and Richard Feynman (1918–1988) and Japanese physicist Sin-Itiro Tomonaga (1906–1979), for which they shared the 1965 Nobel Prize in Physics.

For now, consider what happens when an X-ray scatters off an electron. First, what does the wave picture of light predict? If a wave hits a stationary small object like an electron, Huygens's Principle tells us that a spherical wave originates from the object, scattering (reflecting) the incoming wave. The scattered wave has the same frequency and wavelength as the incoming wave. However, in 1923, American physicist Arthur Holly Compton (1892–1962) discovered that X-rays scattered off electrons at rest produce X-rays with longer wavelengths than the original X-rays. A larger wavelength implies a smaller frequency, and thus lower

energy and momentum for the X-ray photons, according to equation 36.8.

If one accepts that photons have particle-like properties of momentum and energy, then the interaction of an X-ray and an electron can be analyzed just like the scattering of one billiard ball off another. Because photons move with the speed of light and because the energies of X-rays are not negligible compared to the mass of the electron, we have to employ relativistic dynamics (Chapter 35) and cannot simply use the formulas developed in Chapter 7 on momentum and collisions. However, conservation laws of energy and momentum are still applied to arrive at the desired result.

Let's call the energy of the X-ray photon before the collision E and after the collision $E\prime$. Then the magnitudes of the corresponding momenta of the photon before and after the collision are $p = E/c$ and $p\prime = E\prime/c$. The electron has no momentum before the collision because we assume that it is at rest. During the collision, it receives a momentum $\vec{p}_e$. A diagram of the scattering process is shown in Figure 36.11. The energy of the electron before the collision is simply its rest energy, $m_e c^2$, and its energy after the collision is

$$E_e = \sqrt{(p_e c)^2 + (m_e c^2)^2}.$$

Energy and momentum conservation during the collision then imply

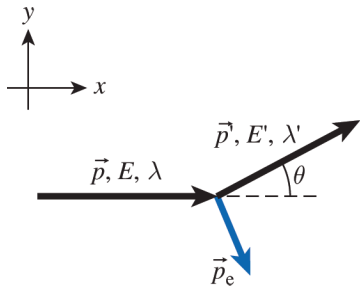

FIGURE 36.11
Momentum conservation in Compton scattering.

$$\overrightarrow{p\prime} + \overrightarrow{p_{\mathrm{e}}} = \overrightarrow{p} \tag{36.18}$$

and

$$E\prime + E_{\mathrm{e}} = E + m_{\mathrm{e}}c^2. \tag{36.19}$$

Derivation 36.2 shows that the final wavelength of the X-ray can be expressed as

$$\lambda\prime = \lambda + \frac{h}{m_{\mathrm{e}}c}(1 - \cos\theta), \tag{36.20}$$

where θ is the angle between the incoming and outgoing photon. This is the formula for **Compton scattering,** linking the wavelength of the photon after scattering to the wavelength of the incoming photon.

DERIVATION 36.2 Compton Scattering

To derive equation 36.20, we isolate $\overrightarrow{p_e}$ in equation 36.18 and E_e in equation 36.19. For the first equation, this results in $\overrightarrow{p_e} = \overrightarrow{p} - \overrightarrow{p'}$. We square both sides, to obtain

$$p_e^2 = \left(\overrightarrow{p} - \overrightarrow{p'}\right)^2 = p^2 + p'^2 - 2pp'\cos\theta. \qquad \textbf{(i)}$$

Page 1129

Rearranging and squaring each side of equation 36.19 yields

$$E_e = E - E' + m_e c^2 \Rightarrow$$
$$E_e^2 = \left(E - E' + m_e c^2\right)^2 \Rightarrow$$
$$p_e^2 c^2 + m_e^2 c^4 = (E - E')^2 + m_e^2 c^4 + 2(E - E')m_e c^2,$$

where we have made use of the relativistic energy-momentum relation, $E_e^2 = p_e^2 c^2 + m_e^2 c^4$ (see Section 35.4) on the left-hand side of the last line of this calculation. We can also use the relation between momentum and energy, $E = pc$, for the photon and obtain

$$p_e^2 c^2 + m_e^2 c^4 = (p - p')^2 c^2 + m_e^2 c^4 + 2(p - p')m_e c^3.$$

Subtracting the term $m_e^2 c^4$ from both sides and then dividing by a common factor c^2 gives

$$p_e^2 = (p - p')^2 + 2(p - p')m_e c. \qquad \textbf{(ii)}$$

Equations (i) and (ii) have the same left-hand side, and so their right-hand sides must be equal:

$$p^2 + p\prime^2 - 2pp\prime\cos\theta = (p - p\prime)^2 + 2(p - p\prime)m_e c.$$

Using $(p - p\prime)^2 = p^2 + p\prime^2 - 2pp\prime$, we then get

$$p^2 + p\prime^2 - 2pp\prime\cos\theta = p^2 + p\prime^2 - 2pp\prime + 2(p - p\prime)m_e c \Rightarrow$$
$$2pp\prime(1 - \cos\theta) = 2(p - p\prime)m_e c.$$

Now we use the relationship in equation 36.17 between a photon's momentum and wavelength, $p = h/\lambda$, and find

$$2\frac{h}{\lambda}\frac{h}{\lambda\prime}(1 - \cos\theta) = 2\left(\frac{h}{\lambda} - \frac{h}{\lambda\prime}\right)m_e c \Rightarrow \frac{h}{m_e c}(1 - \cos\theta$$

which is the result stated in equation 36.20.

The ratio of the constants $h/m_e c$ has the dimension of length, as can be seen from equation 36.20. This characteristic of an electron is called the **Compton wavelength** of the electron and has the value

$$\lambda_e = \frac{h}{m_e c} = \frac{6.626 \cdot 10^{-34}\ \text{J s}}{\left(9.109 \cdot 10^{-31}\ \text{kg}\right)\left(2.998 \cdot 10^{8}\text{m/s}\right)} = 2.42($$

Self-Test Opportunity 36.3

The electrons inside a metal are not quite at rest but have kinetic energies of a few electron-volts. Why is it permissible to assume that the electron is at rest in the derivation of the Compton scattering formula?

SOLVED PROBLEM 36.1 Compton Scattering

PROBLEM

An X-ray photon with a frequency of $3.3530 \cdot 10^{19}$ strikes an electron in a metal foil, and the scattered photon is detected at an angle of 32.300° relative to the direction of the incoming photon.

a) What are the energies of the incoming and scattered photons, in electron-volts?

b) What is the kinetic energy of the electron after the collision?

c) What is the magnitude of the momentum of the electron after the collision?

SOLUTION

THINK

Let's begin with the incoming photon. Converting its frequency into energy is a straightforward application of $E = hf$. Since we want the answer to have units of electron-volts, we need to use Planck's constant expressed in eV s: $h = 4.13567 \cdot 10^{-15}$ eV s. Now, for the electron, we know that energy is conserved in the scattering of a photon off an electron. (This comes as no surprise, since energy conservation was one of the starting principles in our derivation of the Compton scattering formula.) Thus, the kinetic energy that the electron receives in this scattering process is simply equal to the energy lost by the photon.

SKETCH

If we assume that the incoming photon travels along the positive x-axis, that the scattering event takes place in the xy-plane, and that the photon is deflected to positive values of y, we can use Figure 36.11 for our sketch.

RESEARCH

a) We only need to insert the given value for the incoming photon's frequency into $E = hf$ to obtain that photon's energy. To find the energy of the scattered photon, we need to use the Compton scattering formula. For this equation, we need the wavelength of the incoming photon, which we can obtain from the frequency via $\lambda = c/f$. For the Compton scattering process, we have just derived that $\lambda\prime = \lambda + h(1 - \cos\theta)/(m_e c)$. Once we have the wavelength of the scattered photon, we can convert that value to an energy value using $E\prime = hf\prime = hc/\lambda\prime$.

b) As stated above, total energy is conserved. The electron is assumed to be stationary before the scattering event; that is, it has zero kinetic energy. The final kinetic energy of the electron is thus simply equal to the energy lost by the photon: $K_\mathrm{e} = E - E\prime$. Finally, we can calculate the absolute value of the momentum of the electron from the energy-momentum relation derived in Chapter 35:

$$p_\mathrm{e} = \frac{1}{c}\sqrt{(K_\mathrm{e} + m_\mathrm{e}c^2)^2 - m_\mathrm{e}^2c^4}.$$

SIMPLIFY

We can evaluate the expression for the energy of the scattered photon as follows:

$$E\prime = \frac{hc}{\lambda\prime} = \frac{hc}{\lambda + \dfrac{h}{m_\mathrm{e}c}(1 - \cos\theta)} = \frac{hc}{\dfrac{hc}{E} + \dfrac{h}{m_\mathrm{e}c}(1 - \cos$$

For the electron's momentum, we find

$$p_\mathrm{e} = \frac{1}{c}\sqrt{(K_\mathrm{e} + m_\mathrm{e}c^2)^2 - m_\mathrm{e}^2c^4} = \frac{1}{c}\sqrt{K_\mathrm{e}^2 + 2K_\mathrm{e}m_\mathrm{e}c^2}.$$

CALCULATE

a) The energy of the incoming X-ray photon is

$$E = hf = \left(4.13567 \cdot 10^{-15}\text{eV s}\right)\left(3.3530 \cdot 10^{19}\ \text{s}^{-1}\right) = 13$$

The energy of the scattered X-ray photon is

$$E\prime = \frac{1}{\frac{1}{138.67\ \text{keV}} + \frac{1}{511.00\ \text{keV}}(1 - \cos 32.300^\circ)} = 13$$

b) The kinetic energy of the electron after the collision is

$$K_\text{e} = E - E\prime = 138.67\ \text{keV} - 133.08\ \text{keV} = 5.59\ \text{keV}.$$

c) The electron's momentum is

$$p_\text{e} = \frac{1}{2}\sqrt{(5.59\ \text{keV})^2 + 2(5.59\ \text{keV})(511.00\ \text{keV})} = 75.8$$

ROUND

The computed values have been rounded to the proper number of significant figures. But why do the values for the electron's kinetic energy and momentum have only three digits? After all, the input values were given to five significant figures. The answer is that we were able to compute the initial and final photon energies only to the nearest 0.01 keV, and since the electron's kinetic energy is the difference between these two energies, its accuracy is limited to the nearest 0.01 keV.

DOUBLE-CHECK

In order to obtain the electron's momentum, we could use momentum conservation and find

$$\overrightarrow{p_{\mathrm{e}}} = \overrightarrow{p} - \overrightarrow{p\prime}.$$

Since we have calculated the energies of the photons before and after the collision, we can obtain the magnitudes of the momentum vectors for the incoming and scattered photons in units of keV/c:

$$\begin{aligned} p &= \frac{E}{c} = 138.67\,\mathrm{keV/c}, \\ p\prime &= \frac{E}{c} = 133.08\,\mathrm{keV/c}. \end{aligned}$$

The momentum of the incoming photon, $\overrightarrow{p}$, has only an x-component, because we assumed that it traveled along the positive x-axis. Thus,

$$p_x = 138.67\,\mathrm{keV/c} \quad \text{and} \quad p_y = 0.$$

The angle of the scattered photon was specified in the problem statement as 32.300°. We then obtain for the Cartesian components of the momentum vector for this photon:

$$p'_x = (133.08\,\mathrm{KeV}/c)\cos(32.00^\circ) = 112.49\,\mathrm{keV}/c$$

and

$$p'_y = (133.08\,\mathrm{keV}/c)\sin(32.300^\circ) = 71.112\,\mathrm{keV}/c.$$

Thus, the components of the electron's momentum are

$$p_{\mathrm{e},x} = p_x - p'_x = 138.67\,\mathrm{keV}/c - 112.49\,\mathrm{keV}/c = 26.18\,\mathrm{k}$$

and

$$p_{\mathrm{e},y} = p_y - p\prime_y = -71.11\,\mathrm{keV}/c.$$

Now we can obtain the magnitude of the electron's momentum vector by the usual procedure of taking the square root of the sum of the squares of the components:

$$p_{\mathrm{e}} = \sqrt{p_{\mathrm{e},x}^2 + p_{\mathrm{e},y}^2} = 75.8\,\mathrm{keV}/c.$$

This is the same result as we obtained above, showing that our two methods of solution are consistent with each other.

Self-Test Opportunity 36.4

Why do you have to use X-rays to observe the Compton effect? Can you explain why Compton scattering is not observable for visible light?

36.5 Matter Waves

So far, we have established that photons are the quantum particles of light and of all other electromagnetic radiation. However, everything we have said about the wave nature of light is still true; for example, we can demonstrate interference and diffraction, which are typical wave phenomena. Looking at light as quantum particles does not invalidate the wave picture of light, just as the ray picture of light can be seen as a special limiting case of the more general wave description of light.

Given the quantum character of light and the particle character of electromagnetic waves, do things that we ordinarily think of as particles, like electrons and atoms, also have wave properties? This is exactly what Prince Louis de Broglie (1892–1987), a French graduate student at the time, proposed in 1923. His original publication, all of four pages long, contained this hypothesis, and he later was awarded the Nobel Prize in Physics in 1929.

If particles have wave character, then what is the appropriate wavelength? For light, we found (equation 36.17) that the momentum of a photon is $p = h/\lambda$. De Broglie used the same relationship for particles and proposed as the relevant wavelength for **matter waves:**

$$\lambda = \frac{h}{p} = \frac{h}{mv\gamma} = \frac{h}{mv}\sqrt{1 - \frac{v^2}{c^2}}. \qquad \textbf{(36.22)}$$

This wavelength, the de Broglie wavelength, depends on the mass m and speed v of a particle. Equation 36.22 used the relativistic form of the momentum, $p = mv\gamma$, but the literature often presents this nonrelativistic approximation for the **de Broglie wavelength:**

$$\lambda = \frac{h}{mv} \quad \text{(nonrelativistic approximation)}. \quad \textbf{(36.23)}$$

As Figure 36.12 shows for the case of an electron, at speeds of up to 40% of the speed of light, the nonrelativistic approximation is very close to the exact result given by equation 36.22.

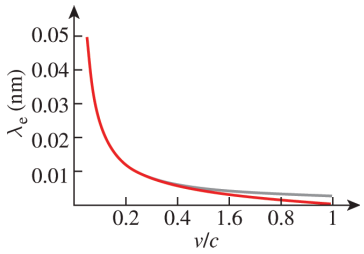

FIGURE 36.12 De Broglie wavelength of an electron as a function of its speed. Red curve is the exact result; gray curve is the nonrelativistic approximation.

Concept Check 36.3

Which of the following statements is true?

a) More massive and faster objects have bigger de Broglie wavelengths than less massive and slower ones.

b) Less massive and faster objects have bigger de Broglie wavelengths than more massive and slower ones.

c) More massive and slower objects have bigger de Broglie wavelengths than less massive and faster ones.

d) Less massive and slower objects have bigger de Broglie wavelengths than more massive and faster ones.

As you can see from Figure 36.12, the de Broglie wavelength of an electron, even one moving at 10% of the speed of light, is on the order of one-tenth of a nanometer. What are typical de Broglie wavelengths for macroscopic objects? Example 36.3 shows a calculation.

EXAMPLE 36.3 De Broglie Wavelength of a Raindrop

Raindrop diameters vary from approximately 0.50 mm to 5.0 mm. Drops at the lower end of this size range fall with speeds of 2 m/s; those at the upper end, with speeds up to 9 m/s.

PROBLEM

What is the range of de Broglie wavelengths for raindrops?

SOLUTION

The mass and diameter of a raindrop are related via

$$m = V\rho = \tfrac{4}{3}\pi r^3\rho = \tfrac{1}{6}\pi d^3\rho,$$

Page 1132

where ρ is the density, r is the radius, and d is the diameter of a drop. The density of water is $\rho = 1000\ \text{kg/m}^3$, so the mass of a drop with $d = 0.50$ mm is $6.5 \cdot 10^{-8}$ kg, and the mass of a drop with $d = 5.0$ mm is $6.5 \cdot 10^{-5}$ kg.

For the extremely small speeds under consideration in this example, we are fully justified in using the nonrelativistic approximation, $\lambda = h/mv$, for the de Broglie wavelength. We then obtain for the smallest raindrops

$$\lambda = \frac{h}{mv} = \frac{6.626 \cdot 10^{-34}\ \text{J s}}{\left(6.5 \cdot 10^{-8}\ \text{kg}\right)\left(2\ \text{m/s}\right)} = 5 \cdot 10^{-27}\ \text{m},$$

and for the largest raindrops, $\lambda = 1 \cdot 10^{-30}$ m.

DISCUSSION

Even the smallest and slowest-moving raindrops have de Broglie wavelengths that are many orders of magnitude smaller

than diameters of individual atoms, which are approximately 10^{-10} m. Thus, we can safely ignore all implications of matter waves for macroscopic objects. Any object that is big enough for us to see it with the unaided eye and that moves fast enough that we can discern some kind of motion at all has a de Broglie wavelength so small that any observation of quantum wave phenomena for the object is ruled out.

Self-Test Opportunity 36.5

Plot the de Broglie wavelength of an electron as a function of its kinetic energy, for kinetic energies between 1 and 1000 eV. Is there a visible difference in this range of energies if you use the nonrelativistic approximation, $p = \sqrt{2mk}$?

As we have seen in Solved Problem 36.1, the kinetic energy–momentum relationship for a particle is given by

$$p = \frac{1}{c}\sqrt{E^2 - m^2c^4} = \frac{1}{c}\sqrt{(K + mc^2)^2 - m^2c^4} = \frac{1}{c}\sqrt{K^2 -}$$

Therefore, the de Broglie wavelength can also be written as a function of the kinetic energy of a particle:

$$\lambda = \frac{h}{p} = \frac{hc}{\sqrt{K^2 + 2Kmc^2}}.$$

So far we have only discussed the theoretical possibility of matter waves, as described by de Broglie's hypothesis. Where is the experimental proof? Before we look at this proof, it is helpful to revisit material from Chapter 34 on wave optics and see what makes a wave a wave.

Double-Slit Experiment with Particles

To provide experimental evidence for the existence of matter waves, it is necessary to show that objects such as electrons, neutrons, protons, or whole atoms, which have mass and are normally thought of as particles, can exhibit wavelike behavior. Chapter 34 showed that the two main physical effects that characterize waves are interference and diffraction. What sort of experiment could show interference and/or diffraction of matter?

Young was able to demonstrate the wave character of light by shining light through two narrow slits, separated by a distance d. The interference pattern produced in this way is shown in Figure 36.13.

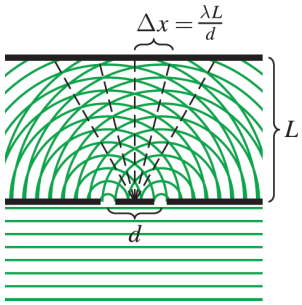

FIGURE 36.13
Double-slit interference for light.

In the double-slit experiment, bright interference fringes appear on the screen a distance L away from the slits. Provided that the line from the center of the two slits to a bright fringe makes a small angle with the perpendicular to the screen, the distance from this fringe to a neighboring fringe is given by

$$\Delta x = \frac{\lambda L}{d}. \qquad \textbf{(36.24)}$$

However, in the derivation in Chapter 34 of this formula for the interference maxima, it was necessary to use the condition that the width of an individual slit is on the order of the wavelength of the

light wave. For moderately fast-moving electrons, the de Broglie wavelength is on the order of one-tenth of a nanometer or less, and thus is more than three orders of magnitude smaller than the wavelength of visible light. Producing a double slit with sufficiently small slit separation d and individual slit width a for carrying out a double-slit experiment using electrons presents a sizable technical challenge. Also, if we want to use heavier particles, such as protons or neutrons, then the technical challenges become even bigger because the de Broglie wavelength is inversely proportional to the mass of a particle moving with a given speed.

For this reason, a double-slit experiment to verify the wave character of electrons was not carried out right after de Broglie proposed his revolutionary idea. Instead, an experiment in 1927 by American physicists Clinton Davisson (1881–1958) and Lester H. Germer (1896–1971), working at the Bell Telephone Laboratories in New Jersey, provided proof for the physical existence of matter waves. Davisson and Germer continued their earlier work on Bragg scattering of X-rays off crystals and scattered a beam of electrons off a nickel crystal, observing interference patterns similar to those produced by X-rays. Today, beams of neutrons can also be scattered off crystals; American physicist Clifford G. Shull (1915–2001) and Canadian physicist Bertram Brockhouse (1918–2003) received the 1994 Nobel Prize in Physics for pioneering such techniques. X-rays, electrons, and neutrons all provide equivalent Bragg-scattering patterns, proof that matter waves are real.

Only since the early 1960s has there existed sufficiently precise technology to conduct double-slit experiments with electrons. Let's think about what should happen in such an experiment and then compare our prediction with the outcome of the experiment. The basic setup of the experiment is shown in Figure 36.14. An electron is emitted from a plate in an electron gun (the plate is heated in order to do this, but the heater is not shown here) and then accelerated by a voltage V. It then passes through a double slit on its way to the screen.

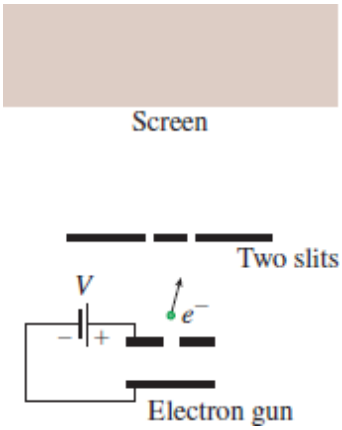

FIGURE 36.14 Experimental setup for an electron double-slit experiment.

If electrons behave like particles, they will travel in straight lines from the electron gun through one of the slits and on to the screen. We then predict that we will see the electrons as two lines on the screen—the images of the two slits. Since the electrons might get slightly deflected as they pass though a slit, the distribution of the electrons passing through each slit will be somewhat smeared out. Because the slit separation d is very small, the distributions of the electrons passing through the two slits will overlap on the screen. This classical particle-like expectation leads to a distribution of electrons hitting the screen as sketched in Figure 36.15a. Here the distribution from the electrons passing through the left slit is shown in blue, and that of the electrons passing through the right slit in red. Shown in green is the sum of the two, the total intensity distribution that should be recorded if our particle-like expectation bears out.

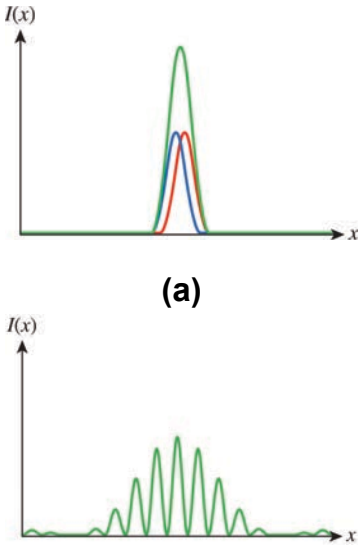

FIGURE 36.15
Intensity distribution (number of electrons hitting the screen per unit length) along the screen in the electron double-slit experiment. (a) Classical particle-like expectation; (b) expected distribution if electrons show matter-wave characteristics.

On the other hand, if electrons show wavelike characteristics, then their intensity distribution on the screen should be governed by the combined effects of interference and diffraction, just as we observed for light in Chapter 34 on wave optics. In this case (compare Section 34.3), the intensity as a function of the coordinate x along the screen should be

$$I(x) = I_{\max}\cos^2\left(\frac{\pi d}{\lambda L}x\right)\left(\frac{\lambda L}{\pi a x}\sin\left(\frac{\pi a}{\lambda L}x\right)\right)^2. \quad \textbf{(36.25)}$$

Here d is the slit separation, a is the width of the individual slits, and L is the distance between the double slit and the screen. This is the same terminology used in Young's double-slit experiment with light, but now λ is the de Broglie wavelength of the electron (equation 36.22). The function $I(x)$ of equation 36.25 is graphed in Figure 36.15b.

Figure 36.16 shows what the pattern of electrons striking the screen (yellow spots) might look like for an intensity distribution as given by equation 36.25, with a de Broglie wavelength of 12.2 pm, a slit separation of 3.0 nm, a slit width of 1.0 nm, and a distance to the screen of 1.0 m. The lower part of Figure 36.16 is the counting histogram—that is, the number of electron hits in a given interval of the coordinate x along the screen. Overlaid in red over the blue counting histogram is the intensity distribution of equation 36.25.

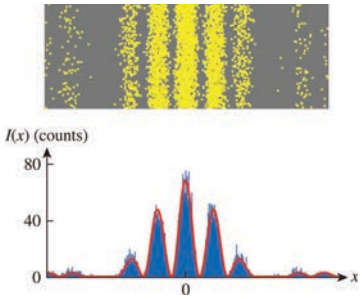

FIGURE 36.16
Connection between hits of individual electrons on the screen (yellow spots in upper part) and the count histogram (blue, lower part), with the predicted intensity distribution (red curve).

W. Bauer and G. D. Westfall

What is the outcome of the actual experiment? Electrons can be shot through the slits and at the screen individually, so the pattern can be observed to emerge as a function of time. This experiment was performed by P. G. Merli and colleagues in 1976; the outcome is shown in Figure 36.17. The lowest panel shows the final outcome of this experiment, with the interference fringes clearly visible. The experiment clearly demonstrates that the electrons show wavelike interference phenomena.

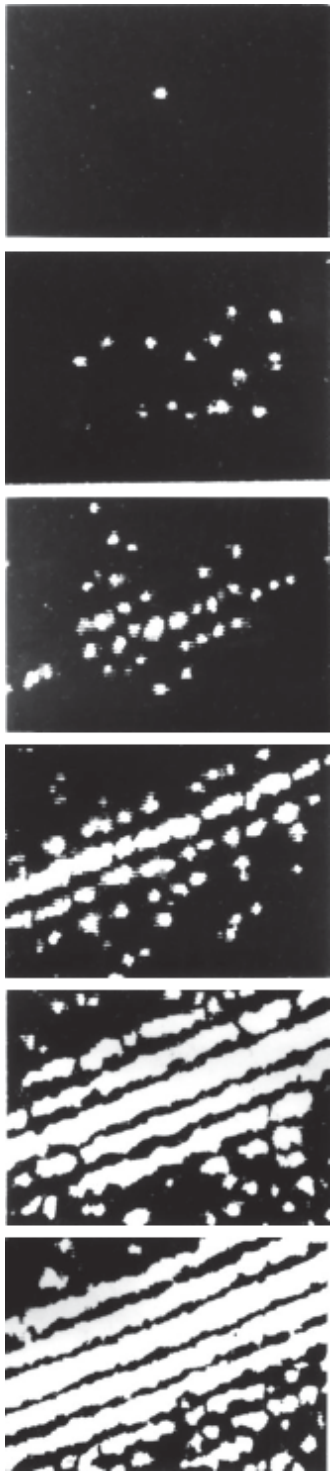

FIGURE 36.17
Experimental double-slit electron interference pattern as it develops over time, from top to bottom.

P.G. Merli, G.F. Missiroli, G. Pozzi, *American Journal of Physics,* "On the Statistical Aspect of Electron Interference Phenomena," 44(3):306-7, March 1976. © 1976, American Association of Physics Teachers

However, Figure 36.17 shows more: You can see that each individual electron leaves a mark by hitting a certain very localized area of the screen. Therefore, the idea that each electron somehow gets distributed over the entire screen, proportional to the overall intensity distribution, is not true either.

Because photons have particle properties, it might be expected that photons striking the double slits would exhibit the granularity shown in Figure 36.17. When the double-slit experiment is performed using one photon at a time, a pattern similar to that shown for electrons in Figure 36.17 is indeed observed.

So, what makes an individual electron follow the path that it does? This is the central question of quantum physics. Finding the answer will tell us most of what is essential about the atomic quantum world.

Are both slits essential for this interference pattern to emerge? In other words, does the electron somehow move through both slits at the same time? If one slit is closed, the interference pattern on the screen disappears, and only one maximum—the image of that slit—is produced. The result corresponds to either the red or the blue curve in Figure 36.15a, depending on which slit is covered.

What if, instead, it were possible to determine which slit the electron moves through without closing the other slit? Perhaps this could be accomplished by taking advantage of the fact that the electron has a charge and thus represents a current as it moves through a slit. It might be possible to measure this current.

Concept Check 36.4

Can you guess the outcome of measuring the current to determine which slit the electron passes through? If we measure the current representing the electron passing through the slits, which of the following will be the result?

a) Exactly one-half of each individual electron passes through each of the two slits.

b) Each individual electron passes through just one slit. The electrons passing through the left slit cause the left part of the interference pattern, and the electrons passing through the right slit cause the right part.

c) Each individual electron passes through just one slit. The electrons passing through the left slit cause the right part of the interference pattern, and the electrons passing through the right slit cause the left part.

d) Each individual electron passes through just one slit, but as we conduct measurements to try to determine this, the interference pattern on the screen is destroyed, and we observe only the central maximum on the screen.

We find that any attempt to associate an electron with a particular slit destroys the interference pattern. This outcome should become more acceptable when we further explore the wave character of electrons and other objects that we normally think of as particles.

36.6 Uncertainty Relation

How precisely is it possible to measure physical properties such as location, momentum, energy, and time? In addition, to what precision can two properties be measured simultaneously? This question is never considered in classical mechanics, where it is assumed that all dynamic quantities can be measured with arbitrary precision with improved instrumentation.

However, in the quantum realm, where particles exhibit wave character (de Broglie matter waves) and where waves behave like particles (photons), the answer is not so simple. How can the precise location of a wave be specified, for example? Perhaps more important, does the process of measuring a physical property of a quantum object influence the outcome of that measurement, as well as all future measurements? For instance, when we measure the position of an object, we typically record the light waves emitted from that object. However, these emitted light waves also carry momentum, as we have seen in this chapter. Thus, we can anticipate that the process of measuring a particle's position and its momentum cannot be done simultaneously with arbitrary precision.

Page 1135

Let the uncertainty in a measurement of a particle's position be Δx and the uncertainty in the measurement of its momentum be Δp_x, in the same sense as is done in statistics. In statistics, the outcome of a series of independent measurements of a quantity is quoted in terms of the mean value, which is the average of the measurements, plus or minus the standard deviation, which is a measure of the width of the distribution of the measurements. When a physical measurement is performed in the lab, the result also must be expressed in terms of the average value plus or minus the uncertainty in the measurement. (This uncertainty can be of

statistical or systematic origin, but we are not concerned with this distinction.)

The astonishing statement arising from quantum physics is that the momentum and the position of an object cannot be measured simultaneously with arbitrary precision. The more precisely we attempt to measure an object's momentum, the less precise the information on its position has to become, and vice versa. This physical statement is cast in mathematical terms in the form of the **Heisenberg Uncertainty Relation:**

$$\Delta x \cdot \Delta p_x \geq \tfrac{1}{2}\hbar. \qquad \textbf{(36.26)}$$

This relation was discovered in 1927 by the German physicist Werner Heisenberg (1901–1976) and caused a revolutionary change in our understanding of the measurement process, as well as of our fundamental ability to know the physical world. Chapter 37 will return to this uncertainty relation and use it for calculations. For now, to motivate this relation, we will use the same considerations suggested by Heisenberg in his original paper. This heuristic derivation uses the so-called gamma-ray microscope.

DERIVATION 36.3 Gamma-Ray Microscope and the Uncertainty Relation

If you want to see something in a microscope, you have to bounce light off that object and catch the reflected light in the lens. The minimum size, Δx, of the object that you can resolve with the microscope is limited by diffraction (see Chapter 34) and is given by

$$\Delta x = \frac{\lambda}{2 \sin \alpha} \approx \frac{\lambda \ell}{d}. \qquad \text{(i)}$$

Here λ is the wavelength of the light and α is the opening angle (Figure 36.18). In this figure, d is the diameter of the lens opening of the microscope, and ℓ is the distance between the object and the lens, which we assume to be large compared to the lens opening; then $2 \sin \alpha \approx d/\ell$. To resolve small sizes, we need to employ light with a short wavelength, that is, gamma rays. These gamma-ray photons carry a momentum $p = h/\lambda$ (see equation 36.17).

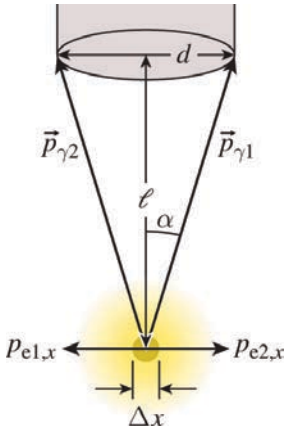

FIGURE 36.18 Geometry of a gamma-ray microscope and the momenta of a photon-electron interaction.

When the object (an electron) is hit with gamma rays (yellow circle, indicating a beam pointing into the page), the photons bounce off the object and get deflected into the lens opening via Compton scattering. In one extreme case, a photon can bounce off the electron and get deflected to the right edge of the opening. This photon has a momentum $\vec{p}_{\gamma 1}$, as shown in the figure. Its momentum component in the x-direction is $p_{\gamma 1,x} = p_{\gamma 1} \sin\alpha = h \sin\alpha/\lambda$. The electron receives the opposite x-component of momentum, $p_{e1,x}$, pointing to the left, due to recoil. At the other extreme, a photon receives momentum $\vec{p}_{\gamma 2}$ after the collision with the electron and gets scattered to the left edge of the lens opening, which causes a recoil of the electron with the same magnitude as before, but in the opposite direction.

We can detect that a photon has entered the lens opening but cannot detect where along the distance d it has done so. This means that it is undetermined which recoil the electron received. Thus, the momentum of the electron has an uncertainty of

$$\Delta p_x = 2\,|\,p_{\gamma 1,x}\,| = \frac{2h\sin\alpha}{\lambda}. \qquad \text{(ii)}$$

Combining equations (i) and (ii), we find

$$\Delta p_x = \frac{2h\sin\alpha}{\lambda} = \frac{h}{\Delta x}.$$

Thus, the product of the minimum uncertainty in the size of the electron and the uncertainty in the momentum of the electron is Planck's constant, h.

Page 1136

DISCUSSION

You may feel that this argument involves hand waving, and to a certain degree, it does. Our result is larger by a factor of 4π higher than the exact answer for the minimum product of momentum and coordinate uncertainties given in equation 36.26. However, an exact numerical relation is not the point of this analysis using a gamma-ray microscope. Instead, it shows a certain lower limit of the uncertainties in coordinate and corresponding momentum that can be observed simultaneously. This in itself is an astounding fact and a consequence of quantum physics.

Heisenberg also stated another uncertainty relation, for the uncertainties in the measurement of the energy of an object, ΔE, and in the measurement of the time, Δt. It is formally similar to the coordinate-momentum uncertainty relation of equation 36.26:

$$\Delta E \cdot \Delta t \geq \tfrac{1}{2}\hbar. \qquad \textbf{(36.27)}$$

DERIVATION 36.4 Energy-Time Uncertainty Relation

The coordinate-momentum uncertainty relation straightforwardly motivates the time-energy relation for a nonrelativistic free particle. For such a particle, the energy is all kinetic energy, and thus the uncertainty in the energy is

$$\Delta E = \Delta\left(\frac{p^2}{2m}\right) = \frac{\Delta\left(p^2\right)}{2m} = \frac{2p\Delta p}{2m} = v\Delta p.$$

The uncertainty in the time is given by

$$\Delta t = \frac{\Delta x}{v}.$$

Multiplying these two results, we find

$$\Delta E \cdot \Delta t = (v\Delta p) \cdot (\Delta x/v) = \Delta x \cdot \Delta p \geq \tfrac{1}{2}\hbar,$$

where we have used equation 36.26 in the last step.

The energy-time uncertainty relation stipulates that classical energy conservation can be violated by some amount of energy for some time interval, because the quantum state may not have a sharp energy value. The larger the "violation" of energy conservation is, however, the shorter the time interval for this "violation" will be.

Do these uncertainty relations conflict with our everyday experience? In other words, how important are the fundamental limitations imposed by the uncertainty relations? Let us examine an example.

Concept Check 36.5

In Example 36.4, if all other parameters remain the same but the mass of the car is doubled, the resulting uncertainty in the speed will be

a) the same.

b) half as large.

c) one-quarter as large.

d) twice as large.

e) four times as large.

EXAMPLE 36.4 Trying to Get Out of a Speeding Ticket

PROBLEM

On the German autobahn, some sections actually do have a speed limit. Occasionally the German police set up speed traps in these sections. They measure the speed of a vehicle and take a picture of the driver at the same time, as proof that they really have the right person committing the offense. A German physics student receives such a picture of herself and her car (a BMW 318Ci of mass 1462 kg, including the driver and the gas in the tank), with a notification that she was driving 132 km/h in a zone with a 100-km/h speed limit. She notices that the picture the police took is very sharp and fixes her position to an uncertainty of 1 mm. She argues that the uncertainty relation prevents the police from determining her speed precisely, and she therefore should not get a speeding ticket, or at least not get one for driving more than 30 km/h above the speed limit, which would cause her to lose her license. Will this strategy be successful?

Page 1137

SOLUTION

If the judge knows physics, the student will not be successful. Here is why: If the mass of the car is known precisely enough, then the uncertainty in the speed is found from the uncertainty in the momentum as

$$\Delta v = \frac{1}{m}\Delta p.$$

Using the uncertainty relation, we find the uncertainty in the momentum to be $\Delta p \geq \frac{1}{2}\hbar/\Delta x$, leading us to a value of the uncertainty in the speed of

$$\Delta v = \frac{1}{m}\Delta p \geq \frac{\hbar}{2m\Delta x}.$$

Using the constant (see equation 36.7) $\hbar = 1.05457 \cdot 10^{-34}$ J s and the values of $\Delta x = 10^{-3}$ m and $m = 1462$ kg given in the problem statement, we find

$$\Delta v \geq \frac{1.05457 \cdot 10^{-34}\,\text{J s}}{2(1462\,\text{kg})\left(10^{-3}\,\text{m}\right)} = 3.6 \cdot 10^{-35}\text{m/s}.$$

The restriction on the minimum measurement uncertainty in the speed due to the uncertainty relation is 35 orders of magnitude too small to be useful for the student's defense!

Self-Test Opportunity 36.6

How precisely would the position of the car in Example 36.4 have to be fixed to validate the student's claim that she should not have to surrender her driver's license because the uncertainty in her speed had to be larger than 2.00 km/h?

The uncertainty relation is perhaps the most important result discussed in this chapter and has far-reaching consequences. It sets a fundamental limit on how precisely we can measure and therefore know anything about our world. For macroscopic objects, the effect of the uncertainty relation can safely be neglected in almost all applications. However, an insurmountable limit exists to the precision of simultaneous measurements of pairs of variables, such as momentum and position, or energy and time. The analysis using the gamma-ray microscope seems to imply that the attempt to measure the location somehow imparts a simple recoil onto the object being measured. But in the quantum world, the objects normally characterized as particles have wave character, just as what we normally understand as a wave has particle character. At its core, the uncertainty relation derives from this particle-wave

duality. This will be explored in detail in Chapter 37, where we will learn how to calculate properties with the tools of quantum mechanics.

36.7 Spin

Stern-Gerlach Experiment

In 1920, two German physicists, Otto Stern (1888–1969) and Walther Gerlach (1889–1979), performed one of the most influential experiments in the history of quantum physics. In this experiment, they tried to distinguish between a classical and a quantum description of atoms.

The basic setup of the Stern-Gerlach experiment is shown in Figure 36.19. An oven produces a gas of (electrically neutral) silver atoms. These atoms are allowed to escape from the oven through a hole and form a "beam" of silver atoms, which move along a straight line (green dots in the figure). The silver atoms then enter a strong inhomogeneous magnetic field and continue on to a screen.

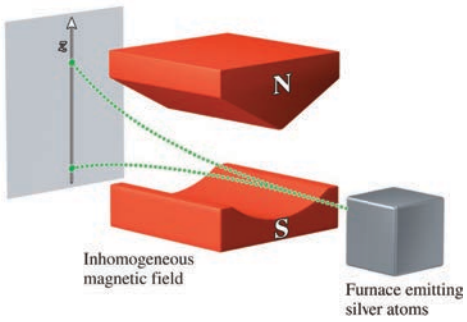

FIGURE 36.19 Basic setup of the Stern-Gerlach experiment.

Section 28.5 mentioned that atoms can have a magnetic moment,

$$\vec{\mu} = -\frac{e}{2m}\vec{L},$$

where $\vec{L}$ is the angular momentum. Section 28.5 considered only the magnetic moment due to a charge in a circular orbit, and the angular momentum was the orbital angular momentum. Section 27.6 showed that the potential energy of a magnetic dipole in a magnetic field is $U = -\vec{\mu} \bullet \vec{B}$. The force is then the negative value

of the gradient of the potential energy. In a magnetic field that changes only as a function of the *z*-coordinate, the force is

$$F_z = -\frac{\partial}{\partial z}\left(-\vec{\mu} \bullet \vec{B}\right) = \mu_z \frac{\partial B}{\partial z}.$$

Stern and Gerlach tried to determine whether the orbital angular momentum was quantized. Sending a beam of atoms that have a magnetic moment through an inhomogeneous magnetic field causes a deflection of the beam, due to the interaction of the field gradient, $\partial B/\partial z$, with the *z*-component of the magnetic moment of each atom, μ_z. Classically, the magnetic moment can have any value along the *z*-axis in the interval between $-\left|\vec{\mu}\right|$ and $+\left|\vec{\mu}\right|$, which should produce a line on the screen that corresponds to all possible deflections. However, in the quantum realm, only discrete values of the *z*-component of the angular momentum are possible, which leads to discrete spots on the screen, separated by empty areas, as illustrated in Figure 36.19.

We know now that the orbital angular momentum of a silver atom in its ground state is zero—this will be shown in Chapter 38, where states of atoms and their orbital angular momenta are calculated. Thus, if the Stern-Gerlach experiment had measured the splitting of the beam of silver atoms due only to the orbital angular momentum, the experiment would have been a failure. However, the total angular momentum of the atom is *not* just the orbital angular momentum. In addition, each elementary particle in the atom has an intrinsic angular momentum, which has no classical equivalent. The intrinsic angular momentum is called **spin.**

Spin of Elementary Particles and the Pauli Exclusion Principle

All elementary particles have a characteristic intrinsic angular momentum, or spin. There are two fundamentally different groups of elementary particles: those that have integer values (in multiples of Planck's constant $\hbar$) of spin, and those that have half-integer values. Some elementary particles have spin 0, but for our purposes, we count this as an integer spin.

Elementary particles with half-integer spins are called **fermions,** in honor of the Italian-American physicist Enrico Fermi (1901–1954). Fermions include the electron, the proton, and the neutron—in other words, all the building blocks of the matter we see around us. A fermion with spin $\frac{1}{2}\hbar$ can have one of two different spin quantum states, indicated by $+\frac{1}{2}\hbar$ and $-\frac{1}{2}\hbar$, which by convention represent the projection of the spin onto the *z*-coordinate axis. We will encounter other quantum numbers in the following chapters, but for now all you need to know is that spin $\frac{1}{2}\hbar$ particles come in two varieties, which are usually called *spin-up* and *spin-down*.

Elementary particles with integer values of spin are called **bosons,** in honor of the Indian physicist Satyendra Nath Bose (1894–1974). Photons are bosons and have spin $1\hbar$.

In Chapters 39 and 40 on elementary particles and nuclear physics, we will return to spin and give other examples of particles with half-integer and integer-valued spins and try to find a more general organizing principle. For now, we can use the two fundamentally different classes of particles—bosons and fermions—as working concepts.

One extremely important rule for fermions is the **Pauli Exclusion Principle:** No two fermions can occupy the same quantum state at the same time at the same location. In any given atom, no two fermions can have exactly identical quantum numbers. Because energy is quantized, each energy quantum state in a given system can be occupied by at most two fermions: one spin-up and the other spin-down. In the remaining chapters of this book, we will return repeatedly to the consequences of this exclusion principle. Chapter 37 introduces wave functions and then

shows that two-particle wave functions for fermions and bosons have fundamentally different symmetries. Chapter 38 will show the effects of the Pauli Exclusion Principle in the construction of multi-electron atoms and the resulting periodic table of the elements. Chapters 39 and 40 will show that this principle gives rise to the Fermi energy inside the nucleus.

36.8 Spin and Statistics

Chapter 19 presented the probability distribution function for *classical* identical particles. For these identical particles, the distribution function is called the **Maxwell-Boltzmann distribution:**

$$g(E) = \frac{2}{\sqrt{\pi}} \left(\frac{1}{k_{\mathrm{B}} T} \right)^{3/2} \sqrt{E} e^{-E/k_{\mathrm{B}} T},$$

where E is the energy, T is the temperature, and k_{B} is Boltzmann's constant. (In deriving the Maxwell-Boltzmann distribution, we examined only the kinetic energy distribution of molecules in a gas, but this function is valid for all energy distributions of classical particles.) In this derivation, we neglected all quantum effects. Now we want to examine how quantum effects change this distribution.

Page 1139

The Maxwell-Boltzmann distribution can be written in a slightly different way for particles in discrete energy states, E_i. For a total of N particles in a system, the expected number of particles with energy E_i is N_i, and the expected fraction of particles in energy state E_i is $n_i = N_i/N$, where

$$n_i = \frac{N}{N} = \frac{g_i e^{-E_1/k_B T}}{Z} = \frac{g_i}{e^{(E_i - \mu)/k_B T}}. \qquad \textbf{(36.28)}$$

Here g_i is the degeneracy of energy state E_i, that is, the number of different states in the system that have the same energy E_i. The quantity μ is called the *chemical potential* and has the same units as energy. The chemical potential is the amount by which the energy of the system would change if an additional particle were

added, while the remaining properties of the system remained fixed. The quantity Z is called the **partition function:**

$$Z = \sum_i g_i e^{-E_i/k_\mathrm{B}T}. \qquad \textbf{(36.29)}$$

The partition function encodes the thermodynamic properties of the system, and taking the appropriate derivatives of the partition function can reproduce many of the properties of the system.

The derivation of the Maxwell-Boltzmann distribution assumed that each of the particles in the ensemble is a classical particle. What we mean by *classical* is that each particle is distinguishable from the others. However, quantum particles are indistinguishable from like particles. (For example, one proton cannot be distinguished from another proton.) Thus, the distribution function has to be modified appropriately.

To see how this can work in practice, let's consider the simplest way of distributing two particles into two different states. Label these states *a* and *b* (Figure 36.20). First, consider the case of distinguishable particles, labeled 1 and 2. This is the classical Maxwell-Boltzmann distribution. In this case, there are four different configurations of the system. We can have both particles in state *a,* we can have particle 1 in state *a* and particle 2 in state *b,* we can have particle 1 in state *b* and particle 2 in state *a,* and finally we can have both particles in state *b*. This means that this two-particle system can have four different states (configurations) that it can be in, if the two particles are distinguishable. Next, consider two spin-0 bosons, indistinguishable quantum particles. This is known as the **Bose-Einstein distribution.** In this case, both particles can be in state *a* or both in state *b,* just as in the case of distinguishable particles. However, if one of them is in state *a* and the other is in state *b,* then it does not matter which one is which, because they are indistinguishable. Therefore, the two-particle system has only three different states for bosons, and not four as in the case of distinguishable particles. Finally, the easiest case is obtained for two identical spin-$\frac{1}{2}$ fermions (for example, two electrons with spin-up). This case is called the **Fermi-Dirac**

distribution. The Pauli Exclusion Principle states that these two identical fermions cannot occupy the same quantum state. (In the lowest panel of Figure 36.20, this fact is indicated by the "forbidden" sign, a red circle with a diagonal bar, over the two configurations in which both fermions would reside in the same state.) In this case, the two-particle system of identical fermions can be in only one configuration, where the quantum states a and b are each occupied by one fermion.

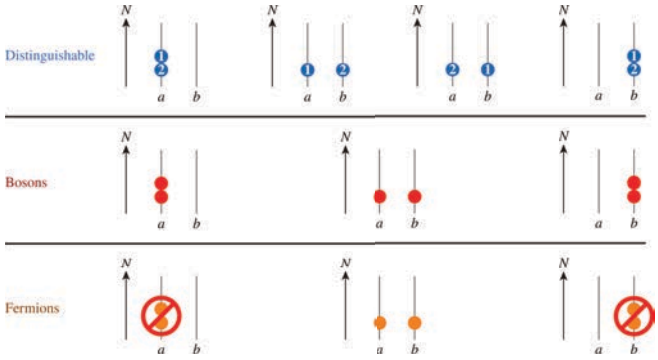

FIGURE 36.20 Distributing two particles over two different states.

Now let us turn to the more complicated case of the energy distribution for the case of a system of 5 particles that share a total of 6 quanta of energy in a one-dimensional model. For classical distinguishable particles, the 6 energy quanta can be shared by one particle carrying all 6 energy quanta and the other 4 particles each with zero energy. This sharing of the total energy of 6 quanta can be written as $6 = 6 + 0 + 0 + 0 + 0$. Since the particles are distinguishable, we have to keep track of which one of the 5 carries 6 quanta; this energy partition can happen in 5 different ways. The energy can also be distributed as $6 = 5 + 1 + 0 + 0 + 0$. Each of the 5 particles can be the carrier of 5 quanta, and then each of the remaining 4 particles can carry the remaining 1 quantum. Thus, this particular energy partition can happen in $g_i = 5 \cdot 4 = 20$ different ways. Figure 36.21 shows all possible partitions of 6 energy quanta over 5 particles. The blue numbers above the diagrams show the number of different ways the same

configuration can happen by exchanging all possible particles. The total number of different energy partitions among the 5 particles is the sum of all of the numbers listed above the diagrams and is 210.

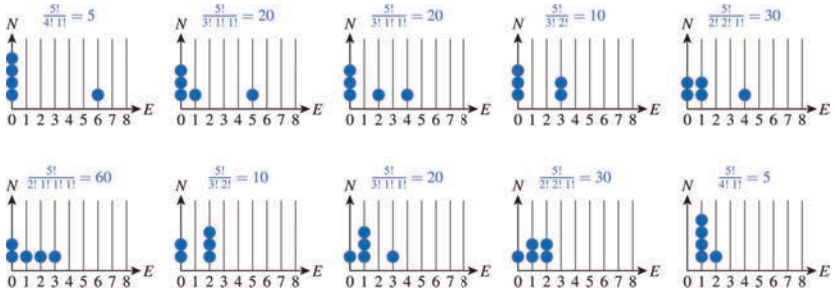

FIGURE 36.21 All possible partitions of 6 quanta of energy among 5 distinguishable particles.

Now we can calculate the probability of each energy state being occupied by counting how many partitions each energy state occurs in, multiplied by how often this partition occurs, and then dividing the result by the total number of partitions.

This is done in Figure 36.22, where the results are represented by the blue squares. For example, let's look at the probability of a particle carrying 4 quanta of energy. The only partitions for which the $E = 4$ state is populated by a particle are shown in the upper middle and upper right diagrams of Figure 36.21 and only one particle is in each of $E = 4$ states. The middle diagram represents 20 states and the right diagram 30 different states. Since the total number of states is 210, the average occupation of the $E = 4$ state is $f(4) = (1 \cdot 20 + 1 \cdot 30)/210 = 0.238$. The average occupation values for the other energy states are found in the same way.

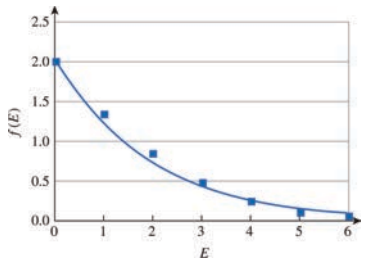

FIGURE 36.22
Average occupation values for the energy states, corresponding to the partitions of Figure 36.21.

Also shown in Figure 36.22 is a plot (blue line) of the analytic exponential function of equation 36.28. It is remarkable that for such a small number of particles and energy states, the exponential limit is approximated so well. The temperature T and the chemical potential μ that appear in equation 36.28 can be extracted from the conditions that the sum over all occupation probabilities has to add up to the number of particles (5 in this case) and that the sum of the products of the occupation probability times the energy has to add up to the total number of energy quanta in the system (6 in this case).

Now we can ask how these considerations have to change if we are dealing with indistinguishable particles. For bosons, we have done most of the work already, because we can arrange the bosons as in Figure 36.21. However, since the bosons are indistinguishable, permutations of the different particles do not yield new states. Therefore, the weight factor that counts the number of states for a given arrangement of particles among energy states is always 1 for each partition diagram in Figure 36.21. Thus, bosons have only 10 energy partitions, instead of the 210 we found for distinguishable particles. If we now calculate the average

occupation of the $E = 4$ state, we find it is $f(4) = (1 + 1)/10 = 0.2$.

The resulting distribution for identical bosons is displayed in Figure 36.23 (red dots) and compared to the classical case (blue line) that we just discussed. The distributions are remarkably similar, but important small differences appear, which are not just numerical artifacts. For instance, the occupation of the $E = 0$ state is slightly enhanced in the boson case relative to the classical distinguishable particles. As increasingly more particles are added to the system, this effect will become increasingly pronounced. It is another manifestation of the fact that bosons often occupy the same states as other bosons.

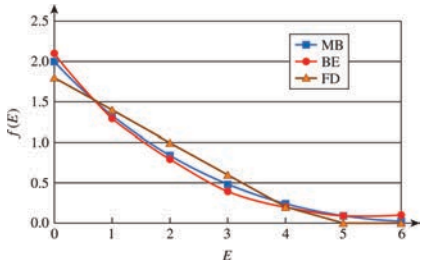

FIGURE 36.23
Comparison of the Maxwell-Boltzmann (MB), Bose-Einstein (BE), and Fermi-Dirac (FD) distributions for 6 energy quanta distributed among 5 particles.

For the distribution of 6 energy quanta over 5 fermions, it might appear that the fermions can be distributed into the energy states as in Figure 36.21. However, the Pauli Exclusion Principle does not allow this. Each energy state can be occupied by at most 1 spin-up fermion and 1 spin-down fermion. Thus, the occupation of each level cannot exceed 2. This eliminates 7 partitions from Figure 36.21, because these have 3 or more particles in the same energy state. The only 3 partitions left are those shown in Figure 36.24. To illustrate, suppose the system has 3 spin-up and 2 spin-down

fermions. For the left and right partitions in Figure 36.24, only 1 fermion is in a singly occupied state, which therefore has to be the unpaired spin-up. The middle partition diagram shows 3 fermions in singly occupied states, and 2 of these have to be spin-up and 1 spin-down. Since each of the 3 energy states can hold the spin-up fermion, this middle diagram represents a total of 3 states. This means that a total of 5 states are available to this system. Calculating the occupation of the $E = 4$ state now results in $f(4) = 1/5 = 0.2$ (which is, by chance, the same value as for the bosons). The orange line in Figure 36.23 shows the average occupations for all energy states. The occupation for the $E = 0$ state is suppressed in the case of fermions relative to classical particles.

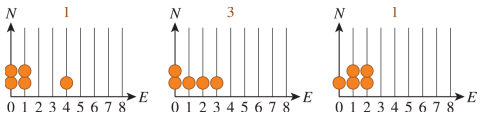

FIGURE 36.24 Possible ways to distribute 6 energy quanta among 5 fermions.

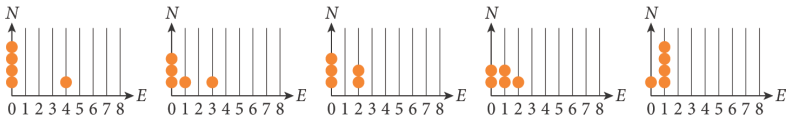
Concept Check 36.6

Which of the following distributions are possible ways to distribute 4 energy quanta over 5 fermions with spin $\frac{1}{2}h$?



Self-Test Opportunity 36.7

Plot the average occupation values for the distribution of 8 energy quanta over 5 particles. How many total states are available for each of these types of particles: fermions, bosons, and classical particles?

Let's now write the distributions for the much larger sets of particles present in physical systems. For bosons, the limiting Bose-Einstein distribution of the number of particles in a given energy state, E_i, is

$$N_i = \frac{1}{e^{(E_i-\mu)/k_B T} - 1}. \qquad \textbf{(36.30)}$$

For fermions, the Fermi-Dirac distribution is

$$N_i = \frac{1}{e^{(E_i-\mu)/k_B T} + 1}. \qquad \textbf{(36.31)}$$

The number of fermions with energy E_i can be found by multiplying the Fermi-Dirac distribution (equation 36.31) by the degeneracy g_i. (In our fermion example, this number is $g_i = 2$ for each state, because the Pauli Exclusion Principle says that each state can only be occupied by one spin-up and one spin-down fermion.)

Sometimes these distributions are expressed by using the definition of the absolute activity,

$$z = e^{\mu/k_B T}.$$

The Bose-Einstein distribution is then written as

$$N_i = \frac{1}{e^{E_i/k_\mathrm{B}T}/z - 1},$$

and the Fermi-Dirac distribution is

$$N_i = \frac{1}{e^{E_i/k_\mathrm{B}T}/z + 1}.$$

Both distribution functions approach the Maxwell-Boltzmann distribution for negligibly small absolute activity, $z \ll 1$.

For energy states that are sufficiently close to one another, the discrete values of the energy states, E_i, can be replaced by a continuous energy variable, E. Then the probability of finding a particle at energy E in the Maxwell-Boltzmann distribution can be written as

$$f_\mathrm{MB}(E) = \frac{1}{ae^{E/k_\mathrm{B}T}}, \qquad \textbf{(36.32)}$$

where a is a normalization constant that is a function of the chemical potential and the degeneracy. In the same way, the probability of finding a particle at energy E in the Fermi-Dirac distribution can be written as

$$f_\mathrm{FD}(E) = \frac{1}{ae^{E/k_\mathrm{B}T} + 1}. \qquad \textbf{(36.33)}$$

The Fermi-Dirac distribution is plotted in Figure 36.25 as a function of the ratio of the energy divided by the chemical potential. The function is shown for three different temperatures. For $k_\mathrm{B}T \ll \mu$, this function approaches a step function that falls from a value of 1 to 0 at $E = \mu$. For higher temperatures, the transition from high occupancy to low occupancy becomes increasingly smooth.

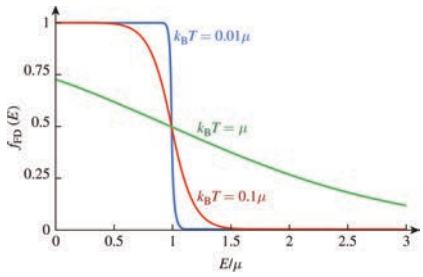


FIGURE 36.25 Fermi-Dirac distribution for three different temperatures as a function of the ratio of energy to chemical potential.

For the Bose-Einstein case,

$$f_{\mathrm{BE}}(E) = \frac{1}{ae^{E/k_{\mathrm{B}}T} - 1}. \qquad \textbf{(36.34)}$$

As we stated, photons are bosons and thus are subject to Bose-Einstein statistics. For the special case of photons, the chemical potential is zero, and thus the normalization constant in equation 36.34 has the value $a = 1$. If the photon energy approaches zero, then $e^{E/k_{\mathrm{B}}T}$ approaches 1, and the denominator vanishes in equation 36.34. This means that the occupation of states with very low energy can increase without limit for photons.

Let's take another look at Planck's radiation formula (equation 36.9) for the spectral brightness as a function of the wavelength: $I_T(f) = 2hc^{-2}f^3/\left(e^{hf/k_{\mathrm{B}}T} - 1\right)$. Since $E = hf$ for photons, the denominator contains the factor $e^{E/k_{\mathrm{B}}T} - 1$, which is also the case for the Bose-Einstein distribution for photons. Thus, the spectral brightness can be expressed as a function of photon energy:

$$I_T(E) = \frac{2E^3}{h^2c^2\left(e^{E/k_\mathrm{B}T} - 1\right)} = \frac{2E^3}{h^2c^2} f_\mathrm{BE}(E). \quad \textbf{(36.35)}$$

Thus, the radiation formula obtained by Planck says that the spectral brightness as a function of photon energy is proportional to the third power of the energy times the Bose-Einstein probability of finding a photon at that energy.

Bose-Einstein Condensate

In his original paper in 1924, Bose discussed the blackbody spectrum for photons. Einstein extended this work in the same year to atoms with integer spin. Einstein noticed that at very low temperatures, a large fraction of the atoms go into the lowest energy quantum state: “One part condenses, the rest remains a ‘saturated ideal gas’.” For this to happen, the atoms must be close enough to their neighbors that their de Broglie waves (see equation 36.23) overlap with one another. It can be shown that this condition implies, for a density ρ of atoms per unit volume, that $\rho \cdot \lambda^3 > 2.61$, where λ is the de Broglie wavelength.

How can one obtain a *Bose-Einstein condensate (BEC)* in the laboratory? Carl Wieman and Eric Cornell used a magnetic trap to collect rubidium atoms, which form spin-1 bosons at low temperatures and in a strong magnetic field. They used laser cooling, but this was still not sufficient to reach the low temperature required for transition to a BEC. By gradually reducing the depth of the trap, they allowed the atoms with higher energies to escape from the trap, leaving only the lower-energy atoms behind. With this method of evaporative cooling, they managed to cool the rubidium atoms to temperatures of a few nanokelvins (nK). They then switched off the trap and allowed the trapped collection of atoms to expand. A simple ideal gas will expand due to thermal motion of the atoms, but the BEC expands only at the minimal rate required by the Heisenberg Uncertainty Relation. A short while later, Wieman and Cornell imaged the expanding cloud, which by this time had reached a spatial extension on the order of 0.2 mm, and observed the distribution shown in Figure 36.26, which shows the results at three different temperatures. Clearly, the picture at 200 nK is qualitatively different from that at 400 nK. At 200 nK, the central peak indicates the presence of the BEC. The right panel shows the situation at a temperature of 50 nK, where essentially all the rubidium atoms are part of the BEC.

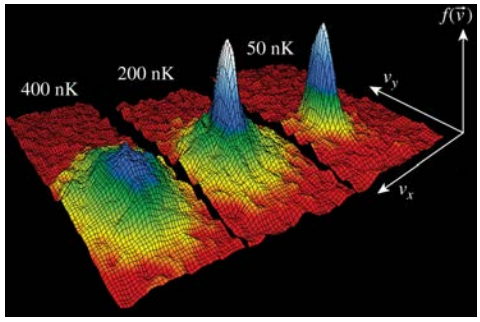

FIGURE 36.26 Bose-Einstein condensation of rubidium atoms in a magnetic trap. This picture was produced by the Wieman-Cornell group in 1995 and is included in their Nobel lecture. (The axes were added by this book's authors.) The middle image shows the appearance of the Bose-Einstein condensate. In the right image, almost all atoms are in the condensate.

Science History Images/Alamy Stock Photo

Only six years after this discovery, their work on the BEC resulted in the 2001 Nobel Prize in Physics for Wieman and Cornell, which they shared with Wolfgang Ketterle, whose group had performed similar work on BECs for other systems at the same time. The study of BECs now flourishes in many laboratories around the world, revealing many astounding facts about atoms, condensates, and quantum mechanics.

SOLVED PROBLEM 36.2 Rubidium Bose-Einstein Condensate

PROBLEM

What is the minimum density of rubidium atoms in a magnetic trap at a temperature of 200. nK. nK that can produce the onset of Bose-Einstein condensation? (*Hint:* The mass of a rubidium-87 atom is $1.5 \cdot 10^{-25}$ kg.)

SOLUTION

THINK

The text stated that the rubidium atoms must be close enough to one another that they can overlap in a quantum mechanical sense. This criterion was expressed as $\rho \cdot \lambda^3 > 2.61$. Thus, our task amounts to finding the de Broglie wavelength of rubidium atoms in thermal motion at a temperature of 200 nK.

SKETCH

A sketch is not really helpful in this case.

RESEARCH

We have already stated that the criterion for the density is

$$\rho \cdot \lambda^3 > 2.61. \qquad \text{(i)}$$

The de Broglie wavelength, λ, was given in equation 36.22:

$$\lambda = \frac{h}{p}. \qquad \text{(ii)}$$

To find the momentum p of a rubidium atom, we use the classical energy equipartition theorem, introduced in Chapter 19, which states that the kinetic energy of an atom in a gas is given by the thermal energy at the given temperature:

$$E = \frac{p^2}{2m} = \tfrac{3}{2}k_B T \Rightarrow p = \sqrt{3mk_{\mathrm{B}}T}. \qquad \text{(iii)}$$

SIMPLIFY

Substituting from equation (iii) into equation (ii), we find for the de Broglie wavelength in this case:

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{3mk_{\mathrm{B}}T}}. \qquad \text{(iv)}$$

Solving equation (i) for the density and then substituting for the de Broglie wavelength from equation (iv) results in

$$\rho > \frac{2.61}{\lambda^3} = \frac{2.61(3mk_{\mathrm{B}}T)^{3/2}}{h^3}.$$

CALCULATE

Inserting the values of the constants $\left(h = 6.63 \cdot 10^{-34}\ \mathrm{J\ s}, k_{\mathrm{B}} = 1.38 \cdot 10^{-23}\ \mathrm{J/K}\right)$ and the given temperature $\left(T = 200\ \mathrm{nK} = 2 \cdot 10^{-7}\ \mathrm{K}\right)$, we obtain for the density

$$\rho > \frac{2.61\left(3\left(1.5 \cdot 10^{-25}\ \mathrm{kg}\right)\left(1.38 \cdot 10^{-23}\ \mathrm{J/k}\right)\left(2.00 \cdot 10^{-7}\right.\right.}{\left(6.63 \cdot 10^{-34}\ \mathrm{J\ s}\right)^3}$$

ROUND

For the minimum density that could result in the formation of a BEC, our appropriately rounded result is $\rho > 1.2 \cdot 10^{19}\ \mathrm{m}^{-3}$.

DOUBLE-CHECK

The de Broglie wavelength of the rubidium atoms is

$$\lambda = \frac{6.63 \cdot 10^{-34}\ \mathrm{J\,s}}{\sqrt{3\left(1.5 \cdot 10^{-25}\ \mathrm{kg}\right)\left(1.38 \cdot 10^{-23}\ \mathrm{J/k}\right)\left(2.00 \cdot 10^{-7}\ \mathrm{K}\right)}}$$

Note that this is a factor of 1000 larger than the atomic diameter of rubidium, which is $5.0 \cdot 10^{-10}\ \mathrm{m}$.

Is a density of $10^{19}\mathrm{atoms/m}^3$ a large or a small value? Let us compare it to the density of water molecules and air molecules. One cubic meter of liquid water contains 3.10^{28} water molecules, and one cubic meter of air contains 3.10^{25} nitrogen and oxygen molecules. Thus, the gas density of rubidium atoms in the trap is approximately a million times lower than the density of air at normal atmospheric conditions.

If we have a million atoms in a trap at a density of $10^{19}\ \mathrm{atoms/m}^3$ in an approximately spherical configuration, what is the radius of this sphere? The total volume occupied by the million atoms is

$$V = \frac{N}{\rho} = \frac{10^6}{10^{19}\ \mathrm{m}^{-3}} = 10^{-13}\mathrm{m}^3.$$

Because the volume of a sphere is $V = \frac{4}{3}\pi r^3$, we find that the radius of the sphere containing a million atoms at this density is

$$r = \left(\frac{3}{4\pi} V \right)^{1/3} = 30 \mu\text{m}.$$

This makes it clear that the Bose-Einstein condensate could not be imaged directly in the experiment conducted by Cornell and Wieman. This is why they needed to turn off the trap and let its contents expand by at least a factor of 10 in each direction before they were able to produce the images shown in Figure 36.26.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- Planck's constant is $h = 6.62606957(29) \cdot 10^{-34}\ \mathrm{J\,s}$, and the energy of a photon is $E = hf$.
- Planck's Radiation Law for the power radiated in the frequency interval between *f* and $f + df$, or the spectral brightness as a function of frequency, is

$$I_T(f) = \frac{2h}{c^2} \frac{f^3}{e^{hf/k_\mathrm{B}T} - 1}.$$

  It avoids the ultraviolet divergence that made its classical predecessors unphysical in the high-frequency region, and it contains the classical radiation laws as limiting cases.
- The spectral brightness as a function of wavelength is

$$I_T(\lambda) = \frac{2hc^2}{\lambda^5 \left(e^{hc/\lambda k_\mathrm{B}T} - 1\right)}.$$

- The spectral emittance is related to the spectral brightness by a simple multiplicative factor of $\pi : \in_T (f) = \pi I_T(f)$.
- Integration of the spectral emittance over all frequencies (or wavelengths) yields the radiated intensity, $I = \int_0^\infty$, where $\epsilon(\lambda) d\lambda = \sigma T^4$ the Stefan-Boltzmann constant is

$$\sigma = \frac{2k_\mathrm{B}^4 \pi^5}{15h^3c^2} = 5.6704 \cdot 10^{-8}\ \mathrm{W\,m^{-2}\,K^{-4}}.$$

- What we normally think of as a wave has particle character. The photoelectric effect is explained with the quantum hypothesis by assigning particle properties to the photon,

the elementary quantum of light. This quantum hypothesis gives the correct frequency dependence of the stopping potential, $eV_0 = hf - \phi$, where ϕ is the work function. The work function is a constant that depends on the material used.

- The Compton effect describes the photon wavelength λ' after a photon of wavelength λ scatters off an electron:

$$\lambda' = \lambda + \frac{h}{m_e c}(1 - \cos\theta).$$

- The Compton wavelength of the electron is

$$\lambda_e = \frac{h}{m_e c} = 2.426 \cdot 10^{-12}\,\mathrm{m}.$$

- What we normally think of as matter also has wave characteristics. The de Broglie wavelength is defined as

$$\lambda = \frac{h}{p}.$$

  Matter waves can be demonstrated by performing double-slit experiments with electrons, which yield the same kind of interference patterns as for photons.

- The Heisenberg Uncertainty Relation stipulates that the product of the uncertainty in momentum and the uncertainty in position has an absolute lower bound, $\Delta x \cdot \Delta p_x \geq \frac{1}{2}\hbar$. The energy-time uncertainty relation is $\Delta E \cdot \Delta t \geq \frac{1}{2}\hbar$.
- Elementary quantum particles have the intrinsic property of spin, which has the dimensions of angular momentum. The spin is quantized, dividing particles into two categories: fermions with spins that are half-integer multiples of $\hbar$, and bosons with spins that are integer multiples of $\hbar$.
- The Pauli Exclusion Principle states that no two fermions can occupy the same quantum state at the same time and at

the same location. In any given atom, no two fermions can have exactly identical quantum numbers.

- Bosons can condense at very low temperatures in such a way that a very significant fraction of them occupy the same quantum state.

ANSWERS TO SELF-TEST OPPORTUNITIES

36.1 $K_{\max} = hf - \phi$: For $\lambda = 250$, 392, and 540 nm and $\phi = 2.1$ eV, $K_{\max} = 2.9$, 1.1, and 0.20 eV.

36.2 148 million km $= 148 \cdot 10^6 \cdot 10^3\,\text{m} = 1.48 \cdot 10^{11}\,\text{m}$.

$$P = \left(4\pi r^2\right) I = 4\pi\left(1.48 \cdot 10^{11}\text{m}\right)^2\left(1370\ \text{W/m}^2\right) = 3.77 \cdot 10^2$$

In the visible spectrum, $P_{\text{visible}} = P/4 = 9.43 \cdot 10^{25}\,\text{W}$.

In 1 s, $9.43 \cdot 10^{25}\,\text{J}$ of energy is emitted by the Sun.

Assume that the average wavelength of the visible photons is $\lambda = 550$ nm. The energy of each photon is then

$$\begin{aligned} E &= hf = h\frac{c}{\lambda} = \left(6.626 \cdot 10^{-34}\,\text{J s}\right)\frac{3.00 \cdot 10^8\,\text{m/s}}{550 \cdot 10^{-9}\,\text{m}} = 3.61 \\ N &= P_{\text{visible}}/E = \left(9.43 \cdot 10^{25}\ \text{W}\right)/\left(3.61 \cdot 10^{-19}\ \text{J}\right) \\ &= 2.6 \cdot 10^{44}\text{visible photons per second.} \end{aligned}$$

36.3 Momentum of 1.00-eV electron: $m_e c^2 = 511\,\text{keV}$.

$$\begin{aligned} E^2 &= \left(m_e c^2\right)^2 + (pc)^2 = \left(m_e c^2 + K\right)^2 \\ pc &= \sqrt{\left(m_e c^2 + K\right)^2 - \left(m_e c^2\right)^2} \\ &= \sqrt{\left(511\,\text{keV} + 1.00 \cdot 10^{-3}\,\text{keV}\right)^2 - \left(511\ \text{keV}\right)^2} = 1.0 \end{aligned}$$

Momentum of 100-keV X-ray:

$$\left(m_e c^2\right)^2 + (pc)^2 = \left(m_e c^2 + K\right)^2$$

$$pc = K = 100\,\text{keV}.$$

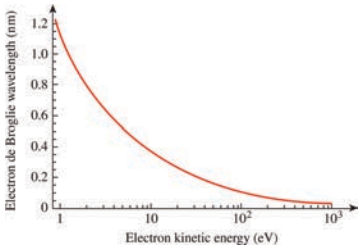
Momentum of electron is 1% of that of X-ray, or negligible.

36.4 The maximum change in wavelength of a photon undergoing Compton scattering occurs when $\theta = 180^\circ$, so

$$\begin{aligned}\Delta\lambda_{\max} &= \frac{h}{m_e c}(1 - \cos 180^\circ) = \frac{2h}{m_e c} \\ &= \frac{2\left(6.63 \cdot 10^{-34}\,\text{Js}\right)}{\left(9.11 \cdot 10^{-31}\,\text{kg}\right)\left(3.00 \cdot 10^{8}\,\text{m/s}\right)} = 4.85 \cdot 10^{-12} \\ &= 0.00485\,\text{nm}.\end{aligned}$$

This maximum change in wavelength is much smaller than the wavelength of visible light, 400 – 700 nm, so it would not be observable.

36.5



The de Broglie wavelength for an electron with a kinetic energy of 1000 eV is

$\lambda = 0.0387879\,\text{nm}.$

Calculating the momentum nonrelativistically gives us

$\lambda = 0.0388068\,\text{nm}.$

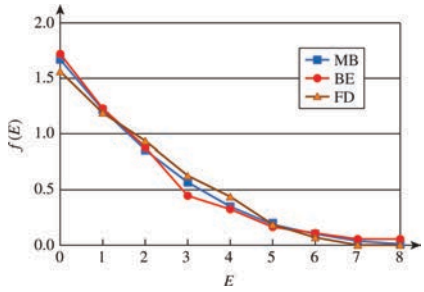
The difference is small.

36.6 $\Delta v = 2.00\,\text{km/h} = 0.556\,\text{m/s}.$

$$\Delta x.\,\Delta p \geq \tfrac{1}{2}\hbar$$

$$\Delta x \geq \frac{\hbar}{2\Delta p} = \frac{\hbar}{2m\Delta v} = \frac{1.05457 \cdot 10^{-34}\,\mathrm{J\,s}}{2(1462\,\mathrm{kg})(0.556\,\mathrm{m/s})} = 6.49 \cdot 10$$

36.7 Numbers of states are 16 for fermions, 18 for bosons, and 495 for classical particles.



PROBLEM-SOLVING GUIDELINES

1. The starting point for most calculations involving photons or matter waves is to relate the particle properties energy, E, and momentum, p, to the wave properties wavelength, λ, and frequency, f. The key relations are $E = hf$, $p = E/c = hf/c = h/\lambda$, and $\lambda = h/p$.

2. Be careful and consistent in applying units. Often, convertingall units to meters and kilograms will help youkeep track of unit exponents. Use of electron-volts will often simplify your calculations, but be sure to use Planck's constant with the appropriate units: $h = 6.626 \cdot 10^{-34}\,\mathrm{J\,s}$ or $h = 4.136 \cdot 10^{-15}\,\mathrm{eV\,s}$.

3. For checking your work, it is helpful to keep in mind some rough orders of magnitude: the size of an atom is 10^{-10} m; the mass of an electron is 10^{-30}kg; the charge of a proton or electron is 10^{-19}C; at room temperature, $k_\mathrm{B}T = \frac{1}{40}\,\mathrm{eV}$.

Multiple-Choice Questions

36.1 Ultraviolet light of wavelength 350 nm is incident on a material with a stopping potential of 0.25 V. The work function of the material is

a) 4.0 eV.

b) 3.3 eV.

c) 2.3 eV.

d) 5.2 eV.

36.2 The existence of a cutoff frequency in the photoelectric effect

a) cannot be explained using classical physics.

b) shows that the model provided by classical physics is not correct in this case.

c) shows that a photon model of light should be used in this case.

d) shows that the energy of the photon is proportional to its frequency.

e) All of the above are true.

36.3 To have a larger photocurrent, which of the following should occur? (Select all the changes that apply.)

a) brighter light

b) dimmer light

c) higher frequency

d) lower frequency

36.4 Which of the following has the smallest de Broglie wavelength?

a) an electron traveling at 80% of the speed of light

b) a proton traveling at 20% of the speed of light

c) a carbon nucleus traveling at 70% of the speed of light

d) a helium nucleus traveling at 80% of the speed of light

e) a lithium nucleus traveling at 50% of the speed of light

36.5 A blackbody is an ideal system that

a) absorbs 100% of the light incident upon it, but cannot emit light of its own.

b) radiates 100% of the power it generates, but cannot absorb radiation of its own.

c) either absorbs 100% of the light incident upon it, or radiates 100% of the power it generates.

d) absorbs 50% of the light incident upon it, and emits 50% of the radiation it generates.

e) blackens completely any body that comes in contact with it.

36.6 Which one of the following statements is true if the intensity of a light beam is increased while its frequency is kept the same?

a) The photons gain higher speeds.

b) The energy of the photons is increased.

c) The number of photons per unit time is increased.

d) The wavelength of the light is increased.

36.7 Which of the following has the highest temperature?

a) a white-hot object

b) a red-hot object

c) a blue-hot object

36.8 Electrons having a narrow range of kinetic energies are impinging on a double slit, with separation D between the slits. The electrons form an interference pattern on a phosphorescent screen, with a separation Δx between the fringes. If the spacing between the slits is reduced to $D/2$, the separation between the fringes will be

a) Δx.

b) $2\Delta x$.

c) $\Delta x/2$.

d) none of these.

CONCEPTUAL QUESTIONS

36.9 Why is a white-hot object hotter than a red-hot object?

36.10 Answer in your own words the question of whether an electron is a particle or a wave.

36.11 If I look in a mirror while wearing a blue shirt, my reflection is wearing a blue shirt, not a red shirt. But according to the Compton effect, the photons that bounce off the mirror should have a lower energy and therefore a longer wavelength. Explain why my reflection shows the same color shirt as I am wearing.

36.12 Vacuum in deep space is not empty, but a boiling sea of particles and antiparticles that are constantly forming and annihilating each other. Determine the maximum lifetime for a proton-antiproton pair to form there without violating Heisenberg's Uncertainty Relation.

36.13 Consider a universe where Planck's constant is 5 J s. How would a game of tennis change? Consider the interactions of individual players with the ball and the interaction of the ball with the net.

36.14 In classical mechanics, what information is needed in order to predict where a particle with no net force on it will be at some later time? Why is this prediction not possible in quantum mechanics?

36.15 What would a classical physicist expect to be the result of shining an increasingly brighter UV lamp on a metal surface, in terms of the energy of emitted electrons? How does this differ from what the theory of the photoelectric effect predicts?

36.16 Which is more damaging to human tissue, a 60-W source of visible light or a 2-mW source of X-rays? Explain your choice.

36.17 Neutrons are spin $-\frac{1}{2}$ fermions. An unpolarized beam of neutrons has equal numbers of neutrons in the $+\frac{1}{2}$ and $-\frac{1}{2}$ spin

states. When a beam of unpolarized neutrons is passed through a gas of unpolarized ^{3}He atoms, the neutrons can be absorbed by the ^{3}He atoms to create ^{4}He atoms. If the ^{3}He atoms are polarized, so that the spins of the neutrons in their nuclei are all aligned, will the same number of neutrons from the unpolarized neutron beam be absorbed by the polarized ^{3}He atoms? How well are neutrons in each of the two spin states of the unpolarized neutron beam absorbed by the ^{3}He?

36.18 You are performing a photoelectric effect experiment. Using a photocathode made of cesium, you first illuminate it with a green laser beam ($\lambda = 514.5\,\text{nm}$) of power 100 mW. Next, you double the power of the laser beam, to 200 mW. How will the energies per electron of the electrons emitted by the photocathode compare for the two cases?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 36.2

36.19 Calculate the peak wavelengths of (a) the solar light received by Earth, and (b) the light emitted by the Earth.

Assume that the surface temperatures of the Sun and the Earth are 5800. K and 300. K, respectively.

36.20 Calculate the range of temperatures for which the peak emission of blackbody radiation from a hot filament occurs within the visible range of the electromagnetic spectrum. Take the visible spectrum as extending from 380 nm to 780 nm. What is the total intensity of the radiation from the filament at the two temperatures at the ends of the range?

36.21 Ultra-high-energy gamma rays with energies up to $3.5 \cdot 10^{12}$ eV, come from the equator of the Milky Way. What is the wavelength of this radiation? How does its energy compare to the rest energy of a proton?

36.22 Consider the radiation emitted by an object at room temperature (20. °C). For radiation at the peak of the spectral energy density, calculate (a) the wavelength, (b) the frequency, and (c) the energy of one photon.

•36.23 The temperature of your skin is approximately 35.0 °C.

a) Assuming that your skin is a blackbody, what is the peak wavelength of the radiation it emits?

b) Assuming a total surface area of 2.00 m^2, what is the total power emitted by your skin?

c) Given your answer to part (b), why don't you glow as brightly as a light bulb?

•36.24 A pure, defect-free semiconductor material will absorb the electromagnetic radiation incident on it only if the energy of the individual photons in the incident beam is larger than a threshold value known as the *band-gap* of the semiconductor. Otherwise, the material will be transparent to the photons. The known room-

temperature band-gaps for germanium, silicon, and gallium-arsenide, three widely used semiconductors, are 0.66 eV, 1.12 eV, and 1.42 eV, respectively.

a) Determine the room-temperature transparency range of each semiconductor.

b) Compare these with the transparency range of ZnSe, a semiconductor with a band-gap of 2.67 eV, and explain the yellow color observed experimentally for the ZnSe crystals.

c) Which of these materials could be used to detect the 1550-nm optical communications wavelength?

•**36.25** The mass of a dime is 2.268 g, its diameter is 17.91 mm, and its thickness is 1.350 mm.

a) Determine the radiant energy emitted by a dime per second at room temperature.

b) Calculate the number of photons leaving the dime per second (assuming that all photons have the wavelength of the peak of the distribution for this estimate).

c) Determine the volume of air that has an energy equal to that of 1 s of radiation from the dime.

Section 36.3

36.26 The work function of a certain material is 5.8 eV. What is the photoelectric threshold frequency for this material?

36.27 What is the maximum kinetic energy of the electrons ejected from a sodium surface by light of wavelength 470 nm?

36.28 The threshold wavelength for the photoelectric effect for a specific alloy is 400. nm. What is the work function in electron-volts?

36.29 In a photoelectric effect experiment, a laser beam of unknown wavelength is shone on a cesium photocathode (work function of $\phi = 2.100$ eV). It is found that a stopping potential of 0.310 V is needed to eliminate the current. Next, the same laser is shone on a photocathode made of an unknown material, and a stopping potential of 0.110 V is needed to eliminate the current.

a) What is the work function for the unknown material?

b) What metal is a possible candidate for the unknown material?

36.30 You illuminate a zinc surface with 550-nm light. How high do you have to turn up the stopping potential to eliminate the photoelectric current completely?

36.31 White light, $\lambda = 400.$ to 750. nm, falls on barium ($\phi = 2.48$ eV).

a) What is the maximum kinetic energy of electrons ejected from the metal?

b) Would the longest-wavelength light eject electrons?

c) What wavelength of light would eject electrons with zero kinetic energy?

•**36.32** To determine the work function of the material of a photodiode, you measured a maximum kinetic energy of 1.50 eV corresponding to a certain wavelength. Later, you decreased the wavelength by 50.0% and found the maximum kinetic energy of the photoelectrons to be 3.80 eV. From this information, determine (a) the work function of the material, and (b) the original wavelength.

Section 36.4

36.33 X-rays of wavelength $\lambda = 0.120$ nm are scattered from carbon. What is the Compton wavelength shift for photons deflected at a 90.0° angle relative to the incident beam?

36.34 A 2.0-MeV X-ray photon is scattered off a free electron at rest and deflected by an angle of 53°. What is the wavelength of the scattered photon?

36.35 A photon with a wavelength of 0.30 nm collides with an electron that is initially at rest. If the photon rebounds at an angle of 160°, how much energy did it lose in the collision?

•**36.36** X-rays having an energy of 400.0 keV undergo Compton scattering from a target electron. The scattered rays are detected at an angle of 25.0° relative to the incident rays. Find (a) the kinetic energy of the scattered X-rays, and (b) the kinetic energy of the recoiling electron.

•**36.37** Consider the case in which photons scatter off a free proton.

a) If 140.-keV X-rays deflect off a proton at 90.0°, what is their fractional change in energy, $(E_0 - E)/E_0$?

b) What initial energy would a photon have to have to experience a 1.00% change in energy at 90.0° scattering?

•**36.38** An X-ray photon with an energy of 50.0 keV strikes an electron that is initially at rest inside a metal. The photon is scattered at an angle of 45°. What are the kinetic energy and the momentum (magnitude and direction) of the electron after the collision? You may use the nonrelativistic relationship between the kinetic energy and the momentum of the electron.

Section 36.5

36.39 Calculate the wavelength of (a) a 2.00-eV photon, and (b) an electron with a kinetic energy of 2.00 eV.

36.40 What is the de Broglie wavelength of a $2.000 \cdot 10^3$-kg car moving at a speed of 100.0 km/h?

36.41 A nitrogen molecule of mass $m = 4.648 \cdot 10^{-26}$ kg has a speed of 300.0 m/s.

a) Determine its de Broglie wavelength.

b) How far apart are the double slits if a beam of nitrogen molecules creates an interference pattern with fringes 0.30 cm apart on a screen 70.0 cm in front of the slits?

36.42 Alpha particles are accelerated through a potential difference of 20.0 kV. What is their de Broglie wavelength?

36.43 Consider an electron whose de Broglie wavelength is equal to the wavelength of green light (550 nm).

a) Treating the electron nonrelativistically, what is its speed?

b) Does your calculation confirm that a nonrelativistic treatment is sufficient?

c) Calculate the kinetic energy of the electron in electron-volts.

•**36.44** After you tell your 60.0-kg roommate about de Broglie's hypothesis that particles of momentum p have wave characteristics with wavelength $\lambda = h/p$ he starts thinking of his fate as a wave and asks you if he could be diffracted when passing through the 90.0-cm-wide doorway of your dorm room.

a) What is the maximum speed at which your roommate could pass through the doorway and be significantly diffracted?

b) If it takes one step to pass through the doorway, how long should it take your roommate to make that step (assuming that the length of his step is 0.75 m/s) for him to be diffracted?

c) What is the answer to your roommate's question? (*Hint:* Assume that significant diffraction occurs when the width of

the diffraction aperture is less than 10.0 times the wavelength of the wave being diffracted.)

•• **36.45** Consider de Broglie waves for a Newtonian particle of mass m, momentum $p = mv$, and energy $E = p^2/(2m)$, that is, waves with wavelength $\lambda = h/p$ and frequency $f = E/h$.

a) For these waves, calculate the dispersion relation, $\omega = \omega(\kappa)$, where κ is the wave number.

b) Calculate the phase velocity ($v_{\mathrm{p}} = \omega/\kappa$) and the group velocity ($v_g = \partial\omega/\partial\kappa$) of these waves.

•• **36.46** Now consider de Broglie waves for a (relativistic) particle of mass m, momentum $p = mv\gamma$, and total energy $E = mc^2\gamma$, with $\gamma = \left[1 - (v/c)^2\right]^{-1/2}$. The waves have wavelength $\lambda = h/p$ and frequency $f = E/h$. as in Problem 36.45, but with the relativistic momentum and energy values.

a) For these waves, calculate the dispersion relation, $\omega = \omega(\kappa)$ where κ is the wave number.

b) Calculate the phase velocity ($v_p = \omega/\kappa$) and the group velocity ($v_g = \partial\omega/\partial\kappa$) of these waves.

c) Which corresponds to the classical velocity of the particle?

Section 36.6

36.47 A 50.0-kg particle has a de Broglie wavelength of 20.0 cm.

a) How fast is the particle moving?

b) What is the smallest uncertainty in the particle's speed if its position uncertainty is 20.0 cm?

36.48 During the period of time required for light to pass through a hydrogen atom $\left(r = 0.53 \cdot 10^{-10}\ \text{m}\right)$, what is the least uncertainty in the atom's energy? Express your answer in electron-volts.

36.49 A free neutron $\left(m = 1.67 \cdot 10^{-27}\ \text{kg}\right)$ has a mean lifetime of 882 s. What is the minimum uncertainty in its mass (in kg)?

36.50 Suppose that Fuzzy, a quantum-mechanical duck, lives in a world in which Planck's constant is $\hbar = 1.00\ \text{J s}$. Fuzzy has a mass of 0.500 kg and initially is known to be within a 0.750-m-wide pond. What is the minimum uncertainty in Fuzzy's speed? Assuming that this uncertainty prevails for 5.00 s, how far away could Fuzzy be from the pond after 5.00 s?

36.51 An electron is confined to a box with a dimension of 20.0 μm. What is the minimum speed the electron can have?

•**36.52** A dust particle of mass $1.00 \cdot 10^{-16}$ kg and diameter 5.00 μm is confined to a box of length 15.0 μm.

a) How will you know whether the particle is at rest?

b) If the particle is not at rest, what will be the range of its velocity?

c) At the lower limit of the velocity range, how long will it take to move a distance of 1.00 μm?

Section 36.8

•• **36.53** A quantum state of energy E can be occupied by any number n of bosons, including $n = 0$. At the absolute temperature T, the probability of finding n particles in the state is given by $p_n = N \exp(-nE/k_\mathrm{B}T)$, where k_B is Boltzmann's constant and N is the normalization factor determined by the requirement that all the probabilities sum to unity. Calculate the mean value of n, that is, the average occupation, of this state, given this probability distribution.

•**36.54** For the same quantum state as in Problem 36.53, with a probability distribution of the same form but with fermions, the only possible occupation values are $n = 0$ and $n = 1$. Calculate the mean occupation $\langle n \rangle$ of the state in this case.

•• **36.55** Consider a system made up of N particles. The energy per particle is given by $\langle E \rangle = \left(\sum E_i e^{-E_i/k_\mathrm{B}T}\right)/Z$, where Z is the partition function defined in equation 36.29. If this is a two-state system with $E_1 = 0$ and $E_2 = E$ and $g_1 = g_2 = 1$, calculate the heat capacity of the system, defined as $N(d\langle E \rangle/dT)$, and approximate its behavior at very high and very low temperatures (that is, $k_\mathrm{B}T \gg 1$ and $k_\mathrm{B}T \ll 1$).

Additional Exercises

36.56 Given that the work function of tungsten is 4.55 eV, what is the stopping potential in an experiment using tungsten cathodes at 360 nm?

36.57 Find the ratio of the de Broglie wavelengths of a 100.-MeV proton and a 100.-MeV electron.

36.58 An *einstein* (E) is a unit of measurement equal to Avogadro's number $\left(6.02 \cdot 10^{23}\right)$ of photons. How much energy is contained in 1 E of violet light $(\lambda = 400.\ \text{nm})$?

36.59 In baseball, a 100.-g ball can travel as fast as 100. mph. The *Voyager* spacecraft, with a mass of about 250. kg, is currently traveling at 125,000 km/h.

a) What is the de Broglie wavelength of this ball?

b) What is the de Broglie wavelength of *Voyager*?

36.60 What is the minimum uncertainty in the velocity of a 1.0-ng particle that is at rest on the head of a 1.0-mm-wide pin?

36.61 A photovoltaic device uses monochromatic light of wavelength 700. nm that is incident normally on a surface of area 10.0 cm^2. Calculate the photon flux rate if the light intensity is 0.300 W/cm^2.

36.62 The solar constant measured by Earth satellites is roughly 1400. W/m^2. Though the Sun emits light of different wavelengths, the peak of the wavelength spectrum is at 500. nm.

a) Find the corresponding photon frequency.

b) Find the corresponding photon energy.

c) Find the number flux of photons (number of photons per unit area per unit time) arriving at Earth, assuming that all light emitted by the Sun has the same peak wavelength.

36.63 Two silver plates in vacuum are separated by 1.0 cm and have a potential difference of 5.0 V between them that opposes electron flow. What is the largest wavelength of light that can be incident on the cathode and produce a current in the anode?

36.64 How many photons per second must strike a surface of area $10.0\ \text{m}^2$ to produce a force of 0.100 N on the surface, if the wavelength of the photons is 600. nm? Assume that the photons are absorbed.

36.65 Suppose the wave function describing an electron predicts a statistical spread of $10.0 \cdot 10^{-4}$ m/s in the electron's velocity. What is the corresponding statistical spread in its position?

36.66 What is the temperature of a blackbody whose peak emitted wavelength is in the X-ray portion of the spectrum?

36.67 A nocturnal bird's eye can detect monochromatic light of frequency $5.8 \cdot 1014$ Hz with a power as small as $2.333 \cdot 10^{-17}$ W. What is the corresponding number of photons per second that the nocturnal bird's eye can detect?

36.68 A particular ultraviolet laser produces radiation of wavelength 355 nm. Suppose this is used in a photoelectric experiment with a calcium sample. What will the stopping potential be?

36.69 What is the wavelength of an electron that is accelerated from rest through a potential difference of $1.00 \cdot 10^{-5}$ V?

•36.70 Compton used photons of wavelength 0.0711 nm.

a) What is the wavelength of the photons scattered at $\theta = 180.^\circ$?

b) What is energy of these photons?

c) If the target were a proton and not an electron, how would your answer to part (a) change?

•36.71 Calculate the number of photons originating at the Sun that are received in the Earth's upper atmosphere per year.

•36.72 Scintillation detectors for gamma rays transfer the energy of a gamma-ray photon to an electron within a crystal, via the photoelectric effect or Compton scattering. The electron transfers its energy to atoms in the crystal, which re-emit it as a light flash detected by a photomultiplier tube. The charge pulse produced by the photomultiplier tube is proportional to the original energy in the crystal; this can be measured so that an energy spectrum can be displayed. Gamma rays absorbed in the photoelectric effect are

recorded as a *photopeak* in the spectrum, at the full energy of the rays. The Compton-scattered electrons are also recorded, at a range of lower energies known as the *Compton plateau*. The highest-energy electrons form the *Compton edge* of the plateau. Gamma-ray photons scattered by 180.° appear as a *backscatter peak* in the spectrum. For gamma-ray photons of energy 511 KeV, calculate the energies of the Compton edge and the backscatter peak in the spectrum.

MULTI-VERSION EXERCISES

36.73 A stationary free electron in a gas is struck by a 6.37-nm X-ray, which experiences an increase in wavelength of 1.13 pm. How fast is the electron moving after the interaction with the X-ray?

36.74 A stationary free electron in a gas is struck by an X-ray with an energy of 175 eV, which experiences a decrease in energy of 175.37 meV. How fast is the electron moving after the interaction with the X-ray?

36.75 A stationary free electron in a gas is struck by an X-ray with an energy of 159.98 eV. After the collision, the speed of the electron is measured to be 92.17 km/s. By how much did the energy of the X-ray decrease?

36.76 A stationary free electron in a gas is struck by an X-ray with a wavelength of 5.43 nm. After the collision, the speed of the electron is measured to be 132.7 km/s. By how much did the wavelength of the X-ray increase?

36.77 A stationary free electron in a gas is struck by an X-ray with a wavelength of 6.13 nm. After the collision, the speed of the electron is measured to be 118.5 km/s. By how much did the frequency of the X-ray change?

36.78 An accelerator boosts a proton's kinetic energy so that its de Broglie wavelength is $3.63 \cdot 10^{-15}$ m. What is the total energy of the proton?

36.79 An accelerator boosts a proton's kinetic energy so that its de Broglie wavelength is $4,43 \cdot 10^{-15}$ m. What is the kinetic energy of the proton?

36.80 An accelerator boosts a proton's kinetic energy so that its de Broglie wavelength is $1.71 \cdot 10^{-15}$ m. What is the speed of the

proton?

Chapter 36 introduced some of the basic ideas of quantum physics, including photons, matter waves, and the uncertainty principle. In this chapter, we extend these ideas to examine particle dynamics on the atomic scale. We emphasize physical concepts rather than mathematical details, which can become pretty involved. However, the ideas of quantum mechanics have produced practical discoveries that could not be imagined using classical physics alone.

Many early researchers in modern physics had serious doubts about what wave functions really are and why probability distributions take a central role in predicting results. For example, the Danish physicist Niels Bohr (1885–1962) once said, “Anyone who has not been shocked by quantum physics has not understood

it." And the great American physicist Richard Feynman (1918–1988) wrote, "I think I can safely say that nobody understands quantum mechanics ... Do not keep saying to yourself, if you can possibly avoid it, 'But how can it be like that? ...' Nobody knows how it can be like that." Yet now, in the 21st century, quantum mechanics has been established as one of the most accurate and comprehensive areas in all of physics.

When we talked about light waves and sound waves, we discussed the concepts of spherical and planar waves. These waves are specific examples of wave functions that solve particular wave equations. We can now ask what the wave function of the electron is, or what the wave function of any other object that we conventionally think of as a particle is. This question will lead us to consider mechanics in the quantum world, conventionally called quantum mechanics, which explores the observable consequences of the wavelike behavior of particles. Recent years have witnessed extensive attempts to go beyond simply understanding quantum systems and to manipulate them and use them for purposes like quantum computing (see Figure 37.1), which carry the promise of revolutionizing nanoscience and nanotechnology.

WHAT WE WILL LEARN

- A particle is described by its complex wave function. The absolute square of the complex wave function is the probability of finding the particle at some position. The integral of the square of the wave function over all of space equals 1.
- The time-independent Schrödinger equation is the nonrelativistic wave equation for a particle in a potential energy distribution, $U(x)$.
- Wave functions that are solutions to the problem of a particle confined to an infinite potential well are sine functions. The energy value of a solution is proportional to the square of the quantum number of the solution. The solutions to the problem of a potential of finite height have exponential tails reaching into the classically forbidden regions.
- If a particle encounters a potential barrier of finite height and width, it can tunnel through this barrier, even if it has energy less than the height of the barrier. The probability of the particle tunneling through the barrier depends exponentially on the width of the barrier.
- The wave function solutions for the harmonic oscillator potential are Hermite polynomials. The corresponding energy eigenvalues are equally spaced. Oscillator wave functions with $n = 0$ have the minimum product of momentum and position uncertainties allowed by the uncertainty principle.
- The correspondence principle states that if the energy difference, ΔE, between neighboring energy states becomes small relative to the total energy, E, then the quantum solution approaches its classical limit.
- The Hamiltonian operator (or simply the Hamiltonian, for short) is the operator that yields the total energy. It is linear. Thus, a linear combination of two solutions to the

Schrödinger equation, which is based on the Hamiltonian, is also a solution.

- The two-particle wave function for (noninteracting) bosons is the symmetrized product of one-particle wave functions, and the two-particle wave function for (noninteracting) fermions is the antisymmetrized product.

37.1 Wave Function

Let's briefly review what we have accomplished so far in our investigation of the quantum world. In Chapter 36, we saw that the photoelectric effect and Compton scattering can be explained only if light has particle properties. However, in Chapter 31 on electromagnetic waves we saw that light is also an electromagnetic wave of the form $E = E_{\max} \sin(\kappa x - \omega t)$, where κ is the wave number and ω is the angular frequency. We also saw that the intensity of the wave is proportional to the square of the electric field. We used this relationship again in Chapter 34 on wave optics to calculate the intensity of the interference pattern of two light waves. Because the oscillation of the electric field in space and time represents the wave function of light, clearly, for light, the intensity is proportional to the square of the wave function.

What is the corresponding wave function of an electron? Or more generally: What is the quantum wave function of any particle?

In common notation, $\psi\left(\vec{r}, t\right)$ is used to represent the **wave function** to denote that it depends on the spatial coordinate $\vec{r}$ and the time t. It is common to use the lowercase Greek letter psi, ψ, for the wave function. We used $y\left(\vec{r}, t\right)$ to describe the wave function in Chapter 15 when we examined general wave phenomena. However, in the early 20th century, the pioneers of quantum physics used $\psi\left(\vec{r}, t\right)$ which became the standard notation. In addition, representing the wave function, which is not a coordinate or a distance, by y could be confused with the common usage of y.

A lot of physical insight can be gained by studying mechanics problems in one spatial dimension. For the one-dimensional wave function, we use the notation $\psi(x, t)$. To start with the simplest case, we'll look at the wave function in coordinate space, returning to the time dependence later. If we are interested in only the spatial distribution of the wave function, we use the notation $\psi(x)$.

What is the wave function $\psi(x)$ of the electrons hitting the screen in the double-slit experiment of Section 36.5? Just as for photons, the wave function is proportional to the square root of the intensity, with the intensity given by equation 36.25. The intensity is shown in Figure 37.2a. Figure 37.2b and Figure 37.2c show two possible wave functions that correspond to this intensity distribution, which differ from each other by a multiplicative factor of -1. Note that the wave function can have positive and negative values, whereas the intensity has a minimum value of zero (that is, it is never negative).

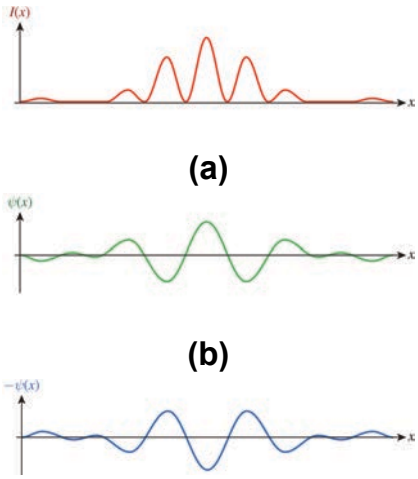

FIGURE 37.2 (a) Intensity distribution for electrons hitting the screen in the electron double-slit experiment; (b,c) two possible wave functions corresponding to this intensity distribution.

Wave Function and Probability

What is the physical meaning of the quantum wave function of a particle? Figure 37.3 shows the connection between the positions at which the electrons hit the screen and the intensity distribution resulting from double-slit interference.

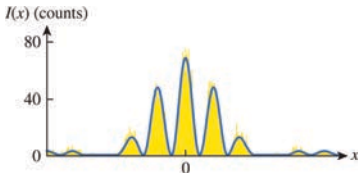

FIGURE 37.3
Intensity distribution (number of electrons hitting the screen per unit length) along the screen in the electron double-slit experiment. The yellow histogram shows the number of electrons hitting the screen in a coordinate interval.

Clearly, the number of counts per bin of some unit length (yellow histogram), and the intensity (blue line) are proportional to each other. The number of counts per bin divided by the total number of electrons is the probability that an electron hits in the interval marked by the bin. We denote the bin width by dx, because we want to use infinitesimally small bins. Thus, the probability of an electron striking in the interval between x and $x + dx$ is proportional to $I(x)dx$. Finally, because we have just established that the intensity is proportional to the square of the wave function, we can express the probability $\prod(x)$ of the electron hitting in the interval between x and $x + dx$ as

$$\Pi(x)dx = |\psi(x)|^2 dx. \qquad \textbf{(37.1)}$$

This is equivalent to saying that $|\psi(x)|^2$ is the probability density of finding the particle at position *x*. The probability is a dimensionless number between 0 and 1, and *dx* has the dimension of length, so the probability density must have the physical dimension of inverse length.

Why is the square of the absolute value of the wave function used in equation 37.1, instead of just the square of the wave function? It turns out that wave functions can have a complex amplitude. Thus, a positive real number is ensured only by taking the absolute square of this amplitude.

The probability of finding a particular electron at any position in space must be 1, because it must be somewhere in space. This gives the normalization condition for the wave function,

$$\int_{-\infty}^{\infty} |\psi(x)|^2 dx = \int_{-\infty}^{\infty} \psi^*(x)\psi(x)dx = 1, \qquad \textbf{(37.2)}$$

where $\psi^*(x)$ is the complex conjugate of $\psi(x)$. This normalization condition will allow us to determine the amplitude of the wave function. Equation 37.2 says that the integral of the absolute square of the wave function over all of space has the value 1, because if we look everywhere in space, then the integrated probability of finding the electron somewhere is 1.

With the aid of complex numbers (see Appendix A for a refresher on complex numbers), we can write a convenient form for the coordinate space dependence of the wave function of a freely moving particle. This wave function must represent a traveling wave, since the particle is traveling freely; thus, it can be expected that the wave function will be sinusoidal, like the waveform for an electromagnetic wave. This wave function depends on space and time. Time dependence will be treated later. For now, we focus on the dependence on the *x*-coordinate alone, setting $t = 0$. The

particle's wave function is written as a linear combination of sine and cosine oscillations with wave number $\kappa = 2\pi/\lambda$, where λ is the de Broglie wavelength introduced in Chapter 36:

$$\psi(x) = C\cos(\kappa x) + D\sin(\kappa x).$$

Using complex number notation, the same wave function can be written as

$$\psi(x) = Ae^{i\kappa x} + Be^{-i\kappa x}. \qquad \textbf{(37.3)}$$

Self-Test Opportunity 37.1

Using Euler's formula for complex numbers, show that the two expressions given here for $\psi(x)$ are identical and that the amplitudes are related via $A + B = C$ and $i(A - B) = D$.

The coefficients C and D and A and B are, in general, complex numbers. The coefficients A and B can be chosen to suit the particular physical situation, under the condition that the overall wave function is normalized, according to equation 37.2.

Why is it more convenient to use the complex numbers? An answer to this question is given in the next subsection in relation to the momentum that corresponds to a wave function.

Momentum

Suppose we have a freely moving particle with a wave function of the form given by equation 37.3. For now, we set $B = 0$. This will simplify our work, and we will soon learn the significance of the coefficient *B*. Therefore, the particle's wave function is

$$\psi(x) = Ae^{i\kappa x}. \tag{37.4}$$

What is the momentum associated with this wave function? According to the de Broglie relation, $\lambda = h/p$, the wave number can be expressed as

$$\kappa = \frac{2\pi}{\lambda} = \frac{2\pi}{h/p} = p\frac{2\pi}{h} = \frac{p}{\hbar},$$

where $\hbar = h/2\pi$. Consequently,

$$p = \hbar\kappa. \tag{37.5}$$

What operation applied to the wave function will result in a product of the wave function times the momentum? Let's try this *Ansatz*:

$$\widehat{\mathbf{p}}\psi(x) = -i\hbar\frac{d}{dx}\psi(x). \tag{37.6}$$

Here we have used the notation

$$\widehat{\mathbf{p}} = -i\hbar\frac{d}{dx}$$

to denote the **momentum operator,** that is, the operator that results in the product of the momentum and the wave function when applied to the wave function. This way of writing the

momentum operator is motivated by noticing that taking the derivative of $\psi(x) = Ae^{i\kappa x}$ with respect to x is equivalent to multiplying the wave function by the factor $i\,\kappa$. However, this momentum operator turns out to be more general and works for all wave functions, not just that of equation 37.4.

We can take the derivative and convince ourselves that our *Ansatz* makes sense for this wave function:

$$-i\hbar\frac{d}{dx}\psi(x) = -i\hbar\frac{d}{dx}Ae^{i\kappa x} = -i\hbar A\frac{d}{dx}e^{i\kappa x} = -i\hbar A(i\kappa)e^{i}$$

Thus, applying momentum operator to the wave function $\psi(x) = Ae^{i\kappa x}$ indeed gives us the product of the wave function with its momentum $p = \hbar\kappa$. Therefore, it is appropriate to interpret the wave function (equation 37.4) as that of a free particle moving with positive momentum $p = \hbar\kappa$. Conversely, the wave function $\psi(x) = Be^{-i\kappa x}$ describes a free particle moving with a negative x-component of momentum, $-p$, that is, along the negative x-axis. That is the significance of the coefficient B. The more general wave function (equation 37.3) therefore describes a superposition of left- and right-moving waves.

Kinetic Energy

We have found that we can apply a momentum operator to the quantum wave function of a particle in order to find the particle's momentum. Are there other operators that can be applied to wave functions to find the equivalent classical quantities? One such classical quantity is the kinetic energy of a particle. Classically, the kinetic energy can be written as $K = p^2/2m$, so, following the idea of equation 37.6, we introduce an operator for the kinetic energy:

$$\widehat{\mathbf{K}}\psi(x) = \frac{1}{2m}\widehat{\mathbf{p}}^2\psi(x) = \frac{1}{2m}\left(-i\hbar\frac{d}{dx}\right)^2\psi(x) = -\frac{\hbar^2}{2m}\frac{d}$$

This equation can be taken to be the general definition of the kinetic energy operator. What happens in the special case where this operator is applied to the wave function of a freely moving particle with momentum $p = \hbar\kappa$, one that has a wave function $\psi(x) = Ae^{i\kappa x}$? In this case, we obtain

$$-\frac{\hbar^2}{2m}\frac{d^2}{dx^2}\psi(x) = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2}Ae^{i\kappa x} = -i\kappa\frac{\hbar^2}{2m}\frac{d}{dx}Ae^{i\kappa x} = \kappa$$

Indeed, this operator works as advertised. Applying the kinetic energy operator to the wave function of a free particle yields the particle's kinetic energy times the wave function. Note that inserting the wave function $\psi(x) = Be^{-i\kappa x}$ would have resulted in the same value for the kinetic energy, because $(-\kappa)^2 = \kappa^2$. Thus, for the superposition of a left- and a right-moving wave with wave number κ, applying the kinetic energy operator to the wave function of equation 37.3 results in

$$\widehat{\mathbf{K}}\left(Ae^{i\kappa x} + Be^{-i\kappa x}\right) \equiv -\frac{\hbar^2}{2m}\frac{d^2}{dx^2}\left(Ae^{i\kappa x} + Be^{-i\kappa x}\right) = \frac{\hbar^2}{2}$$

37.2 Time-Independent Schrödinger Equation

Given that an electron can be represented by a wave function, what is the equation of motion that describes how this wave function depends on space and time? Such an equation would give solutions for the wave function that are consistent with the observations discussed so far in this chapter. In particular, the solutions should have de Broglie wavelengths of the kind found in Chapter 36, and the absolute squares of the solutions should reproduce the results of the double-slit experiment. The Austrian physicist Erwin Schrödinger (1887–1961) found such an equation in 1925, and it now carries his name. It is the foundation for all of nonrelativistic quantum mechanics. By "nonrelativistic," we mean all physical cases where the speeds of the objects are small compared to the speed of light, allowing the kinetic energy to be expressed as $p^2/2m$. The following discussion applies the time-independent Schrödinger equation to electrons, but this equation also holds for any other object conventionally thought of as a particle.

For now, we look only at one-dimensional problems and investigate their static solutions, that is, their solutions independent of time. The **time-independent Schrödinger equation** for this case is

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x). \qquad \textbf{(37.9)}$$

In this equation, $U(x)$ represents the potential energy, which can be different for different positions, and E is the total mechanical energy of the wave. We have already introduced the first term in this equation as the kinetic energy times the wave function, so we may think of the time-independent Schrödinger equation as an expression of the law of energy conservation for the wave function:

$$(K(x) + U(x))\psi(x) = E\psi(x).$$

If the potential energy is zero everywhere, then $U(x) = 0$ and the total energy is equal to the kinetic energy. For this case, we have already found the solution because the time-independent Schrödinger equation then simply reduces to equation 37.8. In the absence of potential energy, the solution to the equation is thus $\psi(x) = Ae^{i\kappa x} + Be^{-i\kappa x}$.

What is the solution for a very large potential energy? Physicists like to use the limit of an *infinite* potential energy in order to obtain a simple solution. For an infinite potential energy at some point in space, the time-independent Schrödinger equation demands that either the energy E is infinite or the wave function has the value zero at that position. We are not interested in the unphysical, infinite-energy case, so the wave function has to be zero at that position. Therefore, it is physically impossible for a particle to be in a region with infinite potential energy. We call this region a *forbidden region*.

Starting from the simple limiting cases of zero potential energy and infinite potential energy, we can construct more complicated wave function solutions to potential energy distributions. To find these solutions, we have to keep in mind that

- the wave function must be continuous in space (that is, it must not make any "jumps," which would create positions where the derivatives of the wave function are undefined),
- the wave function must be zero in regions with infinite potential energy, as just discussed, and
- the wave function is normalized (that is, it fulfills the normalization condition of equation 37.2).

37.3 Infinite Potential Well

Our first example of a potential energy distribution in space is that of an **infinite potential well.** This is the simplest case mathematically, and it provides insight into interesting physical situations. For an infinite potential well, we define the potential energy as a function of the spatial coordinate x as follows:

$$U(x) = \begin{cases} \infty & \text{for} \quad x < 0 \\ 0 & \text{for} \quad 0 \leq x \leq a \\ \infty & \text{for} \quad x > a. \end{cases} \qquad \textbf{(37.10)}$$

For this case, the wave function is zero for all values outside of the coordinate space interval between 0 and a (Figure 37.4), which implies a zero value at the interval boundaries. Inside this coordinate space interval, the wave function is of the kind given by equation 37.3, $\psi(x) = Ae^{i\kappa x} + \mathrm{B}e^{-i\kappa x}$. As stated before, this solution is mathematically equivalent to $\psi(x) = C\cos(\kappa x) + D\sin(\kappa x)$. This way of writing the wave function is advantageous in this case, because we know that $\psi(0) = 0$. Substituting $x = 0$ into the wave function gives

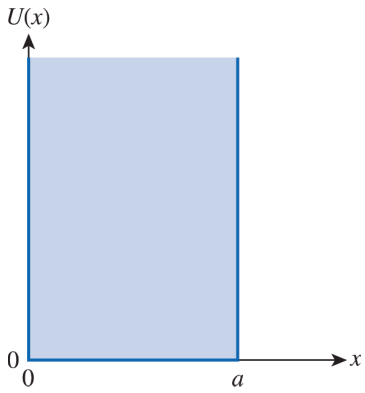

FIGURE 37.4 An infinite potential well. The allowed region with noninfinite values of the potential is shaded in blue.

$$\psi(0) = C\cos(\kappa \cdot 0) + D\sin(\kappa \cdot 0) = C = 0.$$

Thus, the coefficient C must be zero, and the cosine term cannot contribute to the solution, giving the solution $\psi(x) = D\sin(\kappa x)$ in the interval between 0 and a. This makes physical sense, because the superposition of the left-traveling wave $Be^{-i\kappa x}$ and the right-traveling wave $Ae^{i\kappa x}$ results in a standing wave, which is the appropriate form for a wave trapped between two infinitely high potential barriers.

Thus, our preliminary result is that the wave function can be written as

$$\psi(x) = \begin{cases} 0 & \text{for } x < 0 \\ D\sin(\kappa x) & \text{for } 0 \le x \le a \\ 0 & \text{for } x > a. \end{cases}$$

Because the wave function must be continuous, there are constraints on the possible solutions inside the interval between 0 and a, since only those solutions that vanish at the boundaries can be used. At $x = 0$, this vanishing happens automatically because

the sine function is always zero at this point. However, at $x = a$, the boundary condition is

$$\psi(x = a) = D \sin(\kappa a) = 0.$$

This implies that not all values of the wavelength $\lambda = 2\pi/\kappa$ are possible, but only those for which

$$\kappa a = \frac{2\pi a}{\lambda} = n\pi (\text{for all } n = 1, 2, 3, \ldots)$$

is fulfilled, because the sine function is zero whenever its argument is an integer multiple of π. (Technically, $n = 0$ is also permitted, but for any finite value of a this implies an unphysical infinite wavelength. Negative integers would also be permitted, but because $\sin(-x) = -\sin(x)$, these do not give us additional solutions beyond those already contained in the positive integers.) Thus, the only possible wavelengths in this potential well are those given by

$$\lambda_n = \frac{2a}{n} \ (\text{for all } n = 1, 2, 3, \ldots). \qquad \textbf{(37.11)}$$

Then the only possible solutions of the time-independent Schrödinger equation for the case of a particle in an infinite potential well are

$$\psi(x) = \begin{cases} 0 & \text{for} \quad x < 0 \\ D \sin\left(\dfrac{n\pi x}{a}\right) \text{ with } n = 1, 2, 3, \ldots & \text{for} \quad 0 \leq x \leq a \\ 0 & \text{for} \quad x > a. \end{cases}$$

We are almost done, but we still have to determine the amplitude D of the wave function. In order to obtain it, we use the normalization

condition (equation 37.2):

$$
\begin{aligned}
1 = \int_{-\infty}^{\infty} |\psi(x)|^2 dx &= \int_{-\infty}^{0} |\psi(x)|^2 dx + \int_{0}^{a} |\psi(x)|^2 dx + \int_{a}^{\infty} |\psi(x
\\
&= 0 + \int_{0}^{a} \left| D \sin\left(\frac{n\pi x}{a}\right) \right|^2 dx + 0
\\
&= |D|^2 \int_{0}^{a} \sin^2\left(\frac{n\pi x}{a}\right) dx
\\
&= \left|D^2\right| \frac{a}{2}.
\end{aligned}
$$

Therefore, $|D|^2 = 2/a$. Any complex number z can be written as $z = re^{i\theta}$, and $|z| = r$ for any phase angle θ. The magnitude of D is $\sqrt{2/a}$, so in general we can write $D = \sqrt{2/a}\, e^{i\theta}$. For simplicity, we select a phase angle of 0, and thus we have the complete solution for the wave function of a particle confined to a potential well with infinitely high walls:

$$
\psi(x) = \begin{cases} 0 & \text{for} \quad x < \\ \sqrt{\dfrac{2}{a}} \sin\left(\dfrac{n\pi x}{a}\right) \text{ with } n = 1, 2, 3, \ldots & \text{for} \quad 0 \leq \\ 0 & \text{for} \quad x > \end{cases}
$$

In equation 37.12, each value of n corresponds to a different possible wave function for a particle in an infinite well. To distinguish these wave functions, each of them is labeled with an index that indicates the number n, the **principal quantum number.** Thus, $\psi_1(x)$ denotes the solution for quantum number 1, and so on. Figure 37.5a shows the wave function solutions for the four lowest quantum numbers.

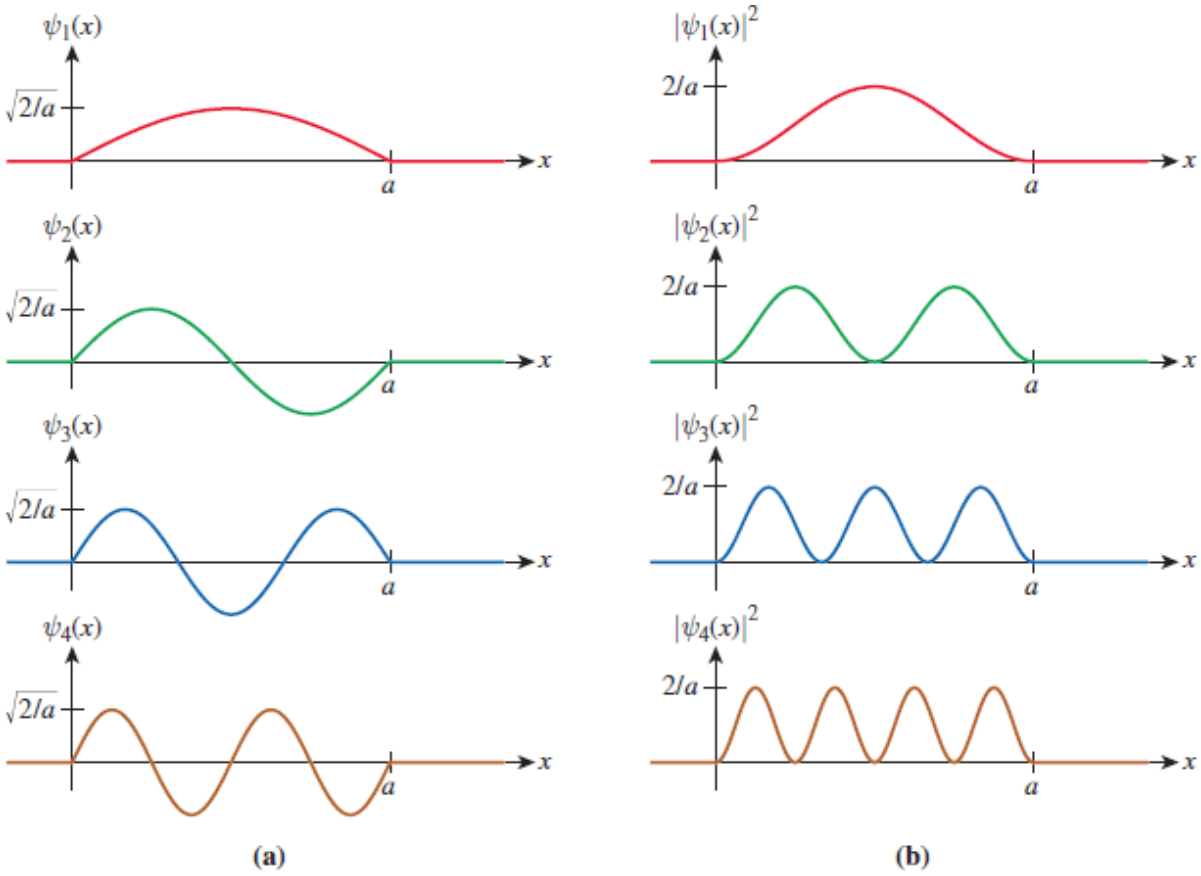

FIGURE 37.5 (a) Wave functions corresponding to the four lowest quantum numbers for a particle in an infinite potential well; (b) probability of finding the particle with the wave function of part (a) at any particular position in the well.

Earlier, we saw that the probability of finding a particle at a given position is proportional to the absolute square of the wave function. Figure 37.5b shows the absolute squares of the wave functions that correspond to the four lowest quantum numbers. Each plot shows the relative likelihood of finding the particle at particular positions in the well when performing a position measurement.

The emergence of simple integer numbers—that is, quantum numbers—is a typical feature of quantum mechanical systems. Boundary conditions on the wave functions force the existence of

solutions that are quantized. The discussions of atoms, atomic nuclei, and elementary particles in Chapters 38 and 39 will show that there are different quantum numbers in many situations.

Chapter 15's solution for a vibrating string has many similarities to the solution for a particle in an infinite potential well. Because the string is clamped at both ends, nodes of the wave function appear at the ends, allowing only the fundamental oscillation and its harmonics. The infinitely high potential outside the interval [0,a] accomplishes the same effect of "clamping down" the wave function of a particle at the boundaries of the potential well. Therefore, the standing wave solutions for the classical vibrating string and the quantum particle in an infinite potential well are mathematically identical.

Finally, let's compare the quantum probability distribution to the classical one for the case we have just considered. In the classical case, the particle remains trapped between 0 and a. Between these two points, it moves with constant speed, $v = \sqrt{2E/m}$.

The probability of finding a particle at a given point in space is proportional to the fraction, dt, of the total time the particle spends in the vicinity, dx, of the point x. In turn, this time interval dt is inversely proportional to the speed, $v(x)$, the particle has at this point, $dt = dx/v(x)$. Thus, the classical probability of finding a particle in the interval between x and $x + dx$ is

$$\Pi_c(x)dx \propto \frac{1}{v(x)}. \qquad \textbf{(37.13)}$$

If v is independent of position, then the classical probability of finding a particle must be a constant as a function of the position. The resulting probability distribution is shown in Figure 37.6.

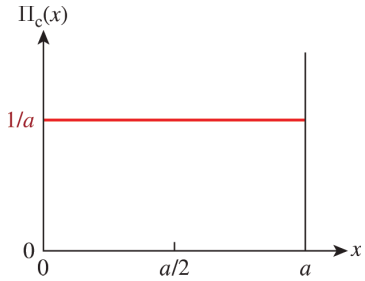

FIGURE 37.6
Classical probability distribution for finding a particle at any particular position trapped in an infinite potential well.

Comparing the distribution in Figure 37.6 with the quantum mechanical probability distribution in Figure 37.5b, we see clear differences. Each quantum mechanical probability distribution oscillates between 0 and a maximum value of $2/a$, whereas the classical probability value is the average of this oscillation, $1/a$. The relationship between classical and quantum mechanical probability distributions is discussed in more detail later in this chapter.

Energy of a Particle

The time-independent Schrödinger equation (37.9) depends on the total energy of the particle. Now that we have the complete wave function solution for a particle in an infinite potential well, let's find the total energy that corresponds to this solution. Outside the interval between $x = 0$ and $x = a$, the wave function is zero, so the particle has zero probability of residing in that region. Thus, the outside region does not contribute to the energy. Inside the interval between 0 and a, there is no potential energy. Therefore, the total energy is equal to the kinetic energy of the particle. Equation 37.7 allows us to calculate this kinetic energy:

$$\widehat{\mathbf{K}}\psi(x) = -\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2}.$$

For each quantum number n, however, a different result will be obtained for the kinetic energy and therefore the total energy. We label this total energy corresponding to the quantum number n as E_n. For the case of the particle in the infinite potential well,

$$\begin{aligned} E_n\psi_n(x) &= -\frac{\hbar^2}{2m}\frac{d^2\psi_n(x)}{dx^2} \\ &= -\frac{\hbar^2}{2m}\frac{d^2}{dx^2}\left(\sqrt{\frac{2}{a}}\sin\Big(\frac{n\pi x}{a}\Big)\right) \\ &= -\frac{\hbar^2}{2m}\Big(\frac{n\pi}{a}\Big)\frac{d}{dx}\left(\sqrt{\frac{2}{a}}\cos\Big(\frac{n\pi x}{a}\Big)\right) \\ &= \frac{\hbar^2}{2m}\Big(\frac{n\pi}{a}\Big)^2\left(\sqrt{\frac{2}{a}}\sin\Big(\frac{n\pi x}{a}\Big)\right) \\ &= \frac{\hbar^2}{2m}\Big(\frac{n\pi}{a}\Big)^2\psi_n(x). \end{aligned}$$

The total energy E_n corresponding to the quantum number n is thus proportional to the square of n:

$$E_n = \frac{\hbar^2 \pi^2}{2ma^2} n^2 \quad (\text{for } n = 1, 2, 3, \ldots). \qquad \textbf{(37.14)}$$

The total energy also depends inversely on the square of the width of the potential well, a, and inversely on the mass of the particle, m. The total energies can be represented as horizontal lines in a plot of energy versus position. Such a plot, called an **energy-level diagram,** is shown in Figure 37.7. Because the energies of these states are lower than the (infinite) height of the potential well, the states are referred to as **bound states.** The infinite potential well has an infinite number of bound states.

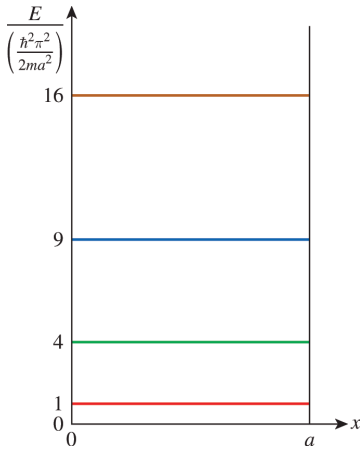

FIGURE 37.7 The four lowest energy levels in an infinite potential well. The colors of the energy levels correspond to the colors of the corresponding wave functions in Figure 37.5.

This solution for an infinite potential well is sometimes called a "particle in a box" and it allows us to simply model an electron bound to an atom or a proton bound in an atomic nucleus, as the following example shows.

Concept Check 37.1

If the width of the potential well is reduced to half its original value, the energy of the $n = 3$ wave function will

a) stay the same.

b) be reduced by a factor of 2.

c) be reduced by a factor of 4.

d) be increased by a factor of 2.

e) be increased by a factor of 4.

EXAMPLE 37.1 Electron in a Box

PROBLEM

What is the kinetic energy of the wave function with the lowest quantum number for an electron confined to a box of width $2.00\,\text{Å} \equiv 2.000 \cdot 10^{-10}\,\text{m}$?

SOLUTION

The mass of the electron is $m = 9.109 \cdot 10^{-31}\,\text{kg}$. Substituting numerical values into equation 37.14 gives

$$E_1 = \frac{\hbar^2\pi^2}{2ma^2} = \frac{\left(1.0546 \cdot 10^{-34}\,\text{J s}\right)^2\pi^2}{2\left(9.109 \cdot 10^{-31}\,\text{kg}\right)\left(2.000 \cdot 10^{-10}\text{m}\right)^2} =$$

Alternatively, this energy value can be expressed in units of electron-volts:

$$E_1 = \left(1.506 \cdot 10^{-18}\,\text{J}\right)/\left(1.602 \cdot 10^{-19}\text{J/eV}\right) = 9.401\,\text{eV}.$$

DISCUSSION

Chapter 38 will show that atoms have typical diameters of $10^{-10}\,\text{m}$, so this result allows us to estimate that the typical energy scale for electrons in atoms has to be on the order of 10 eV. Real atoms are much more complicated than a simple model of a box with infinitely high walls, but this model allows us to make educated guesses about the energy scales involved in a physical problem.

Performing the same exercise for a proton (with a mass approximately 1800 times that of the electron) confined to a box of width $4.0 \cdot 10^{-15}\,\text{m}$, which is the typical dimension of an atomic nucleus, yields the answer of $13 \cdot 10^6\,\text{eV}$. We conclude that typical nuclear energy scales are on the order of 13 MeV, a remarkably good first guess.

Self-Test Opportunity 37.2

How do the solutions for the wave functions and energies of a particle in an infinite potential well change if the potential energy function of equation 37.10 is replaced with with one that is still infinite outside the interval between 0 and a, but has a constant value of $c \neq 0$ inside this interval?

Multidimensional Wells

The idea of a one-dimensional infinite potential well can be extended to a two-dimensional well in which a particle is confined in the *xy*-plane, or even to a rectangular box in three-dimensional space. We will not derive the full solutions for these situations, but instead will stress the general features.

First, let's think about what will be different as our calculations are extended from one to two spatial dimensions. The potential energy in this case can be a function of both variables, *x* and *y*, and so we write it as *U*(*x*,*y*). This means that the wave function must also be written as a function of these two variables, $\psi(x,y)$. In our classical considerations of kinetic energy, we saw that it can be expressed as

$$K = \frac{p^2}{2m} = \frac{p_x^2}{2m} + \frac{p_y^2}{2m}.$$

In analogy with what we derived for the one-dimensional case (see equation 37.6), the *x*- and *y*-components of the momentum operator can be written as

$$\begin{aligned}\widehat{\mathbf{p}}_x\psi(x,y) &= -i\hbar\frac{\partial}{\partial x}\psi(x,y)\\ \widehat{\mathbf{p}}_y\psi(x,y) &= -i\hbar\frac{\partial}{\partial y}\psi(x,y).\end{aligned}$$

The only change relative to the one-dimensional case is that partial derivatives must be used, as is appropriate for multivariable calculus. (A partial derivative with respect to one variable treats the other variables as constants.) Then the kinetic energy operator for the quantum wave function can be written as

$$\begin{aligned}\widehat{\mathbf{K}}\psi(x,y) &= \frac{1}{2m}\widehat{\mathbf{p}}_x^2\psi(x,y) + \frac{1}{2m}\widehat{\mathbf{p}}_y^2\psi(x,y)\\ &= -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\psi(x,y) - \frac{\hbar^2}{2m}\frac{\partial^2}{\partial y^2}\psi(x,y).\end{aligned}$$

Finally, the two-dimensional time-independent Schrödinger equation is

$$-\frac{\hbar^2}{2m}\frac{\partial^2\psi(x,y)}{\partial x^2}-\frac{\hbar^2}{2m}\frac{\partial^2\psi(x,y)}{\partial y^2}+U(x,y)\psi(x,y)=E\psi(x$$

To proceed, we need to specify the shape of the potential energy well. If the potential energy can be written as a sum of a function that depends only on x and another that depends only on y—that is to say, $U(x,y)=U_1(x)+U_2(y)$—then the problem becomes **separable.** This means that the wave function is a product of two functions and that each one depends on only one variable: $\psi(x,y)=\psi_1(x)\cdot\psi_2(y)$.

Further, if we use the simplifying case of a two-dimensional rectangular infinite potential well,

$$U(x,y)=U_1(x)+U_2(y),$$

$$\text{with } U_1(x)=\begin{cases}\infty & \text{for} \quad x<0\\ 0 & \text{for} \quad 0\le x\le a,\\ \infty & \text{for} \quad x>a\end{cases} \quad U_2(y)=\begin{cases}\infty & \text{for} \quad y\\ 0 & \text{for} \quad 0\\ \infty & \text{for} \quad y\end{cases}$$

then the solutions we obtain are products of the wave functions given by equation 37.12 in the x- and y-directions. Explicitly, these wave functions are

$$\psi(x,y)=\psi_1(x)\cdot\psi_2(y)$$

$$\psi_1(x) = \begin{cases} 0 & \text{for} \quad x \\ \sqrt{\frac{2}{a}} \sin\left(\frac{n_x \pi x}{a}\right) \text{with } n_x = 1, 2, 3, \ldots & \text{for} \quad 0 \\ 0 & \text{for} \quad x \end{cases}$$

$$\psi_2(y) = \begin{cases} 0 & \text{for} \quad y \\ \sqrt{\frac{2}{a}} \sin\left(\frac{n_y \pi y}{b}\right) \text{with } n_y = 1, 2, 3, \ldots & \text{for} \quad 0 \\ 0 & \text{for} \quad y \end{cases}$$

These solutions are displayed in Figure 37.8 for the lowest values of the quantum numbers n_x and n_y.

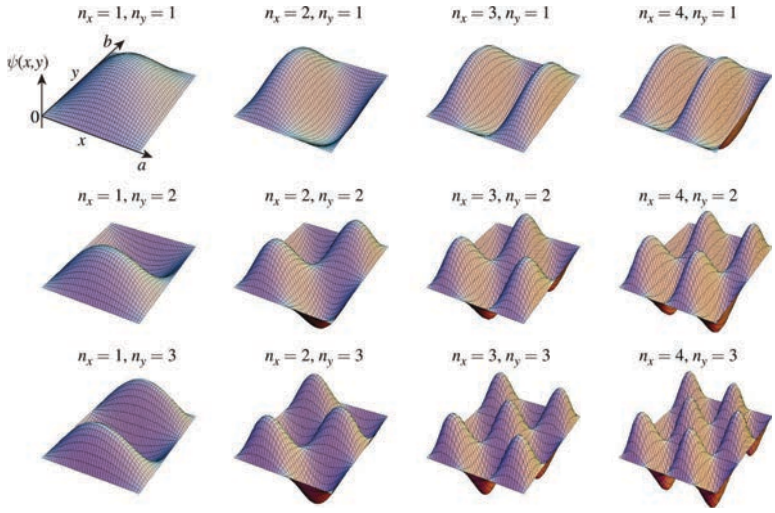

FIGURE 37.8 Wave functions corresponding to the lowest quantum numbers for a particle in a twodimensional rectangular infinite potential well.

Self-Test Opportunity 37.3

Using the same considerations, write the wave functions and energies for a three-dimensional rectangular infinite potential well.

In the same way that we arrived at the solution for the energy values corresponding to the one-dimensional quantum numbers n in equation 37.14, we obtain for the energies corresponding to these two-dimensional wave functions:

$$E_{n_x,n_y} = \frac{\hbar^2\pi^2}{2ma^2}n_x^2 + \frac{\hbar^2\pi^2}{2mb^2}n_y^2. \qquad \textbf{(37.16)}$$

If, for example, $a = b$ (a square potential well), then the same energy value can usually be obtained in more than one way. For instance, the states with quantum numbers $(n_x = 1, n_y = 2)$ and $(n_x = 2, n_y = 1)$ have the same energy. This situation is referred to as *degeneracy*.

If the potential well is not rectangular, then the solution usually cannot be written in a simple form. However, in many cases the problem can still be solved numerically. Experimentally, very high (not quite infinite) two-dimensional potential wells for electrons can be generated by arranging several atoms on a flat surface in the shape of a corral. Figure 37.9 shows one example, where the color coding (large image) or the ripples (gray-scale inset) represent the probability distributions for the electron wave function inside corrals consisting of iron atoms arranged in different shapes on a flat copper surface. The instrument used to arrange the atoms in the ways shown and to generate these experimental images is a scanning tunneling microscope, which will be discussed in more detail later in this chapter.

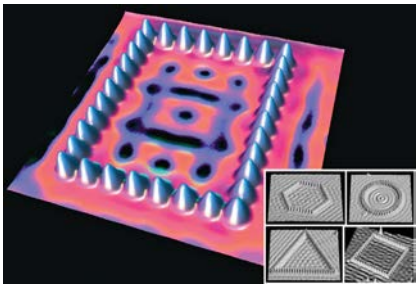

FIGURE 37.9 Two-dimensional rectangular quantum corral made of individual iron atoms, arranged on a copper surface. The color coding inside the corral shows the electron wave probability density. The gray-scale insets show several corrals of different shapes, and the ripples indicate the electron wave probability density. These arrangements were created using a scanning tunneling microscope.

To conclude this discussion of the infinite potential well, let's stress the main point. Even though the infinite potential well is a fairly unrealistic abstraction, it exhibits some characteristic features that are common to all quantum systems: discreteness of energy levels, nonzero ground-state energy, increased separation of

energy levels under tightened constraints, a quantum number for each dimension, and so on. These features, combined with the relative mathematical simplicity, make the infinite potential well worth studying. It introduces the qualitatively new aspects of quantum physics without clouding them with too many mathematical complications.

37.4 Finite Potential Wells

Let's return to the one-dimensional case and solve a problem that is a bit more complicated than that of a potential well with infinitely high potential outside it. Here we consider the case where the wall of the well is not infinitely high, but instead has a finite height.

The shape of the **finite potential well** we want to study is shown in Figure 37.10: The potential energy $U(x)$ is zero inside the interval from 0 to a, is infinite for all values of $x < 0$, and has a finite constant value of $U_1 > 0$ for $x > a$:

$$U(x) = \begin{cases} \infty & \text{for } x < 0 \\ 0 & \text{for } 0 \le x \le a \\ U_1 & \text{for } x > a. \end{cases}$$

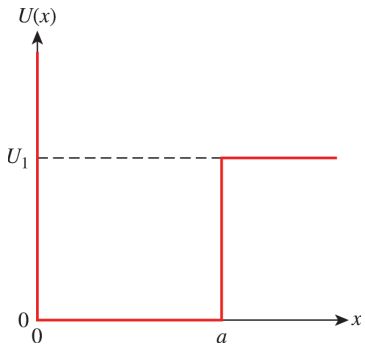

FIGURE 37.10 Finite potential energy well.

Just as in the case of the infinite potential well, we construct a solution for each of the three regions separately and then match these solutions to each other at the boundaries. The solution remains the same as before for $x < 0$, where the wave function must have a constant value of zero. In the interval from 0 to a, the wave function again must have the general form

$\psi(x) = C\cos(\kappa x) + D\sin(\kappa x)$. And again, because the wave function has to be continuous and $\psi(0) = 0$, the coefficient C must be 0, giving the solution $\psi(x) = D\sin(\kappa x)$ in the interval between 0 and a.

For $x > a$, however, there are new effects. In this region, the time-independent Schrödinger equation is

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U_1\psi(x) = E\psi(x).$$

Rearranging this equation leads to

$$\frac{d^2\psi(x)}{dx^2} = \frac{2m(U_1 - E)}{\hbar^2}\psi(x). \qquad \textbf{(37.17)}$$

Let's look at the form of this equation: The second derivative of the wave function is equal to the wave function itself, multiplied by a constant, $2m(U_1 - E)/\hbar^2$. We do not yet know what the energy E is, but we can distinguish two different cases.

Case 1: Energy Larger Than the Well Depth

For $E > U_1$, we have $2m(U_1 - E)/\hbar^2 < 0$, and we obtain oscillatory solutions of the same kind as those we found inside the interval between 0 and a, but with a different wavelength and thus a different wave number:

$$\psi(x) = F\cos\left(\kappa' x\right) + G\sin\left(\kappa' x\right) \text{ (for } x > a \text{ and } E > U_1).$$

How are the wave numbers κ' and κ related to each other? Remember that inside the interval [0,a] there is no potential energy, the total energy is all kinetic energy, and we found that $E = p^2/2m = \hbar^2\kappa^2/2m$. For $x > a$ and $E > U_1$, the kinetic energy is then simply $E - U_1$, and thus $E - U_1 = \hbar^2\kappa'^2/2m$. Therefore,

$$\kappa' = \sqrt{\kappa^2 - \frac{2mU_1}{\hbar^2}}. \qquad \textbf{(37.18)}$$

Thus, the relationship of the wave numbers is $\kappa' < \kappa$, and so the wavelength of the spatial oscillation is larger in the region where $U(x) = U_1 > 0$ than in the region where $U(x) = 0$.

The wave function for this case when the total energy is larger than the height of the potential well, $E > U_1$, is then

$$\psi(x) = \begin{cases} 0 & \text{for } x < 0 \\ D\sin(\kappa x) & \text{for } 0 \le x \le a \\ F\cos(\kappa' x) + G\sin(\kappa' x) & \text{for } x > a. \end{cases}$$

How do we determine the complete solution? We must find the values of the amplitude coefficients D, F, and G. These three numbers can be determined from the following three conditions:

- The wave function must be continuous at the boundary $x = a$ (as explained earlier).

- The derivative of the wave function must be continuous at $x = a$ (as explained below).
- The absolute square of the wave function must be normalized to 1.

The rationale for the second condition is that the momentum is related to the derivative of the wave function, so if the derivative of the wave function were discontinuous, then the momentum would be undefined at the point of discontinuity. Note that the wave numbers κ and κ' are not further constrained by these conditions, and neither are the possible values of the energy E. All energies larger than the value U_1 turn out to be possible.

We will not work through all of the algebra; this is usually done during an upper-level course on quantum mechanics. From the structure we have worked out so far, however, we can make a sketch (Figure 37.11) of the type of wave function that we can expect. This wave function is continuous and has a continuous derivative everywhere. Also, in general, the oscillations in the region with $U > 0$ have larger wavelength (because of equation 37.18) and amplitude (because of the larger wavelength and the first two conditions given above) than the oscillations in the region with $U = 0$. We emphasize once more that an infinite continuum of wavelengths, not just discrete wavelengths, is allowed in this case.

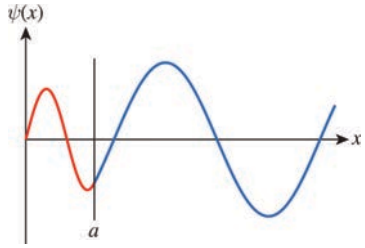

FIGURE 37.11
Wave function for the finite potential well, with energy larger than the height of the potential well.

Case 2: Energy Smaller Than the Well Depth, Bound States

In the second case, the energy of the particle is smaller than the depth of the potential well, so the wave functions that fulfill the condition $E < U_1$ form bound states. Part of our task is to find out if there are any bound states at all. Because even the lowest possible energy of a wave function in the infinite well has a finite nonzero value, we expect that for very shallow potential wells, no bound state occurs.

For $E < U_1$, the constant $2m(U_1 - E)/\hbar^2$ has a value larger than zero. Thus, instead of oscillatory solutions, we obtain exponential solutions to the differential equation 37.17. To show this in quantitative detail, we introduce a constant γ:

$$\gamma = \sqrt{\frac{2m(U_1 - E)}{\hbar^2}}. \qquad \textbf{(37.19)}$$

Then the differential equation 37.17 that we have to solve for the region $x > a$ becomes

$$\frac{d^2\psi(x)}{dx^2} = \gamma^2\psi(x).$$

It has this solution:

$$\psi(x) = Fe^{-\gamma x} + Ge^{\gamma x} \text{ (for } x > a \text{ and } E < U_1).$$

(That this is a solution can be verified by taking its second derivative and inserting that back into the differential equation.) We discard the exponentially rising term $e^{\gamma x}$ because it becomes infinite as $x \to \infty$. Then the wave function would not be normalizable; that is, the integral of the absolute square of the wave function could not have the value 1 according to equation 37.2. Thus, $G = 0$, and our solution becomes

$$\psi(x) = Fe^{-\gamma x} \text{ (for } x > a \text{ and } E < U_1).$$

Again, the wave function for all three regions can be written as follows:

$$\psi(x) = \begin{cases} 0 & \text{for } x < 0 \\ D \sin(\kappa x) & \text{for } 0 \leq x \leq a \\ Fe^{-\gamma x} & \text{for } x > a. \end{cases} \qquad \textbf{(37.20)}$$

The conditions for a normalized wave function that is continuous and has a continuous derivative at $x = a$ provide three equations for the two unknown amplitudes D and F, as well as the wave number κ. The other constant that appears in this solution, γ, is not independent of κ. This can be seen by using the defining equation (37.19) for γ and the fact that when the potential energy is zero in the region $0 \leq x \leq a$, the total energy E, which is constant, is simply $E = \hbar^2\kappa^2/2m$. This results in

$$\gamma^2 = \frac{2m(U_1 - E)}{\hbar^2} = \frac{2mU_1}{\hbar^2} - \frac{2mE}{\hbar^2} = \frac{2mU_1}{\hbar^2} - \kappa^2. \textbf{(37}$$

Before we examine a representative case in greater detail, let's first think about the general features of the solution that we expect to obtain. Just as in the case of an infinite potential well, the wave function in the case of a finite potential well oscillates in sine form in the region where the potential energy vanishes. However, the wave function in the latter case is allowed to "leak" through the wall, although it has an exponentially decreasing value as x increases beyond a. This leakage allows the wavelength for $x < a$ to be somewhat longer than the wavelength in the infinite well because now the function spills over into $x > a$. A longer wavelength implies a smaller wave number. Since the total energy is proportional to the square of the wave number, the energy values corresponding to the wave functions in the finite potential well can be expected to be lower than their counterparts in the infinite well. Another way of stating this result is to say that the wave functions

in the infinite well are more *localized*, and thus have larger kinetic energies, than their corresponding counterparts in the well of finite depth.

SOLVED PROBLEM 37.1 Finite Potential Well

PROBLEM

Suppose an electron is to have at least two bound states in a well of the shape indicated in Figure 37.10. If the width of the well is $a = 1.30\,\text{nm}$, how high does the potential step U_1 (the depth of the well) need to be for the wavelength of the $n = 2$ state to be 20.0% greater than it would be in an infinite potential well of the same width?

SOLUTION

THINK

This problem must be approached in steps. First, equation 37.11 gave the result for the infinite well, $\lambda_n = 2a/n$, for all $n = 1, 2, 3, \ldots$. Thus, we obtain for $n = 2$ the wavelength $\lambda_2 = 2a/2 = a$. (As usual, we do not insert the value for a at this point, but leave the result general and insert the numbers only at the end.)

A wavelength 20.0% larger than that for the infinite well in this case is $\lambda_2' = 1.20\lambda_2 = 1.20a$. The corresponding value of the wave number is thus $k_2' = 2\pi/\lambda_2' = 2\pi/(1.20a)$. Since the wave number is inversely proportional to the wavelength, and the wavelength needs to increase by 20.0%, the wave number needs to be reduced by the same factor: $k_2' = \kappa_2/1.20$. (Again, we postpone inserting numerical values for the wave numbers until the end.)

SKETCH

We can use Figure 37.10 as our sketch.

RESEARCH

The general wave function for this problem is given by equation 37.20:

$$\psi_2(x) = \begin{cases} 0 & \text{for } x < 0 \\ D\ \sin(k_2' x) & \text{for } 0 \le x \le a \\ Fe^{-\gamma x} & \text{for } x > a. \end{cases}$$

Let's look at the boundary conditions at $x = a$. Demanding continuity of the wave function requires that

$$D\sin\left(k_2' a\right) = Fe^{-\gamma a} \Rightarrow \sin\left(k_2' a\right) = \frac{F}{D} e^{-\gamma a}. \quad \textbf{(i)}$$

We take the derivative of the wave function, and then look at the continuity condition for that derivative. The derivative is

$$\frac{d}{dx}\psi_2(x) = \begin{cases} 0 & \text{for } x < 0 \\ k_2' D\ \cos(k_2' x) & \text{for } 0 \le x \le a \\ -\gamma F e^{-\gamma x} & \text{for } x > a. \end{cases}$$

A continuous first derivative at $x = a$ thus requires that

$$k_2' D\cos\left(k_2' a\right) = -\gamma F e^{-\gamma a} \Rightarrow -\frac{k_2'}{\gamma}\cos\left(\kappa'_2 a\right) = \frac{F}{D} e^{-}$$

SIMPLIFY

Equations (i) and (ii) have the same right-hand sides. Therefore, their left-hand sides must also be equal, and we obtain

$$-\frac{k_2'}{\gamma}\cos(k_2' a) = \sin(k_2' a) \Rightarrow \quad \textbf{(37.22)}$$
$$\gamma = -k_2' \cot(k_2' a).$$

Taking the square of equation 37.22 results in

$$\gamma^2 = \kappa'^2_2 \cot^2\left(k'_2 a\right). \qquad \textbf{(iii)}$$

However, we also have the following expression for γ^2 from equation 37.21:

$$\gamma^2 = \frac{2mU_1}{\hbar^2} - \kappa'^2_2. \qquad \textbf{(iv)}$$

Combining equations (iii) and (iv) gives

$$\begin{aligned}
\kappa'^2_2 \cot^2(k'_2 a) &= \frac{2mU_1}{\hbar^2} - \kappa'^2_2 \Rightarrow \\
\frac{2mU_1}{\hbar^2} &= \kappa'^2_2\left(1 + \cot^2(k'_2 a)\right) \Rightarrow \\
U_1 &= \frac{\hbar^2 \kappa'^2_2}{2m}\left(1 + \cot^2(k'_2 a)\right).
\end{aligned}$$

Formally, this is our answer.

CALCULATE

Now we can insert the numbers. We have already noted that $k'_2 = 2\pi/\lambda'_2 = 2\pi/(1.20a)$; therefore, $k'_2 a = 2\pi/1.20$. We can then calculate the factor $\cot^2(k'_2 a)$:

$$\cot^2\left(k'_2 a\right) = \cot^2(2\pi/1.20) = 0.3333 = \tfrac{1}{3}.$$

Therefore, the potential step has to have a height of $1 + \frac{1}{3} = \frac{4}{3}$ times the energy E_2 of the wave function ψ_2. This energy is

$$E_2 = \frac{\hbar^2 \kappa_2'^2}{2m} = \frac{\hbar^2 (2\pi/1.20a)^2}{2m} = \frac{h^2}{2.88ma^2}$$
$$= \frac{\left(6.626 \cdot 10^{-34}\ \text{J s}\right)^2}{2.88\left(9.109 \cdot 10^{-31}\ \text{kg}\right)\left(1.30 \cdot 10^{-9}\text{m}\right)^2}$$
$$= 9.90 \cdot 10^{-20}\ \text{J} = 0.618\ \text{eV}.$$

ROUND

To three significant figures, our answer is $U_1 = \frac{4}{3} E_2 = 0.824\ \text{eV}$.

DOUBLE-CHECK

Note that $k_2' = \kappa_2/1.20$ as demanded by the problem statement. Since $E \propto \kappa^2$ for the potential well, the energy E_2 is lower than that in the infinite well by a factor of $(1/1.20)^2 = 0.694$.

This problem is fairly typical. It shows how to use the conditions of continuity of the wave function and its derivatives at boundaries to set up equations that provide the undetermined constants in the generic solution. In this case, the generic solution was of the same type as equation 37.20, with constants U_1, D, F, k_2', and γ, which were to be determined. The continuity of the wave function was expressed in equation (i), and the continuity of the derivative in equation (ii). A third equation was obtained from the relationship between γ and k_2' expressed in equation 37.21. Because k_2' was specified by the problem statement, we would need four equations to solve for the remaining four unknown quantities. The continuity of ψ and its derivative at the boundary and the relationship between γ and k_2' would be enough to solve for U_1. To find D and F, we would need to use the normalization condition (equation 37.2).

Solved Problem 37.1 presented a condition that predetermined the shape of the wave function by specifying the desired value of

the wave number. A much more conventional problem is figuring out what wave functions fit into a potential of given depth. We will do this in the following example, simplifying the task by using the same numbers as in Solved Problem 37.1.

EXAMPLE 37.2 Bound States

PROBLEM

An electron is trapped in a finite potential well of the kind shown in Figure 37.10 with a depth of $U_1 = 0.824\,\text{eV}$ and a width of $a = 1.30\,\text{nm}$. What wave numbers correspond to the possible bound states in this well?

SOLUTION

The well depth is the same as in Solved Problem 37.1, so one solution for the wave number κ should correspond to the value $2\pi/(1.20a)$, the starting point in that problem. We also found two conditions for the exponential decay constant γ. Equation 37.22 gave $\gamma = -\kappa\cot(\kappa a)$, and equation 37.21 gave $\gamma = \sqrt{2mU_1/\hbar^2 - \kappa^2}$. Combining these results gives

Page 1167

$$\sqrt{\frac{2mU_1}{\hbar^2} - \kappa^2} = -\kappa\cot(\kappa a) \Rightarrow$$
$$\sqrt{\frac{2a^2mU_1}{\hbar^2} - (\kappa a)^2} = -(\kappa a)\cot(\kappa a). \qquad \text{(i)}$$

We omitted the index 2 for the wave number κ from equation 37.22, because we want to search for all possible values of κ that satisfy equation (i). This equation usually does not have an algebraic solution, but we can solve it numerically quite straightforwardly. The numerical constants in this case are $a = 1.30\,\text{nm}$ and $2a^2mU_1/\hbar^2 = 36.5$. Thus, we have to solve the equation

$$\sqrt{36.5 - y^2} = -y\cot y, \text{ with } y = \kappa a.$$

Figure 37.12 plots the two functions $\sqrt{36.5 - y^2}$ (in blue) and $-y \cot y$ (in red) and shows the positions where they intersect.

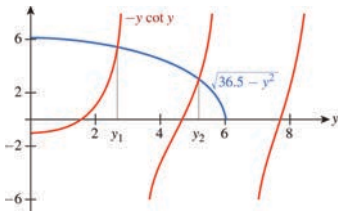

FIGURE 37.12
Finding the wave numbers for the bound states.

As you can see, there are only two positions where the two functions have the same value. Therefore, the potential well of depth $U_1 = 0.824\,\text{eV}$ and width $a = 1.30\,\text{nm}$ has only two bound states. Numerically, we find $y_1 = \kappa_1 a = 2.68$ and $y_2 = \kappa_2 a = 5.24$. This second value is nothing other than $2\pi/1.20$, the value in Solved Problem 37.1. However, the value of $\kappa_1 = 2.68/a$ is new information. Note that, unlike the case of the infinite potential well, $\kappa_2 \neq 2\kappa_1$ for the finite potential well.

In conclusion, Figure 37.13 shows the energies that correspond to the two bound states, overlaid on the shape of the potential energy function used for the potential well.

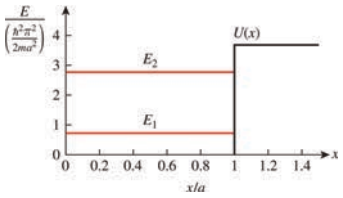

FIGURE 37.13
Energies of the lowest two possible wave functions in the finite potential well.

Figure 37.14a shows the wave functions that correspond to the two values found in Example 37.2 for the wave number, as functions of the spatial coordinate x/a. The upper graph is for the wave function times $\sqrt{a}$, corresponding to wave number κ_1 and energy E_1, and the lower graph is for κ_2 and E_2. The red part of the curve corresponds to the sinusoidal part of the wave function in the potential-free region. The blue part is the exponential penetration of the wave function into the region where the potential energy is greater than the energy of the electron; this is the classically forbidden region. It is apparent from the figure that the two parts of each wave function are properly matched, since each wave function is continuous and has a continuous derivative at the boundary $x/a = 1$. In order to obtain each of these wave functions, we would have to solve a system of equations of the kind used in Solved Problem 37.1.

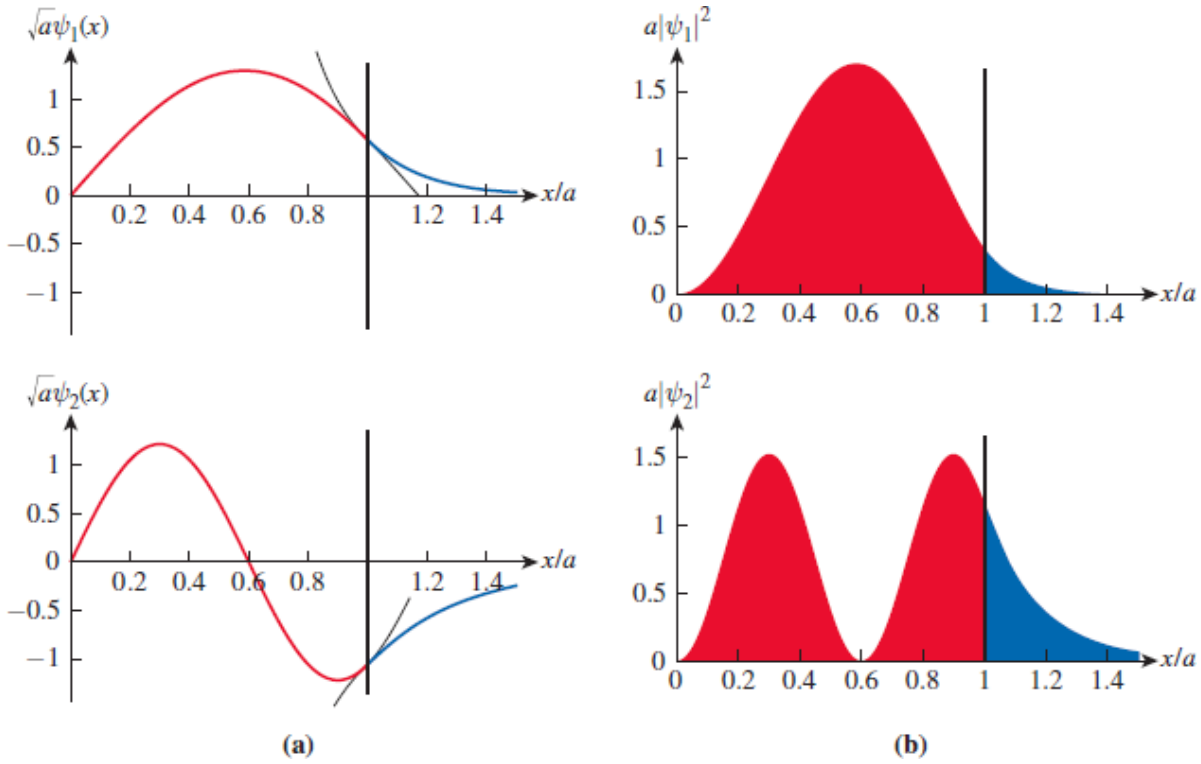

FIGURE 37.14 (a) The two wave functions with lowest values of the wave number for a finite potential step at $x = a$ as a function of x/a. The red line shows the sine function for the zero-potential region, and the blue line shows the exponential function in the classically forbidden region. (b) Corresponding probability distributions for finding the electron at a given coordinate. The blue area indicates the probability of finding the electron in the classically forbidden region. All four plots have scale factors such that the boundary at $x = a$ appears at the value of 1 on the abscissa and the areas in part (b) are the probabilities for finding the particle within the corresponding abscissa region.

Concept Check 37.2

If the width of the potential well in Example 37.2 is doubled, to 2.6 nm, and the depth remains the same, the number of bound states will

a) stay the same.

b) increase.

c) decrease.

The fact that an electron can penetrate the potential boundary and move into the classically forbidden region where $x > a$ is a phenomenon that is unique to the quantum world. Classically, the electron would simply bounce off the wall and could only be found at some point between $x = 0$ and $x = a$. In the quantum world, this is not the case any more. According to equation 37.1, the probability of the electron being in the spatial interval dx can be calculated as $\Pi(x) = |\psi(x)|^2 dx$.

Figure 37.14b plots $a|\psi(x)|^2$ for both of the bound-state wave functions. Integrating the area under the curve in the top graph gives the result that, for the bound state with wave number κ_1, the probability of finding the electron between $x = 0$ and $x = a$ is 96.9% (red area), and the probability of finding the electron in the classically forbidden region, $x > a$, is 3.1% (blue area). If the electron resides in the bound state with wave number κ_2, it has a probability of 18.6% of being found in the classically forbidden region and a probability of 81.4% of being found in $0 < x < a$. Since the energy of the second state is higher than that of the first state and close to the depth of the potential well, the electron in the second state can penetrate farther into the classically forbidden region and consequently has a greater probability of being found there.

Tunneling

If the wave function can reach into the classically forbidden region, then what happens if the potential step of finite height shown in Figure 37.10 has only a finite width? This situation is shown in Figure 37.15a, which shows a plot of the potential energy function

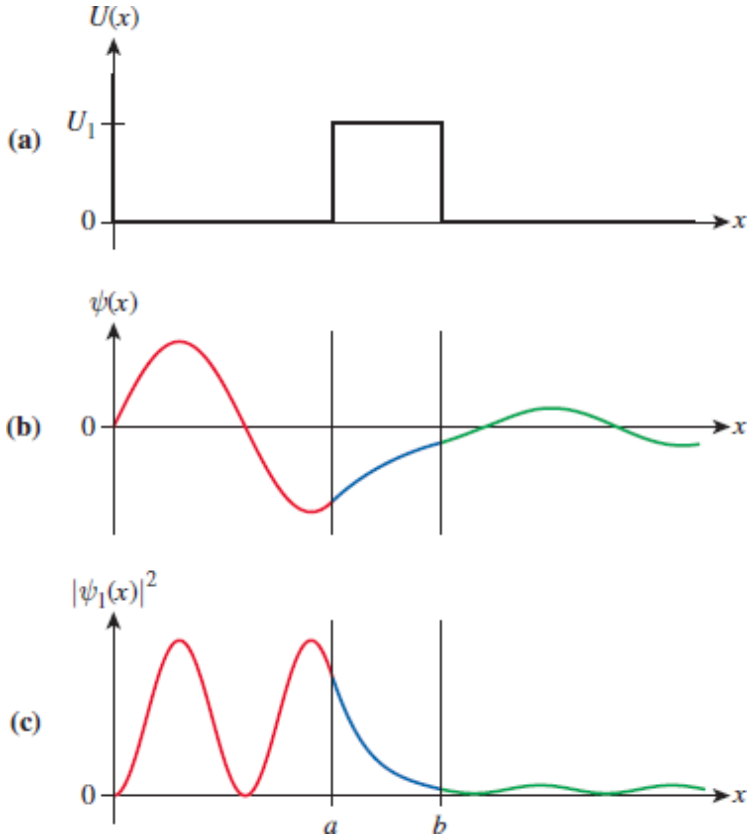

FIGURE 37.15 (a) Potential energy step of finite height and finite width; (b) wave function tunneling through the potential energy barrier; (c) probability density distribution for finding the particle at a position x.

$$U(x) = \begin{cases} \infty & \text{for } x < 0 \\ 0 & \text{for } 0 \leq x \leq a \\ U_1 & \text{for } a < x < b \\ 0 & \text{for } x \geq b. \end{cases}$$

Self-Test Opportunity 37.4

Can you use the conditions of continuity of the wave function and of its derivative at the boundary $x = b$ to derive the values of the phase shift φ and the amplitude G for the wave function for the tunneling of a particle through a potential energy step?

Again, the wave function in the different regions can be written as follows:

$$\psi(x) = \begin{cases} \infty & \text{for } \; x < 0 \\ D \;\sin(\kappa x) & \text{for } \; 0 \leq x \leq a \\ Fe^{-\gamma x} & \text{for } \; a < x < b \\ G \;\sin(\kappa x + \phi) & \text{for } \; x \geq b. \end{cases}$$

Note that the same value can be used for the wave number κ on both sides of the barrier in this case because the potential is zero in both of these regions. In the first part of this section we solved for the wave function in the region $0 \leq x \leq b$. The wave function has a sinusoidal part (red part of the curve in Figure 37.15b) in the region between 0 and a and an exponentially decreasing part (blue part of the curve in part b) between a and b. What is different here is that the wave function does not continue to decay exponentially beyond $x = b$, but it oscillates in sinusoidal fashion for $x > b$ with the same wave number κ as it has between 0 and a. This process is called **tunneling.** The exact shape of the wave function (green part of the curve in part b) for $x > b$ is again determined by matching the wave function and its first derivative at the boundary $x = b$, just as we did before at $x = a$.

Figure 37.15c shows the plot of the probability density for this wave function. Clearly, there is some nonzero probability that the wave function will tunnel through the potential energy barrier and emerge on the other side. Classically, by contrast, a particle located at $0 < x < a$ with the same total energy would not have enough energy to escape and would remain trapped forever in the region $0 \leq x \leq a$.

The **transmission coefficient,** *T,* is defined as the ratio of the absolute square of the wave amplitude at the exit from the barrier to the absolute square of the wave amplitude at the entrance to the barrier. For the wave function $Fe^{-\gamma x}$ in the region of the barrier, the transmission coefficient is found to be

$$T = \frac{|\psi(b)|^2}{|\psi(a)|^2} = \frac{\left|Fe^{-\gamma b}\right|^2}{\left|Fe^{-\gamma a}\right|^2} = \left|e^{-\gamma(b-a)}\right|^2 = e^{-2\gamma(b-a)}. \quad \textbf{(37.2}$$

Thus, the transmission coefficient depends exponentially on the width of the barrier, $b - a$. Note that the probability that the particle is to the left of the barrier $(x \leq a)$ is proportional to $|\psi(a)|^2$. The probability that the particle is to the right of the barrier $(x \geq a)$ is proportional to $|\psi(b)|^2$. The transmission coefficient T therefore measures the probability that a particle hitting the barrier on the left will emerge on the right.

Fascinatingly, this process of tunneling through a potential energy barrier can be observed in nature—for example, in the alpha decay of heavy nuclei. It is a crude, but effective, model of the alpha decay process to imagine the alpha particle to be trapped inside a potential energy well formed by the heavy nucleus and having roughly the shape shown in Figure 37.15a. Over time, the wave function of the alpha particle leaks out of the potential energy well. When this happens, we say that the nucleus *alpha decays*, meaning

that it emits an alpha particle and transmutes into another nucleus. The details of this decay process will be covered in Chapter 40.

EXAMPLE 37.3 Neutron Tunneling

PROBLEM

If a neutron of kinetic energy 22.4 MeV encounters a rectangular potential energy barrier of height 36.2 MeV and width 8.40 fm, what is the probability that the neutron will be able to tunnel through this barrier?

SOLUTION

The tunneling probability was given in equation 37.23 as $\Pi_t = T = e^{-2\gamma(b-a)}$. Knowing that the width of the barrier is $b - a = 8.40\,\text{fm}$, all we have to do to solve this problem is to figure out the value of the decay constant γ. Equation 37.19 applies in this case, and we can write

$$\gamma = \sqrt{\frac{2m(U_1 - E)}{\hbar^2}}.$$

In order to put in numbers, we can express $\hbar$ in units that are very useful in nuclear and particle physics: $\hbar c = 197.33\,\text{MeV fm} \Leftrightarrow \hbar = 197.33\,\text{MeV fm}/c$. The mass of the neutron has the value $m_n = 1.6749 \cdot 10^{-27}\text{kg} = 939.57\,\text{MeV}/c^2$. Inserting the numerical values, we find for the decay constant:

$$\gamma = \sqrt{\frac{2(939.57\,\text{MeV}/c^2)(36.2\,\text{MeV} - 22.4\,\text{MeV})}{(197.33\,\text{MeV fm}/c^2)}} = 0.8$$

Therefore, we obtain for the tunneling probability:

$$\Pi_t = e^{-2\gamma(b-a)} = e^{-2(0.816)(8.40)} = 1.11 \cdot 10^{-6}.$$

Concept Check 37.3

To increase the tunneling probability for the neutron in Example 37.3, it would be necessary to

a) increase the barrier height and/or increase the barrier width.

b) increase the barrier height and/or decrease the barrier width.

c) decrease the barrier height and/or increase the barrier width.

d) decrease the barrier height and/or decrease the barrier width.

Scanning Tunneling Microscope

In 1981, the Swiss physicist Heinrich Rohrer $(1933-2013)$ and the German physicist Gerd Binnig $(1947-)$ discovered that the tunneling effect can be used to image surfaces of materials, and, for the first time, they obtained images of atoms. They were awarded half of the 1986 Nobel Prize in Physics for this discovery. Their work was a conceptual leap and a great technical achievement at the time, but the underlying basic physics is actually relatively straightforward to understand applying the concepts we have developed so far.

Figure 37.16a plots the potential of an electron in an atom in black. Chapter 23 showed that this potential is the Coulomb potential, $U(r) \propto 1/r$. This potential is represented as a function of one spatial coordinate, and the atom sits at x_0. The blue curve is a qualitative sketch of the absolute square of the electron wave function in this potential. (Chapter 38 will show exact calculations for the hydrogen atom.) In Figure 37.16b–d, a second atom, located at x_1, is moved closer and closer to the atom located at x_0. As we move the second atom, we monitor the resulting potential distribution, as well as the corresponding wave function. The potential barrier that prevents the electron from moving from the atom at x_0 to the atom at x_1 becomes narrower and at the same time lower as the atoms are moved closer to each other. Thus, the electron wave function is able to tunnel through the barrier. Quantitative calculations show that the tunnel current rises very steeply if the distance between the two atoms decreases below a certain point.

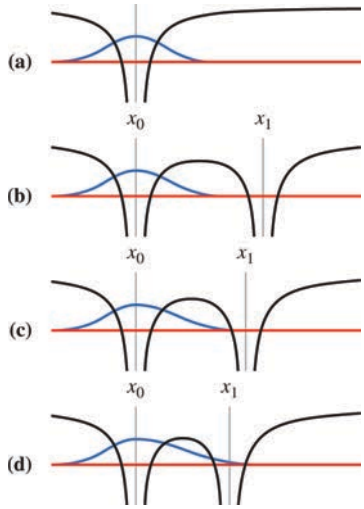

FIGURE 37.16
Black curves: potential of an electron in an atom as a function of the spatial coordinate; blue curve: sketch of the corresponding electron probability distribution. (a) Single isolated atom; (b, c, d) two atoms at various relative distances.

The technique used by the **scanning tunneling microscope (STM)** is to very carefully move a tip the size of a single atom closer and closer to the surface of the material that we want to probe and to record the current due to tunneling electrons (Figure 37.17). How is it possible to produce a tip the size of a single atom? To start with, a very thin wire is cut at an angle. This produces a very fine tip, but not the size of a single atom. However, one of the atoms at the end will usually stick out just a tiny bit farther than those surrounding it. This tiny bit is sufficient, because the tunnel current depends sensitively on the distance. Thus, this tip acts like a single atom.

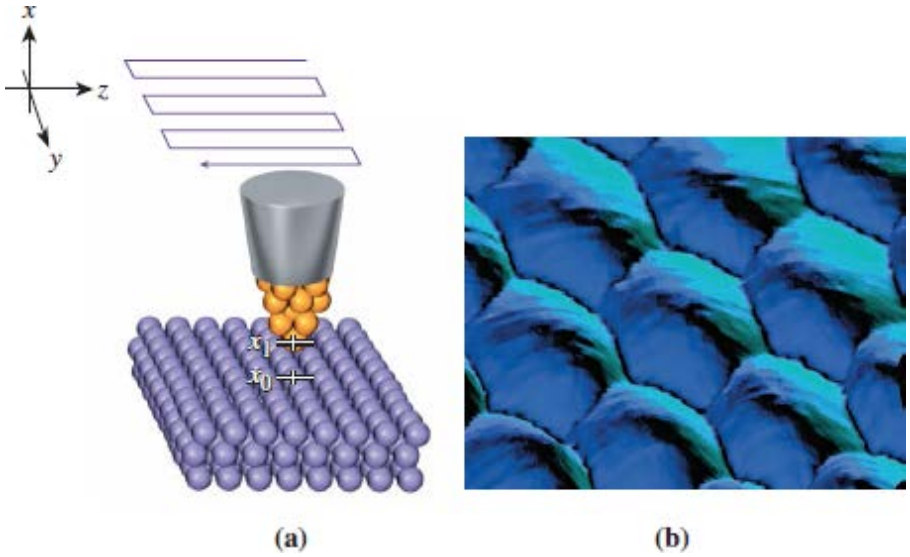

FIGURE 37.17 (a) Scanning the surface with a single-atom tip; (b) resulting image of the surface of a platinum sample.

b: Image reproduced by permission of IBM Research, Almaden Research Center.
Unauthorized use not permitted

The tip is moved up and down in a feedback loop that attempts to keep the measured tunnel current at a constant value. Then the tip is guided over the surface in a scanning path as shown by the purple line in Figure 37.17a. This process produces images of surfaces at an atomic resolution. For example, the surface of a piece of platinum is shown in Figure 37.17b.

37.5 Harmonic Oscillator

The three most commonly used potentials in quantum mechanical calculations are the potential well, the central $1/r$ potential, and the oscillator potential. Chapter 38 will address the central $1/r$ potential, and Sections 37.3 and 37.4 extensively investigated the potential well. This leaves only the oscillator potential.

Classical Harmonic Oscillator

Chapter 14, which covered harmonic oscillations, showed that oscillators occur in many physical situations. Now the question arises: What is the quantum representation of a harmonic oscillator? That is, we want to know the possible wave functions and energies that correspond to the following potential energy function for a harmonic oscillator:

$$U(x) = \tfrac{1}{2}kx^2 = \tfrac{1}{2}m\omega_0^2 x^2.$$

This potential energy function is plotted in Figure 37.18. Here k is the *spring constant* and is measured in units of $\mathrm{N/m}$ while ω_0 is the angular frequency, $\omega_0 = \sqrt{k/m}$. (*Note*: In this chapter, we use several similar symbols: k is the symbol for the spring constant, κ is used for the wave number, K is the value of the kinetic energy, and $\widehat{\mathrm{K}}$ is the kinetic energy operator. It is easy to confuse them, so be extra careful!)

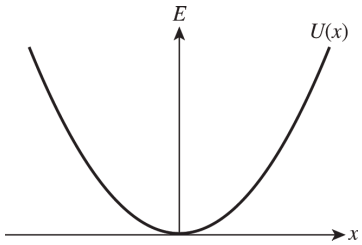

FIGURE 37.18
Potential energy as a function of position for a harmonic oscillator.

Before we go on, let's first review the situation for a classical particle that is a harmonic oscillator in a potential well—for example, a mass on a spring or a pendulum. For a given total energy E, the kinetic energy of this particle can be calculated by

taking the difference between the total energy and the potential energy: $K(x) = E - U(x)$. Keeping in mind that kinetic energy cannot assume negative values, we then obtain a region in coordinate space in which a particle with a given total energy is allowed to be, labeled "classically allowed" in Figure 37.19.

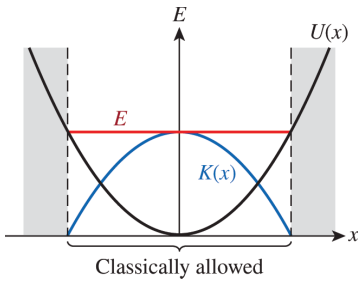

FIGURE 37.19
Classically allowed region for a particle in an oscillator potential.

The points at which the kinetic energy (blue curve in Figure 37.19) reaches the value zero form the boundary of this classically allowed region. These points are called *classical turning points* because a classical oscillator "turns around" here. Outside the turning points lies the classically forbidden region (shaded region in Figure 37.19), into which a classical particle with total mechanical energy E is never able to penetrate.

Quantum Harmonic Oscillator

Now let's investigate the quantum harmonic oscillator. Inserting its potential energy function into the time-independent Schrödinger equation (37.9), we find

$$\begin{aligned} &-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + \tfrac{1}{2}m\omega_0^2x^2\psi(x) = E\psi(x) \Rightarrow \\ &\frac{d^2\psi(x)}{dx^2} = -\frac{2m}{\hbar^2}\left(E - \tfrac{1}{2}m\omega_0^2x^2\right)\psi(x) \Rightarrow \\ &\frac{d^2\psi(x)}{dx^2} = -\left(\frac{2mE}{\hbar^2} - \frac{m^2\omega_0^2}{\hbar^2}x^2\right)\psi(x). \end{aligned} \qquad \textbf{(37.24)}$$

Again we find that the energy can assume only discrete values. In this case, they are

$$E_n = \left(n + \tfrac{1}{2}\right)\hbar\omega_0 \text{ (for } n = 0, 1, 2, \ldots). \qquad \textbf{(37.25)}$$

The wave functions have the general form of Gaussians $\left(e^{-ax^2}\right)$ multiplied by special polynomials, called *Hermite polynomials*. The wave functions corresponding to the lowest values of the energy quantum number, *n*, are

$$
\begin{aligned}
\psi_0(x) &= \frac{1}{\sqrt{\sigma}\pi^{1/4}} e^{-x^2/2\sigma^2} \\
\psi_1(x) &= \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{2}} \left(2\frac{x}{\sigma}\right) e^{-x^2/2\sigma^2} \\
\psi_2(x) &= \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{8}} \left(4\frac{x^2}{\sigma^2} - 2\right) e^{-x^2/2\sigma^2} \\
\psi_3(x) &= \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{48}} \left(8\frac{x^3}{\sigma^3} - 12\frac{x}{\sigma}\right) e^{-x^2/2\sigma^2} \\
\psi_4(x) &= \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{384}} \left(16\frac{x^4}{\sigma^4} - 48\frac{x^2}{\sigma^2} + 12\right) e^{-x^2/2\sigma^2},
\end{aligned}
$$

where the constant σ is defined as

$$
\sigma = \sqrt{\frac{\hbar}{m\omega_0}}. \tag{37.27}
$$

This constant has the physical dimension of length and is the half-width of the Gaussian. The general form of the wave function for the harmonic oscillator can be written as

$$
\psi_n(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{n!\,2^n}} H_n(x/\sigma) e^{-x^2/2\sigma^2}. \tag{37.28}
$$

The Hermite polynomial $H_n(x)$ is a polynomial of rank n; that is, the highest power of x is x^n. This polynomial can be defined in terms of the derivatives of the Gaussian function:

$$H_n(x) = (-1)^n e^{x^2} \frac{d^n}{dx^n} e^{-x^2}.$$

DERIVATION 37.1 Oscillator Wave Function and Energy

The entire derivation of the complete solution (equation 37.28) is somewhat lengthy and will not be shown here. Still, it is instructive to verify that one of the solutions given in equation 37.26 satisfies equation 37.24. We show as an example that $\psi_1(x)$ is indeed a solution to the time-independent Schrödinger equation (37.24) with energy $E_1 = \left(\frac{1}{2} + 1\right)\hbar\omega_0 = \frac{3}{2}\hbar\omega_0$.

We start by taking the second derivative of $\psi_1(x)$ with respect to x. To do this more efficiently, we rewrite the wave function as

$$\psi_1(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}}\frac{1}{\sqrt{2}}\left(2\frac{x}{\sigma}\right)e^{-x^2/2\sigma^2} = \mathrm{Axe}^{-x^2/2\sigma^2}.$$

Here A is just a normalization constant, so the first and second derivatives of this function are

$$\frac{d}{dx}\psi_1(x) = Ae^{-x^2/2\sigma^2} - A\frac{x^2}{\sigma^2}e^{-x^2/2\sigma^2}$$

$$\frac{d^2}{dx^2}\psi_1(x) = -A\frac{3x}{\sigma^2}e^{-x^2/2\sigma^2} + A\frac{x^3}{\sigma^4}e^{-x^2/2\sigma^2}.$$

Inserting this second derivative into the time-independent Schrödinger equation results in

$$\frac{d^2\psi(x)}{dx^2} = -\left(\frac{2mE}{\hbar^2} - \frac{m^2\omega_0^2}{\hbar^2}x^2\right)$$

$$-A\frac{3x}{\sigma^2}e^{-x^2/2\sigma^2} + A\frac{x^3}{\sigma^4}e^{-x^2/2\sigma^2} = -\left(\frac{2mE}{\hbar^2} - \frac{m^2\omega_0^2}{\hbar^2}x^2\right)$$

$$= -\left(\frac{2mE}{\hbar^2}x - \frac{m^2\omega_0^2}{\hbar^2}x^3\right)$$

Now we factor out the common term $Ae^{-x^2/2\sigma^2}$ and sort the terms by powers of x:

$$Ae^{-x^2/2\sigma^2}\left(\left(\frac{2mE}{\hbar^2} - \frac{3}{\sigma^2}\right)x + \left(\frac{1}{\sigma^4} - \frac{m^2\omega_0^2}{\hbar^2}\right)x^3\right) =$$

Because $Ae^{-x^2/2\sigma^2} \neq 0$, equation (i) can be fulfilled for all x only if the coefficients of x and x^3 are both equal to 0. For the coefficient of x^3, we find

$$\frac{1}{\sigma^4} - \frac{m^2\omega_0^2}{\hbar^2} = 0 \Rightarrow \sigma = \sqrt{\frac{\hbar}{m\omega_0}}.$$

This confirms equation 37.27. We further find for the coefficient of x in equation (i):

$$\frac{2mE}{\hbar^2} - \frac{3}{\sigma^2} = 0 \Rightarrow E = \tfrac{3}{2}\frac{\hbar^2}{m\sigma^2}.$$

Using the result of equation 37.27, which we just derived, we then find

$$E = \tfrac{3}{2}\frac{\hbar^2}{m\sigma^2} = \tfrac{3}{2}\frac{\hbar^2}{m(\hbar/m\omega_0)} = \tfrac{3}{2}\hbar\omega_0.$$

Thus, we have shown that $\psi_1(x)$ as defined in equation 37.26 is indeed a solution to the time-independent Schrödinger equation with energy E_1 as given in equation 37.25.

It is important to note that the possible energy values for a one-dimensional harmonic oscillator are evenly spaced, with a constant energy difference of $\hbar\omega_0$ between neighboring energy levels. A wide variety of condensed matter systems and other systems studied in atomic and nuclear physics exhibit discrete energy spectra with constant spacing between the levels.

The wave functions of the quantum harmonic oscillator given in equation 37.26 are plotted in Figure 37.20. To avoid possible confusion, notice that two different plots using different vertical axes are superimposed on each other, with a common horizontal x-axis. The black parabola shows the potential energy as a function of x, and the red horizontal lines show the possible total energies that correspond to solutions of the time-independent Schrödinger equation. The vertical axes for both plots are in units of energy. The intersections of the red total-energy lines with the potential-energy parabola mark the classical turning points and are indicated by the short vertical green lines. However, the blue lines show the wave functions and do not have units of energy, and thus correspond to a different vertical scale. For each wave function, the $\psi = 0$ line is adjusted to fall on the horizontal line that marks the function's lowest energy value. This provides an elegant way of displaying the wave functions, their classical turning points, and the corresponding energy values, all in the same plot. We can quantitatively show how each wave function "leaks" into the classically forbidden region.

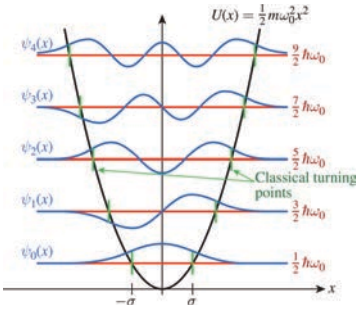

FIGURE 37.20
Wave functions (blue) corresponding to the five lowest energy values (red) of the harmonic oscillator potential (black). The classical turning points for each wave function are indicated by short vertical green lines.

Figure 37.21 shows the probability distributions that correspond to the wave functions. Again, they are simply the absolute squares of the wave functions. Note that the higher the quantum number n, the smaller the penetration range of the corresponding wave function beyond the classical turning point. This result can be understood by looking at the shape of the potential $U(x)$: For higher values of the energy E, the potential becomes steeper at the positions of the classical turning points for that energy.

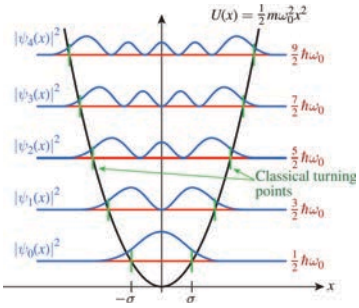

FIGURE 37.21
Probability distributions for finding an electron in a harmonic oscillator potential with a particular energy at a particular point in space.

SOLVED PROBLEM 37.2 Half-Oscillator

PROBLEM

Suppose you know that an electron is confined to the following potential, where a is a constant:

$$U(x) = \begin{cases} a^2x^2 & \text{for} \quad x > 0 \\ \infty & \text{for} \quad x \leq 0. \end{cases}$$

What is the energy of the first excited state, if the ground-state energy of the electron in this potential has a value of 3.5 eV?

SOLUTION

THINK

The potential here is a mixture of an infinite potential well, where $U(x) = \infty$ outside certain regions in space, and a harmonic oscillator potential, $U(x) = \frac{1}{2}m\omega_0^2x^2$, with the $a = \sqrt{\frac{1}{2}m\omega_0^2}$. The key to solving this problem is that the only constraint that an infinite potential wall imposes on a wave function is that it has to be zero at the interface between the infinite and the finite part of the potential function. In this case, this requirement can be written as $\psi(x = 0) = 0$.

SKETCH

Figure 37.22 shows the shape of the potential function given in the problem statement.

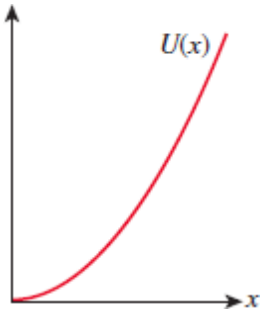

FIGURE 37.22
Half-oscillator potential.

RESEARCH

We have already established that the wave functions on the left side ($x \leq 0$) have to be 0. On the right side, the wave functions need to be those of a harmonic oscillator as given in equation 37.26, where the lowest-energy wave functions in the harmonic oscillator potential are

$$\psi_0(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}} e^{-x^2/2\sigma^2}$$

$$\psi_1(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{2}} \left(2\frac{x}{\sigma}\right) e^{-x^2/2\sigma^2}$$

$$\psi_2(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{8}} \left(4\frac{x^2}{\sigma^2} - 2\right) e^{-x^2/2\sigma^2}$$

$$\psi_3(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{48}} \left(8\frac{x^3}{\sigma^3} - 12\frac{x}{\sigma}\right) e^{-x^2/2\sigma^2}$$

$$\psi_4(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{384}} \left(16\frac{x^4}{\sigma^4} - 48\frac{x^2}{\sigma^2} + 12\right) e^{-x^2/2\sigma^2}$$

with the constant σ defined as $\sigma = \sqrt{\hbar/m\omega_0}$, and the energies corresponding to these wave functions are

$$E_n = \left(n + \tfrac{1}{2}\right)\hbar\omega_0 \text{ (for } n = 0, 1, 2, \ldots).$$

SIMPLIFY

Clearly, the wave functions $\psi_0(x)$, $\psi_2(x)$, $\psi_4(x)$, and all others with even n have nonzero values for $x = 0$ and thus do not qualify as solutions for the half-oscillator. These are the even-parity wave functions with the property $\psi(-x) = \psi(x)$. However, the odd-parity wave functions, $\psi_1(x)$, $\psi_3(x)$, and all others with odd n, have the required property that $\psi(x = 0) = 0$. In general, odd-parity wave functions have the property $\psi(-x) = -\psi(x)$ and thus must vanish at the origin in order to be continuous.

This means that the ground state for this electron must have the wave function

$$\psi_{\text{gs}}(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{2}} \left(2\frac{x}{\sigma}\right) e^{-x^2/2\sigma^2}$$

with energy

$$E_{\text{gs}} = \left(1 + \tfrac{1}{2}\right)\hbar\omega_0 = \tfrac{3}{2}\hbar\omega_0,$$

and the first excited state must have the wave function

$$\psi_{\text{ex}}(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}} \frac{1}{\sqrt{48}} \left(8\frac{x^3}{\sigma^3} - 12\frac{x}{\sigma}\right) e^{-x^2/2\sigma^2}$$

with energy

$$E_{\text{ex}} = \left(3 + \tfrac{1}{2}\right)\hbar\omega_0 = \tfrac{7}{2}\hbar\omega_0.$$

Thus, the ratio of the energy of the first excited state to that of the ground state is

$$\frac{E_{\text{ex}}}{E_{\text{gs}}} = \frac{\frac{7}{2}\hbar\omega_0}{\frac{3}{2}\hbar\omega_0} = \frac{7}{3}.$$

CALCULATE

The energy of the ground state was given in the problem statement as 3.5 eV; so we find that

$$E_{\text{ex}} = \tfrac{7}{3} E_{\text{gs}} = \tfrac{7}{3} \cdot 3.5\,\text{eV} = 8.1666666\,\text{eV}.$$

ROUND

We round our answer to two significant digits:

$$E_{\text{ex}} = 8.2\,\text{eV}.$$

DOUBLE-CHECK

For oscillator wave functions, it is characteristic that the energy difference between neighboring energy levels is constant. This is also the case for this half-oscillator, for which only the odd-parity wave functions are valid solutions. If we calculated the energy of the second excited state, we would find a value of $\tfrac{11}{3} E_{\text{gs}} = 12.8\,\text{eV}$.

37.6 Wave Functions and Measurements

In Sections 37.3, 37.4, and 37.5, we calculated the wave functions for particular quantum systems. While we were able to obtain analytic solutions in the cases we considered, numerical calculations performed with computers are necessary to obtain the wave functions for almost all potentials representing actual physical systems. However, the common features we have identified so far characterize all single-particle wave functions: a discrete number of nodes, associations with particular values of energy, and the fact that the probability of finding a particle somewhere is proportional to the absolute square of the wave function.

In experimental situations, the probability distribution can usually be measured. However, a complete reconstruction of the wave function is generally impossible, because the phase is usually unknown and not knowable. This fact was illustrated by our selection of the value of 0 for the phase angle when finding the wave function of a particle confined to an infinite potential well (equation 37.12). Reconstructing quantum wave functions with the aid of additional constraints is a research topic of great current interest. As an example of a result of such studies, Figure 37.23 displays the quantum wave function for a particular experimental system obtained recently by Jeff Lundeen and colleagues at the Institute for National Measurement Standards, Ottawa, Canada.

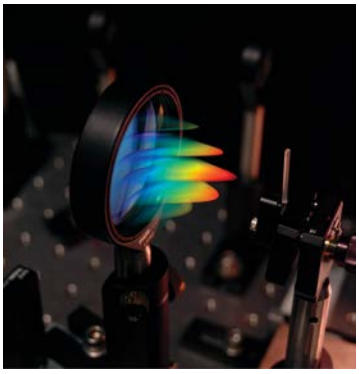

FIGURE 37.23 The wave function obtained in a quantum optics experiment artistically superimposed on the optical bench elements used in the experiment.

(*Source:* Jeff Lundeen and Charles Bamber, *Nature* 2011.)

Dr. Jeff Lundeen NRC - Institute for National Measurement Standards

Suppose we obtain a quantum wave function for a particular situation. How can this wave function be used to gain information about the physical properties of the object with which it is associated? How can the object's position, velocity, momentum, kinetic energy, and so on be calculated?

Equation 37.2 introduced the normalization condition for the wave function:

$$\int_{-\infty}^{\infty} |\psi(x)|^2 dx = \int_{-\infty}^{\infty} \psi^*(x)\psi(x)\, dx = 1.$$

To measure the average value of any observable quantity, we apply an operator that corresponds to this operation to the wave function ψ (for example, $\widehat{\mathbf{p}}\psi = p\psi$). Then we multiply the result by ψ^* (to get the probability $\psi^*\psi$ in the integrand) and integrate over all of space. For example, to figure out the average momentum associated with a wave function, we apply the momentum operator (equation 37.6) to the wave function and then integrate:

$$\langle p \rangle = \int_{-\infty}^{\infty} \psi^*(x)\widehat{\mathbf{p}}\psi(x)dx = -i\hbar \int_{-\infty}^{\infty} \psi^*(x)\frac{d}{dx}\psi(x)\,dx. \quad \textbf{(37}$$

In a similar way, any quantity that is a function of the momentum can be calculated using integrals that involve the derivative of the wave function. For example, the average kinetic energy can be obtained as follows:

$$\langle K \rangle = \frac{1}{2m}\langle p^2 \rangle = \frac{1}{2m} \int_{-\infty}^{\infty} \psi^*(x)\widehat{\mathbf{p}}^2\psi(x)dx = -\frac{\hbar^2}{2m} \int_{-\infty}^{\infty}$$

It is somewhat more straightforward to find the average values for quantities that depend on the position x. To find the average position, we can evaluate this integral:

$$\langle x \rangle = \int_{-\infty}^{\infty} \psi^*(x)x\psi(x)\,dx. \qquad \textbf{(37.31)}$$

The average values denoted with angle brackets $\langle\rangle$ are often referred to as **expectation values,** that is, the expected outcomes of measurements. This description of the formal process of finding average values is rather abstract, so let's look at an example to see how actual numbers are obtained.

EXAMPLE 37.4 Position and Energy

PROBLEM

What is the average position of an electron (mass $m = 9.109 \cdot 10^{-31}\text{kg} = 511\,\text{keV}/c^2$) in the $n = 0$ wave function of the harmonic oscillator potential with an angular frequency constant of $\omega_0 = 1.00 \cdot 10^{16}\,\text{s}^{-1}$? What is the electron's average kinetic energy?

SOLUTION

According to equation 37.26, the solution to the time-independent Schrödinger equation for this harmonic oscillator potential is

$$\psi_0(x) = Ae^{-x^2/2\sigma^2} = \frac{1}{\sqrt{\sigma}\pi^{1/4}} e^{-x^2/2\sigma^2}.$$

The electron's mass and the oscillator's angular frequency enter into the width of the potential, $\sigma = \sqrt{\hbar/m\omega_0}$. Here we again use the normalization constant $A = 1/\left(\sqrt{\sigma}\pi^{1/4}\right)$ to simplify the writing of the integrals.

First, we calculate the average position using equation 37.31:

$$\begin{aligned}\langle x \rangle &= \int_{-\infty}^{\infty} \psi^*(x) x \psi(x) dx \\ &= \int_{-\infty}^{\infty} A e^{-x^2/2\sigma^2} x A e^{-x^2/2\sigma^2} dx \\ &= A^2 \int_{-\infty}^{\infty} x e^{-x^2/\sigma^2} dx \\ &= 0.\end{aligned} \qquad \textbf{(i)}$$

These steps deserve an explanation. First, when we inserted the wave function, we used the fact that it is real, with no imaginary part, so in this case $\psi^*(x) = \psi(x)$. In the next step, we removed the constant factor A^2 from the integral and multiplied the two Gaussians by adding their arguments. Finally, we arrived at a value of 0 for the integral by realizing that x is an odd function and e^{-x^2/σ^2} is an even function of x; therefore, their product must be an odd function of x, resulting in an integral of zero value when the integration limits are symmetrical.

In fact, we could have looked at Figure 37.21 and immediately realized this answer from the fact that the probability distribution $|\psi_0(x)|^2$ is symmetric with respect to 0. However, because the integral in equation (i) is the first of several similar ones, it is instructive to go through all the steps explicitly to confirm that we indeed find the expected solution.

Now, let's address the more complicated problem of finding the electron's average kinetic energy. According to equation 37.30, we have to solve

$$\langle K \rangle = -\frac{\hbar^2}{2m} \int_{-\infty}^{\infty} \psi^*(x) \frac{d^2}{dx^2} \psi(x) dx$$
$$= -\frac{\hbar^2}{2m} \int_{-\infty}^{\infty} A e^{-x^2/2\sigma^2} \frac{d^2}{dx^2} A e^{-x^2/2\sigma^2} dx. \quad \textbf{(ii)}$$

Taking the first and second derivatives of the oscillator wave function for $n = 0$ yields

$$\frac{d}{dx} A e^{-x^2/2\sigma^2} = -A \frac{x}{\sigma^2} e^{-x^2/2\sigma^2}$$
$$\frac{d^2}{dx^2} A e^{-x^2/2\sigma^2} = A \left(\frac{x^2}{\sigma^4} - \frac{1}{\sigma^2} \right) e^{-x^2/2\sigma^2}.$$

These derivatives are plotted in Figure 37.24, where the classical turning points are also shown. For the quantum wave function, these are the points where the second derivative of the wave function has a value of 0. (We can see from equation 37.9 that if $E = U$, then $\frac{d^2}{dx^2}\psi(x) = 0$.)

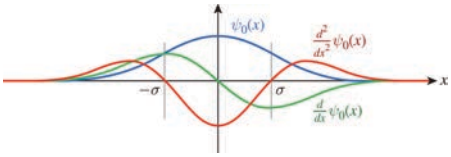

FIGURE 37.24 The $n = 0$ oscillator wave function (blue) and its first (green) and second (red) derivatives as a function of position. The gray vertical lines mark the classical turning point.

Now we can proceed with the integration in equation (ii):

$$\begin{aligned}
\langle K \rangle &= -\frac{A^2\hbar^2}{2m} \int_{-\infty}^{\infty} e^{-x^2/2\sigma^2} \frac{d^2}{dx^2} e^{-x^2/2\sigma^2} dx \\
&= -\frac{A^2\hbar^2}{2m} \int_{-\infty}^{\infty} e^{-x^2/2\sigma^2} \left(\frac{x^2}{\sigma^4} - \frac{1}{\sigma^2} \right) e^{-x^2/2\sigma^2} dx \\
&= -\frac{A^2\hbar^2}{2m} \int_{-\infty}^{\infty} e^{-x^2/\sigma^2} \left(\frac{x^2}{\sigma^4} - \frac{1}{\sigma^2} \right) dx \\
&= -\frac{A^2\hbar^2}{2m\sigma^4} \int_{-\infty}^{\infty} x^2 e^{-x^2/2\sigma^2} dx + \frac{A^2\hbar^2}{2m\sigma^2} \int_{-\infty}^{\infty} e^{-x^2/\sigma^2} dx \\
&= -\frac{A^2\hbar^2}{2m\sigma^4} \tfrac{1}{2}\sqrt{\pi}\sigma^3 + \frac{A^2\hbar^2}{2m\sigma^2}\sqrt{\pi}\sigma \\
&= \frac{\hbar^2}{4m\sigma^2}.
\end{aligned}$$

In the last step, we used $A^2 = 1/\left(\sigma\sqrt{\pi}\right)$, which follows from the definition of A. We are almost done. Using $\sigma = \sqrt{\hbar/m\omega_0}$ (see equation 37.27), we find

$$\langle K \rangle = \frac{\hbar^2}{4m(\hbar/m\omega_0)} = \tfrac{1}{4}\hbar\omega_0.$$

Finally, inserting the given value for ω_0 gives us our numerical answer:

$$\begin{aligned}\langle K \rangle = \tfrac{1}{4}\hbar\omega_0 &= \tfrac{1}{4}\left(1.055 \cdot 10^{-34}\ \text{J s}\right)\left(1.00 \cdot 10^{16}\ \text{s}^{-1}\right) \\ &= 2.64 \cdot 10^{-19}\ \text{J} \\ &= 1.65\ \text{eV}.\end{aligned}$$

Page 1178

DISCUSSION

Our result amounts to exactly half of the total energy of the oscillator in the $n = 0$ state! Also, note that this answer depends only on the value of the angular frequency, ω_0, and not on the mass, m. Another particle with a different mass, trapped in the same oscillator potential, would have the same average kinetic energy in the $n = 0$ state.

Self-Test Opportunity 37.5

Calculate the average value of the electron's momentum in the $n = 0$ state, or simply state the result as a result of symmetry arguments.

Self-Test Opportunity 37.6

Calculate the average value of the electron's kinetic energy in the $n = 0, 1, 2, 3$ states of the harmonic oscillator. Is there a simple shortcut, or do you have to evaluate the integral for a new wave function each time?

Uncertainty Relationship for Oscillator Wave Functions

Chapter 36 explored the fundamental importance of the Heisenberg Uncertainty Relation, $\Delta x \cdot \Delta p \geq \frac{1}{2}\hbar$. There we were able to motivate the relationship only by examining the gammaray microscope that Heisenberg envisioned as a *Gedankenexperiment* (thought experiment) in his original 1927 paper on the uncertainty relation. The same paper also contained a much more general mathematical proof. We will not reconstruct this proof here. However, we can calculate the uncertainties in momentum and position for the oscillator wave functions that we have found. Let's do this for the $n = 0$ state.

The square of the uncertainty in position is $\left(\Delta x^2\right) = \left\langle \left(x - \langle x \rangle\right)^2 \right\rangle$. We just found for the $n = 0$ state that $\langle x \rangle = 0$. In this case (and only when $\langle x \rangle = 0$), we find $\left(\Delta x\right)^2 = \left\langle x^2 \right\rangle$. Thus, to find the uncertainty in position, we have to evaluate the following integral:

$$\begin{aligned}\left(\Delta x\right)^2 = \left\langle x^2 \right\rangle &= \int_{-\infty}^{\infty} A e^{-x^2/2\sigma^2} x^2 A e^{-x^2/2\sigma^2} dx \\ &= A^2 \int_{-\infty}^{\infty} x^2 e^{-x^2/\sigma^2} dx \\ &= \tfrac{1}{2} A^2 \sqrt{\pi}\sigma^3 = \tfrac{1}{2}\sigma^2 \Rightarrow \\ &\qquad \Delta x = \frac{\sigma}{\sqrt{2}}.\end{aligned}$$

For this wave function, the uncertainty in momentum is $\left(\Delta p\right)^2 = \left\langle \left(p - \langle p \rangle\right)^2 \right\rangle = \left\langle p^2 \right\rangle$, because the average momentum is also zero. Furthermore, the average kinetic energy for this wave function, $\langle K \rangle = \left\langle p^2 \right\rangle / 2m$, was calculated in Example 37.4. Thus, we find that

$$(\Delta p)^2 = \left\langle p^2 \right\rangle = 2m \left\langle K \right\rangle = 2m \frac{\hbar^2}{4m\sigma^2} = \frac{\hbar^2}{2\sigma^2} \Rightarrow$$
$$\Delta p = \frac{\hbar}{\sqrt{2}\sigma}.$$

Multiplying the uncertainties in position and momentum for the harmonic oscillator in the $n = 0$ state gives

$$\Delta x \cdot \Delta p = \frac{\sigma}{\sqrt{2}} \frac{\hbar}{\sqrt{2}\sigma} = \tfrac{1}{2}\hbar.$$

This means that the $n = 0$ state of the harmonic oscillator is a state with the physically minimum possible uncertainty. Also, note that this result is independent of the width σ and thus does not depend on the angular frequency or the mass. It can also be shown that the product of the uncertainties in position and momentum for an oscillator wave function with quantum number n is given by $\Delta x \cdot \Delta p = \left(\tfrac{1}{2} + n\right)\hbar$.

37.7 Correspondence Principle

When we investigated relativistic mechanics, we found a smooth transition to nonrelativistic (Newtonian) mechanics as an object's speed becomes small compared to the speed of light. In the limit $v \ll c$, the classical mechanical case is recovered from the relativistic description. In a similar way, we can ask if we can recover the classical mechanical case from quantum mechanics, and in what limit. To address this question, we examine the probability distribution for finding an electron in an oscillator potential at a particular point in coordinate space; then we compare the results for the classical and quantum oscillators.

Just as we did for the classical particle in a box, we can calculate the classical probability distribution for finding a particle with total energy E in an oscillator potential. Equation 37.13 states that the classical probability of finding a particle at some point in coordinate space is inversely proportional to the particle's speed at that point. The speed can be determined as a function of position for the harmonic oscillator potential using energy conservation:

$$E = K + U = \tfrac{1}{2}mv^2 + \tfrac{1}{2}m\omega_0^2 x^2.$$

Solving this equation for the speed gives

$$v = \sqrt{\frac{2E}{m} - x^2\omega_0^2}.$$

Thus, the classical probability distribution of a particle in a harmonic oscillator potential can be written as follows:

$$\Pi_c(x) = \frac{\omega_0}{\pi\sqrt{\dfrac{2E}{m} - x^2\omega_0^2}}.$$

This function is defined only between the two classical turning points located at

$$x_t = \pm\sqrt{\frac{2E}{m\omega_0^2}}.$$

(The factors of ω_0 in the numerator and π in the denominator of the probability distribution function ensure that its integral equals 1.) Figure 37.25 shows the resulting probability distribution, with the classical turning points marked by the two green vertical lines.

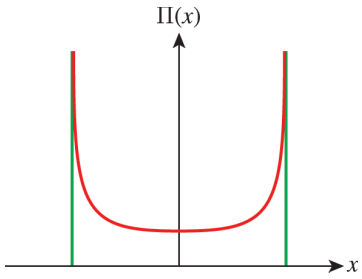

FIGURE 37.25 Classical probability distribution for finding a particle at a particular position in an oscillator potential (red curve); classical turning points (green vertical lines).

The quantum probability distributions in Figure 37.21, however, do not seem to agree at all with the classical probability distribution in Figure 37.25. In the classical case, the probability of finding the particle peaks near the classical turning points. In the quantum case shown in Figure 37.21, on the other hand, the probability distribution seems flat or even peaked in the middle.

From our experience with a particle in a box, we are perhaps not surprised that the quantum wave function penetrates partially beyond the classical turning points. However, it should cause some concern that the gross features of the classical and quantum probability distributions do seem not to correspond to each other at all.

This observation changes when we examine a quantum oscillator wave function for a large value of the quantum number n, as shown in Figure 37.26 for $n = 20$. For higher quantum numbers, the quantum oscillator probability distribution still oscillates and still penetrates slightly beyond the classical turning points. However, it starts to oscillate around an average value that corresponds to the classical limit.

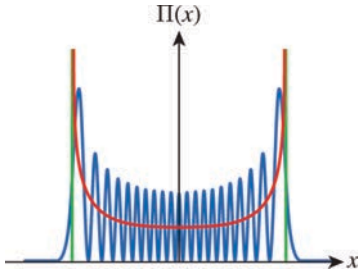

FIGURE 37.26 The classical probability distribution of Figure 37.25 with the probability distribution for the $n = 20$ quantum oscillator wave function superimposed.

Recall that the energy difference between neighboring allowed quantum oscillator energies is a constant, $\Delta E = \hbar\omega_0$. If this energy difference, ΔE, becomes small relative to the total energy, E, that is, if $\Delta E/E \ll 1$—which is equivalent to saying that the quantum number is large—then the quantum mechanical solution approaches the classical limit. This is a general feature of quantum

mechanics, conventionally called the **correspondence principle.**

37.8 Time-Dependent Schrödinger Equation

Up to now, we have concerned ourselves only with time-independent problems—that is, with probability distributions that do not change in time. However, electrons and other particles move around. How can the time dependence of the corresponding matter wave be described mathematically? Besides describing the dependence on the spatial coordinate *x*, the wave function also has to account for the dependence on the time *t*. We will still restrict the particle to motion in one spatial direction, and we will assume that the potential energy is constant in time; that is, it is a function of the coordinate *x* only. The time-dependent Schrödinger equation is then

Page 1180

$$-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\Psi(x,t)+U(x)\Psi(x,t)=i\hbar\frac{\partial}{\partial t}\Psi(x,t). \quad \textbf{(37.32)}$$

Here we use $\Psi(x, t)$ to denote the quantum wave function that is dependent on space and time. At this point, we are not interested in the general solutions to this partial differential equation or in deriving it from some general principles. However, we would like to see if we can find special solutions that allow us to write the general wave function as a product of two functions that each depend on only one variable:

$$\Psi(x,t)=\psi(x)\chi(t).$$

This method of solving a partial differential equation is commonly called *separation of variables*. Let's see what happens if we insert

this *Ansatz* into the time-dependent Schrödinger equation (37.32):

$$-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}(\psi(x)\chi(t)) + U(x)(\psi(x)\chi(t)) = i\hbar\frac{\partial}{\partial t}(\psi(x)\chi(t))$$

We divide both sides of this equation by the product $\psi(x)\chi(t)$ and find

$$\left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\psi(x) + U(x)\psi(x)\right)\frac{1}{\psi(x)} = \left(i\hbar\frac{\partial}{\partial t}\chi(t)\right)\frac{1}{\chi(t)}.$$

Now the left-hand side is a function of x only, and the right-hand side is a function of t only. This equality can hold for all x and t only if each side is equal to the same constant. Motivated by the time-independent Schrödinger equation (37.9), we call this constant E, the energy that entered into that equation. The left-hand side of the above equation then leads to

$$\left(-\frac{\hbar^2}{2m}\frac{d^2}{dx^2}\psi(x) + U(x)\psi(x)\right)\frac{1}{\psi(x)} = E \Rightarrow -\frac{\hbar^2}{2m}\frac{d^2}{dx^2}\psi(x)$$

which we recognize as the time-independent Schrödinger equation. With the same argument, we find for the right-hand side of the above equation

$$\begin{aligned}
&E = \left(i\hbar\frac{d}{dt}\chi(t)\right)\frac{1}{\chi(t)} \Rightarrow \\
&\frac{d}{dx}\chi(t) = -\frac{i}{\hbar}E\chi(t) \Rightarrow \\
&\chi(t) = Ae^{-iEt/\hbar} = Ae^{-i\omega t},
\end{aligned}$$

where we have again introduced the angular frequency ω via $E = \hbar\omega$. We can set the nor malization constant A equal to 1, because $\left|e^{-i\omega t}\right|^2 = 1$, and thus the normalization condition for the wave function is fulfilled. Our overall solution is therefore

$$\Psi(x,t) = \psi(x)e^{-i\omega t}, \qquad \textbf{(37.33)}$$

with $\psi(x)$ being a normalized solution to the time-independent Schrödinger equation with energy $E = \hbar\omega$. A wave function of the form of equation 37.33 is called a *stationary solution*, or a **stationary state,** of the time-dependent Schrödinger equation (37.32). The minimum condition for the existence of such stationary states is that the potential energy be time independent, that is, constant in time. A stationary state is a state with an exact energy if the potential energy is constant in time. This is just as in Newtonian mechanics, where the total mechanical energy E is conserved. Keep in mind that there can be many other solutions to equation 37.32, but the special class of solutions with well-defined energy can be written in the separable form of equation 37.33.

Eigenfunctions and Eigenvalues

Just as we defined the operator $\widehat{\mathbf{K}}$ for the kinetic energy in equation 37.7, we can also introduce an operator $\widehat{\mathbf{H}}$, which, applied to the wave function, yields the product of the total energy and the wave function:

$$\widehat{\mathbf{H}}\psi(x) = E\psi(x). \qquad \textbf{(37.34)}$$

If you compare this to the time-independent Schrödinger equation, you see that this operator can be formally written as

$$\widehat{\mathbf{H}} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + U(x) = \widehat{\mathbf{K}} + \widehat{\mathbf{U}}. \qquad \textbf{(37.35)}$$

The operator $\widehat{\mathbf{H}}$ is called the **Hamiltonian operator**. In linear algebra, if it is possible to apply an operator to a function and obtain a constant times that same function, then the function is called an **eigenfunction** and the constant an **eigenvalue.** Thus, a stationary state is an eigenfunction of the Hamiltonian operator $\widehat{\mathbf{H}}$ with eigenvalue E.

The Hamiltonian operator is linear: For any functions $\xi_1(x)$ and $\xi_2(x)$ and constants a_1 and a_2,

$$\widehat{\mathbf{H}}(a_1\xi_1(x) + a_2\xi_2(x)) = a_1\widehat{\mathbf{H}}\xi_1(x) = a_2\widehat{\mathbf{H}}\xi_2(x). \qquad \textbf{(37.36)}$$

Further, if two functions $\psi_1(x)$ and $\psi_2(x)$ are solutions with eigenvalues E_1 and E_2, then applying the Hamiltonian operator to the linear combination $\psi(x) = a_1\psi_1(x) + a_2\psi_2(x)$ yields

$$\begin{aligned}\widehat{\mathbf{H}}\psi(x) &= \widehat{\mathbf{H}}(a_1\psi_1(x) + a_2\psi_2(x)) \\ &= a_1\widehat{\mathbf{H}}\psi_1(x) + a_2\widehat{\mathbf{H}}\psi_2(x) \\ &= a_1E_1\psi_1(x) + a_2E_2\psi_2(x).\end{aligned}$$

Note that $\psi(x) = a_1\psi_1(x) + a_2\psi_2(x)$ is *not* an eigenfunction of $\widehat{\mathbf{H}}$ in the general case where $E_1 \neq E_2$.

37.9 Many-Particle Wave Function

So far, we have discussed quantum mechanics only for cases in which a single particle is present. To proceed further, we have to discuss the general features of the wave function when two or more particles are present.

Two-Particle Wave Function

Let's start with two particles and assume that we know the wave function for the case where only one of these particles is present. Further, let's again restrict ourselves to the static (time-independent) case. Then the Schrödinger equation for the one-particle wave function, $\psi(x)$, is given by equation 37.9. If two particles are present in the same potential, we need to determine how each of the particles interacts with the external potential and how they interact with each other. The general case of the two particles interacting with each other is outside the scope of this book. However, considering the case in which the two particles do not interact with each other lets us gain important physical insight and is helpful in many physical situations.

First, let's think about the notation. We want to characterize the coordinate of particle 1 as x_1 and that of particle 2 as x_2. Then the single-particle wave function of particle 1 in state a is denoted as $\psi_a(x_1)$ and that of particle 2 in state b, as $\psi_b(x_2)$. For the two-particle wave function as a function of both coordinates x_1 and x_2, we use the notation $\Psi(x_1, x_2)$.

Recall the discussion of spin and statistics in Section 36.8. We now need to discuss three different cases:

Distinguishable Particles—An example is an electron and a neutron in an infinite potential well. This is the most straightforward case, because the wave function for the two-particle state is simply the product of the wave functions for the two single-particle states:

$$\Psi(x_1, x_2) = \psi_a(x_1) \cdot \psi_b(x_2). \qquad \textbf{(37.37)}$$

Identical Bosons—An example is two pions (discussed in Chapters 39 and 40), one of them in state *a* and the other in state *b*. Since bosons of one species (identical bosons) are indistinguishable particles, we cannot say definitely that boson 1 is in state *a* and boson 2 is in state *b*. It is equally possible that boson 2 is in state *a* and boson 1 is in state *b*. The two-particle wave function has to be symmetric (stay the same) under exchange of the indexes of the two particles. Instead of just writing the two-particle wave function as the product of the single-particle wave functions, we have to add an exchange term, as in the following:

$$\Psi^{\mathrm{B}}(x_1, x_2) = \frac{1}{\sqrt{2}}(\psi_a(x_1) \cdot \psi_b(x_2) + \psi_a(x_2) \cdot \psi_b(x_1)$$

Here we use the superscript B to remind us that this is the symmetrized two-particle wave function for bosons. The factor $1/\sqrt{2}$ in front of the sum ensures that the two-particle wave function is normalized to 1.

Identical Fermions—An example is two electrons in an atom, one of them in state *a* and the other in state *b*.

Fermions of one species are also indistinguishable, but they cannot occupy the same state simultaneously. The two-particle wave function thus has to be antisymmetric (change its sign) under the exchange of the indexes of the two particles, so $\Psi = 0$ when $a = b$, as we discuss below. Mathematically, this is expressed as

$$\Psi^{\mathrm{F}}(x_1, x_2) = \frac{1}{\sqrt{2}}(\psi_a(x_1) \cdot \psi_b(x_2) - \psi_a(x_2) \cdot \psi_b(x_1))$$

Again we use a superscript, in this case F, to remind us that this is the antisymmetrized two-particle wave function for identical fermions.

Concept Check 37.4

In equation 37.39, the term $\psi_a(x_2) \cdot \psi_b(x_1)$ has a negative sign, and the term $\psi_a(x_1) \cdot \psi_b(x_2)$ has a positive sign. How important is this sign convention?

a) These are the only signs possible for the two terms, because the second term is the exchange term and thus must have a negative sign.

b) It does not matter which term gets which sign; all that matters is that they have opposite signs. If you multiply a wave function by an overall factor of -1, you still obtain a valid wave function.

c) The sign of the exchange term is arbitrary; it could be positive or negative. But the first term must always be positive.

d) Both terms can have either sign, and each of the four sign combinations $(++, --, -+, +-)$ leads to a valid wave function.

You can see that the expressions for the two-particle wave function of bosons (equation 37.38) and fermions (equation 37.39) differ only in the sign of the exchange term, positive for bosons and negative for fermions. Note that the wave function in equation 37.39 fulfills the basic requirement of the Pauli Exclusion Principle, which states that two fermions cannot occupy the same quantum state at the same time. If we set $b = a$ in equation 37.39, we obtain

$$\Psi^{\mathrm{F}}(x_1, x_2) = \frac{1}{\sqrt{2}}(\psi_a(x_1) \cdot \psi_a(x_2) - \psi_a(x_2) \cdot \psi_a(x_1)) = 0.$$

Further, if we exchange the indexes of the two fermions, we find

$$\begin{aligned}\Psi^{\mathrm{F}}(x_2, x_1) &= \frac{1}{\sqrt{2}}(\psi_a(x_2) \cdot \psi_b(x_1) - \psi_a(x_1) \cdot \psi_b(x_2)) \\ &= -\frac{1}{\sqrt{2}}(\psi_a(x_1) \cdot \psi_b(x_2) - \psi_a(x_2) \cdot \psi_b(x_1)) \\ &= -\Psi^{\mathrm{F}}(x_1, x_2).\end{aligned}$$

Thus, if we exchange the positions of the two fermions, the wave function undergoes a sign change.

This change in sign is central to several current research topics in physics: The sign change in the two-fermion wave function severely restricts the use of computer modeling for physical systems in which fermions can trade places as part of the time evolution of the system. The problem is that this sign change causes many quantities that must be calculated for the computer simulations to average out to zero, and then two quantities that must be divided by each other are often each very close to zero, which results in huge uncertainties in the numerical results. This *fermion sign problem* is universal in many-body theoretical physics, and physicists have suggested many clever approaches to try to overcome the computational limitations that it imposes, so far without success.

Can we also have a symmetric wave function in coordinate space for a two-fermion system? The answer is yes! The requirement of antisymmetrization of the two-fermion wave function means that the overall wave function has to satisfy equation 37.39. However, the wave function is the product of the spin wave function and the coordinate-space wave function. Thus, if the spin wave function is symmetric under exchange (two fermions with identical spin projection), then the coordinate-space wave function has to be antisymmetric. Also, if the spin wave function is antisymmetric (two fermions with opposite spin projection), then the coordinate-space wave function has to be symmetric under exchange, as Example 37.5 shows.

EXAMPLE 37.5 Hydrogen Molecule

One of the most impressive examples of the importance of exchange symmetry in a wave function is covalent bonding in the hydrogen molecule. A hydrogen molecule consists of two hydrogen atoms, each consisting of one electron and one proton. In an isolated hydrogen atom, the electron is bound to the proton by the Coulomb potential, which we saw in Chapter 23 is proportional to $1/r$. Chapter 38 will show how to calculate the wave function of the electron in the hydrogen atom. For now, we need to know only that this wave function has its largest value at the origin, the position of the nucleus, and falls off exponentially in the radial direction.

When two hydrogen atoms are in close proximity to each other, they can interact by sharing both of their electrons equally. This process of sharing electrons in forming a chemical bond is called *covalent bonding*, as opposed to *ionic bonding*, where one or more electrons get pulled off one atom and then are predominantly held by the other atom.

Figure 37.27a shows the antisymmetric coordinate-space two-electron wave function for the hydrogen molecule, and Figure 37.27b shows the symmetric case. The top row shows the wave functions along the axis through both nuclei, which you can compare to the two single-electron wave functions centered at ± 0.37 Å, the equilibrium separation of the two nuclei in the hydrogen molecule. The middle row shows the absolute square of each wave function, which is the probability density of finding an electron at a given value of the x-coordinate. The bottom row shows the probability density of finding the electron in the xy-plane, where yellow corresponds to the lowest values and black to the highest.

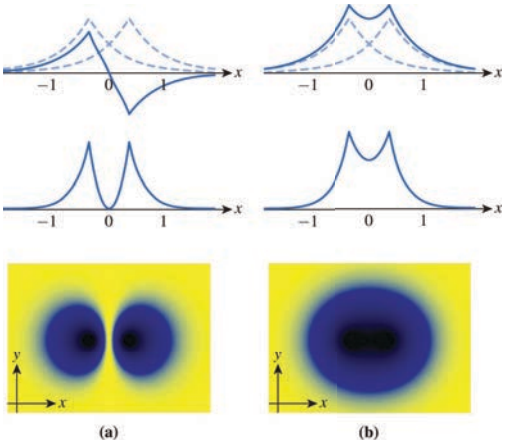

FIGURE 37.27 Coordinate-space electron wave functions in the hydrogen molecule: (a) antisymmetric wave function; (b) symmetric wave function. Shown are the two-particle wave functions (top row), probability densities (middle row) along the major axis, and density distributions in the two-dimensional plane (bottom row).

For the symmetric coordinate-space wave function (Figure 37.27b), a significant portion of the probability of finding an electron is shifted to the region between the two nuclei. This means that both nuclei experience an attractive potential in the direction of the other nucleus, due to the Coulomb interaction of the nuclei with the electrons. The depth of this potential due to the exchange interaction is 4.52 eV at the equilibrium separation of 0.74 Å, leading to a net attractive force between the two atoms that produces the covalent bonding in the H_2 molecule. The condition for this bonding is that the two electrons must have opposite spin projections—one *spin-up* and one *spin-down*. If both have the same spin projection, then the coordinate-space wave function needs to be antisymmetric, as shown in Figure 37.27a. The resulting net depletion of the electron density in the region between the two

nuclei leads to a repulsive potential at all separation distances and thus no bonding.

Many-Fermion Wave Function

Equation 37.39 is equivalent to the determinant of a two-by-two matrix of the single-particle wave functions:

$$\Psi^{\mathrm{F}}(x_1, x_2) = \frac{1}{\sqrt{2}} \begin{vmatrix} \psi_a(x_1) & \psi_a(x_2) \\ \psi_b(x_1) & \psi_b(x_2) \end{vmatrix}.$$

This determinant is commonly called a **Slater determinant.** The Slater determinant can be generalized to a system consisting of many fermions. If there are n fermions, then the n-fermion wave function is the determinant of an $n \times n$ matrix, where each row is a given single-particle state and each column is a particle coordinate:

$$\Psi^{\mathrm{F}}(x_1, x_2, \ldots, x_n) = \frac{1}{\sqrt{n!}} \begin{vmatrix} \psi_1(x_1) & \psi_1(x_2) & \cdots & \psi_1(x_n) \\ \psi_2(x_1) & \psi_2(x_2) & \cdots & \psi_2(x_n) \\ \vdots & \vdots & \ddots & \vdots \\ \psi_n(x_1) & \psi_n(x_2) & \cdots & \psi_n(x_n) \end{vmatrix}$$

This Slater determinant contains all possible permutations of the single-particle wave functions over all particle coordinates. Again, the factor $1/\sqrt{n!}$ ensures that the many-fermion wave function is normalized—that is, that the integral over all space of the absolute square of the wave function is equal to 1 when the single-particle wave functions are properly normalized.

Quantum Computing

Currently, one of the most active research areas in quantum mechanics is the field of quantum computing. A large number of physicists around the world are using different physical systems to try to implement quantum computers. Among the many systems considered are chains of trapped atoms, quantum dots in semiconductors, electrons on the surface of liquid helium, coupled superconducting Josephson-junctions, radio-frequency cavities, and collections of buckyballs (C_{60} molecules shaped like soccer balls). New ideas regarding which systems to use are generated on a regular basis, and many groups are working on refining them. What all proposed quantum computers have in common is that they work with many-particle wave functions.

To understand the potential power of quantum computing, let's first look at the workings of a classical computer. A classical computer is based on algorithms that are applied to digitized information, which is stored in *bits*. A bit can be in one of two states, either on or off. Conventionally, the numbers 1 and 0 represent these two states. Note that nothing appears between 0 and 1 in today's conventional computers; it's all or nothing. A *byte* is a collection of 8 bits. Thus, a possible representation for one particular value of a byte could be 01100010, in which the 8 bits are in their on or off states as indicated by the numbers, one digit for each bit.

Now let's consider a quantum two-state system, in which transitions between states can be induced through some interaction with an outside force but do not happen spontaneously through emission or absorption of a single photon. Left alone, a particle in one of the two states should stay in that state for a long time.

Conventionally, the two quantum states are denoted as $|0\rangle$ and $|1\rangle$ to make an analogy with a classical bit that can have a value of either 0 or 1. However, a quantum mechanical system can be in a superposition of two states, as noted earlier in this chapter. Therefore, the quantum equivalent of the bit, the **qubit,** is defined as a wave function that is a superposition of the two states $|0\rangle$ and $|1\rangle$:

$$|\psi\rangle = c_1 |1\rangle + c_0 |0\rangle,$$

where c_1 and c_0 are complex numbers and represent the probabilities that the system is in state $|1\rangle$ or in state $|0\rangle$, respectively (Figure 37.28). The numbers c_1 and c_0 are not completely independent, because the requirement that the sum of the probabilities that the particle is in state $|0\rangle$ or $|1\rangle$ equals 1 necessitates $|c_1|^2 + |c_0|^2 = 1$.

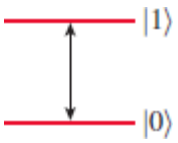

FIGURE 37.28 Simple pictorial representation of a single qubit.

Conceptually, it is straightforward to generalize from one qubit to n qubits. Assume a collection of individual two-state systems that are not independent of one another. Then the state of the overall system can be written as the sum of the combinations of the individual states. For a system of two qubits, the wave function can be written as

$$|\psi\rangle = c_{11} |11\rangle + c_{10} |10\rangle + c_{01} |01\rangle + c_{00} |00\rangle,$$

where c_{00}, c_{01}, c_{10}, and c_{11} are again complex numbers, with the normalization condition that $|c_{11}|^2 + |c_{10}|^2 + |c_{01}|^2 + |c_{00}|^2 = 1$. For three qubits, we can write

$$|\psi\rangle = c_{111} |111\rangle + c_{110} |110\rangle + c_{101} |101\rangle + c_{100} |100\rangle$$
$$+ c_{011} |011\rangle + c_{010} |010\rangle + c_{001} |001\rangle + c_{000} |000\rangle.$$

We can easily generalize this equation to hold for larger numbers of qubits. The number of terms in the wave function for 1 qubit is 2, for 2 qubits is 4, and for 3 qubits is 8—the number of terms in the wave function for n qubits is 2^n. All of the promise of quantum computing power arises from this number, 2^n. If a classical computer operates on a register of n bits, then it executes n operations simultaneously. However, if a quantum computer operates on a register of n qubits, then it executes 2^n operations simultaneously. A diagram of one proposed way to implement a quantum computer is shown in Figure 37.29.

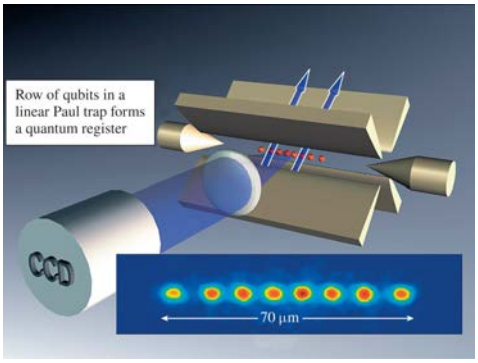

FIGURE 37.29 A schematic diagram of a possible implementation of a quantum computer as a chain of eight calcium ions held inside a Paul trap, which is a device that uses oscillating electric fields to trap ions. The inset is a picture of the induced fluorescence of the trapped ions.

From R. Blatt, "Quantum Information Processing: Dream and Realization," *Entangled World,* pp. 235–70, Wiley-VCH, Weinheim 2006. Image courtesy R. Blatt, University of Innsbruck

Many cautionary statements are in order here. First, probing the wave function of the qubit states necessarily changes the information stored in the qubits. This requires developing special error-correction algorithms, which correct an error without destroying the quantum state. Second, an actual quantum computer that can do more than execute just a few simple demonstration operations has yet to be implemented. Furthermore, quantum computing is by its very construction probabilistic in nature. A calculation must be repeated several times to obtain a reliable result. Only for a small number of

algorithms has it been proven that a quantum computer can take full advantage of the theoretically possible 2^n simultaneous operations. One of these algorithms is the factorization of large integers into prime numbers. This problem has attracted a huge amount of interest and also funding, because the encryption schemes most commonly used rely on the fact that present-day computers cannot factorize large integers in a human lifetime. By comparison, a working quantum computer with approximately 100 qubits could do this job in seconds. This achievement is commonly called "quantum supremacy." In 2022, first claims of this success were filed for very special algorithms and cases, but a general-purpose quantum computer is still not available.

37.10 Antimatter

In Section 37.8, we discussed the Hamiltonian operator, which represents the total energy of a particle. However, we used the classical formula, $K = p^2/2m$, for the kinetic energy, which is appropriate only for speeds that are small compared to the speed of light. In Chapter 35 on relativity, we noted that the more general relationship between momentum and energy is

$$E^2 = p^2c^2 + m^2c^4.$$

This raises a question: Is it possible to construct a framework of quantum physics that is also correct for speeds that are *not* small compared to the speed of light? In other words, can we construct a relativistic quantum theory? The first person who figured out how to do this was the British physicist Paul Adrien Maurice Dirac (1902–1984). He published his famous **Dirac equation** in 1928 and for this accomplishment shared the 1933 Nobel Prize in Physics with Erwin Schrödinger.

We will not attempt to derive or even motivate the Dirac equation. Most university physics departments never even mention this equation in general introductory courses. However, we can look at the equation and its notation, compare it to the equivalent nonrelativistic Schrödinger equation, and explore some of its physical consequences. (You can treat the following couple of pages as a resource you may want to return to in the course of future studies. Or perhaps seeing this equation will motivate you to explore this topic further at the present time.)

The Dirac equation for a "free" particle—that is, a particle that is not subjected to any external potential or force—is

$$\left(\gamma^0 mc^2 + \sum_{i=1}^{3} \gamma^i \widehat{p}_i c\right) \Psi\left(\overrightarrow{r}, t\right) = i\hbar \frac{\partial}{\partial t} \Psi\left(\overrightarrow{r}, t\right). \quad \textbf{(37.41)}$$

In this equation, c is the speed of light, m is the rest mass of the particle, and $\widehat{p}_i$ is the momentum operator in one of the three orthogonal directions (x, y, z), which we introduced in Section 37.1. The symbols $\gamma^0, \gamma^1, \gamma^2, \gamma^3$ refer to the so-called Dirac matrices:

$$\gamma^0 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \quad \gamma^1 = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{pmatrix}, \quad \gamma^2 = \begin{pmatrix}$$

The wave function $\Psi\left(\overrightarrow{r}, t\right)$ in equation 37.41 is a four-component *spinor*, instead of a one-component scalar, as is the case for the quantum mechanical wave functions that we have discussed so far:

$$\Psi\left(\overrightarrow{r}, t\right) = \begin{pmatrix} \Psi_1\left(\overrightarrow{r}, t\right) \\ \Psi_2\left(\overrightarrow{r}, t\right) \\ \Psi_3\left(\overrightarrow{r}, t\right) \\ \Psi_4\left(\overrightarrow{r}, t\right) \end{pmatrix}.$$

The Dirac equation (37.41) is the relativistically correct extension of the time-dependent Schrödinger equation (37.32) for the three-dimensional potential-free case:

$$\left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} - \frac{\hbar^2}{2m}\frac{\partial^2}{\partial y^2} - \frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} \right) \Psi\left(\overrightarrow{r}, t\right) = i\hbar\frac{\partial}{\partial t}\Psi\left(\overrightarrow{r},$$

We can find the solutions of the Dirac equation by proceeding in a manner similar to what we did for the Schrödinger equation. For

example, we can express the time dependence of the solutions for the free particle as

$$\Psi\left(\overrightarrow{r},t\right) = \Psi_0\left(\overrightarrow{r}\right)e^{-iEt/\hbar}. \qquad \textbf{(37.42)}$$

The static wave function $\Psi_0\left(\overrightarrow{r}\right)$ satisfies the time-independent Dirac equation with the energy eigenvalue *E*:

$$\left(\gamma^0 mc^2 + \sum_{i=1}^{3}\gamma^i \widehat{p}_i c\right)\Psi_0\left(\overrightarrow{r}\right) = E\Psi_0\left(\overrightarrow{r}\right). \qquad \textbf{(37.43)}$$

We look for solutions of the form of a plane wave moving along one particular coordinate axis, conventionally chosen to be the *z*-axis:

$$\Psi_0\left(\overrightarrow{r}\right) = we^{ipz/\hbar}. \qquad \textbf{(37.44)}$$

Here p is the momentum of the particle. (Because it is moving along the *z*-axis, its momentum component along that axis is also the absolute value of its momentum, that is, the length of its momentum vector.) Also, w is a constant four-component spinor. Inserting this *Ansatz* for $\Psi_0\left(\overrightarrow{r}\right)$ into the static Dirac equation (37.43) results in the matrix equation

$$\begin{pmatrix} mc^2 & 0 & pc & 0 \\ 0 & mc^2 & 0 & -pc \\ pc & 0 & -mc^2 & 0 \\ 0 & -pc & 0 & -mc^2 \end{pmatrix}\begin{pmatrix} w_1 \\ w_2 \\ w_3 \\ w_4 \end{pmatrix} = E\begin{pmatrix} w_1 \\ w_2 \\ w_3 \\ w_4 \end{pmatrix}. \qquad \textbf{(37.45)}$$

The solutions for the possible energies are

$$E(p) = \pm\sqrt{m^2c^4 + p^2c^2}. \qquad \textbf{(37.46)}$$

This is satisfying, because it matches the energy-momentum relationship that we arrived at in Chapter 35 using relativistic mechanics. The upper two components of the spinor w, or w_1 and w_2 represent the solutions for positive energies: one for spin-up and one for spin-down. The lower two components, w_3 and w_4 are the spin-up and spin-down solutions for negative energies.

The importance of the Dirac equation lies in the fact that it unifies the two extensions of classical mechanics into one consistent description. Chapter 35 showed that a relativistic description is needed for object speeds that are comparable to the speed of light and that relativistic mechanics contains classical mechanics as a special case for speeds that are small compared to the speed of light. In Chapter 36 and this chapter, we have found that we need a quantum description for very small systems and that the correspondence principle also establishes classical mechanics as a special case of quantum mechanics. Dirac's equation contains relativistic quantum mechanics and has nonrelativistic quantum mechanics as a special case; it thus provides a very satisfying and aesthetically appealing general framework.

What about the negative energy solutions in equation 37.46? How can these be interpreted? So far, in our discussion of quantum mechanics, we have assumed that the energy of a free particle is always positive. This enables us to think of the concept of the ground state as the state with lowest energy. However, if states with negative energies are available, what prevents an electron placed into a positive energy state from decaying into a negative energy state and then on through a sequence of successively lower energy states by emitting a photon each time?

To overcome this problem of endless radiation, Dirac proposed the solution illustrated in Figure 37.30: All possible negative energy states are already occupied completely by one spin-up and one spin-down particle. This picture of what we perceive to be empty space as a "sea" of occupied negative-energy electron states is commonly called the **Dirac sea.** What are these postulated particles in negative energy states? Do they have the same mass as the electron? Are they real or just a mental construct to help a flawed model survive consistency checks? In particular, is it possible to remove one of these negative energy electrons from the Dirac sea and create a hole in its place?

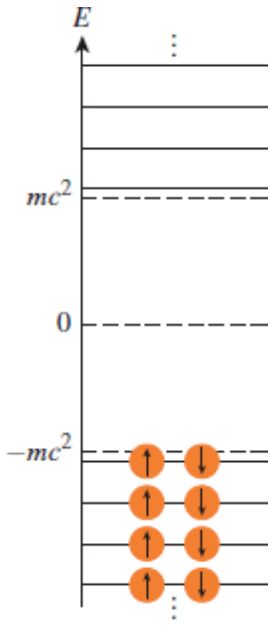

FIGURE 37.30 The Dirac vacuum, where all negative energy states are completely occupied.

The answer to this last question is yes. A hole in the Dirac sea acts just like a spin-$\frac{1}{2}$ particle with the same mass as an electron, but with an opposite charge and spin projection. To create such a hole in the Dirac sea, one of the electrons in a negative energy state

must be lifted to a positive energy state. Lifting the electron across the forbidden gap from $-mc^2$ to mc^2 requires depositing into the vacuum an energy of at least twice the mass of the electron times the speed of light squared (Figure 37.31). Because the mass-energy of the electron is 511 keV, at least 1.022 meV of energy is needed to lift an electron into a positive energy state and at the same time create a hole in the Dirac sea.

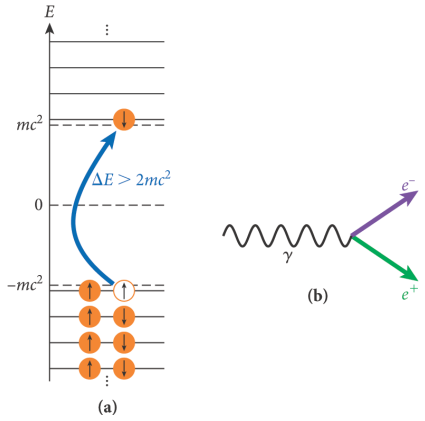

FIGURE 37.31
Creation of a hole in the Dirac sea: electron-positron pair creation. (a) Energy diagram; (b) sketch in coordinate space.

This positively charged hole in the Dirac sea with the same mass as the electron is not just a convenient algebraic trick, but a real particle. The American physicist Carl Anderson (1905–1991) discovered this particle, named the *positron*, in 1932 using photographic plates exposed to cosmic radiation. This experiment provided a triumphant confirmation of Dirac's theory. Despite this success, the idea of the Dirac sea with an infinite number of particles filling all available energy states does not seem very elegant. In particular, the notion that the vacuum has infinite energy seems counterintuitive. More modern quantum field theories have replaced some of these concepts, but the basic difficulties of infinite quantities are still present, leading many practitioners to believe that further breakthroughs are needed.

The **positron** is the **antiparticle** to the electron, an example of **antimatter.** Every fermion obeys the Dirac equation, and so the concept of a filled Dirac sea applies to the vacuum ground state. Thus, each fermion has an antiparticle. The Italian physicist Emilio Segrè (1905–1989) and American Owen Chamberlain (1920–2006) discovered the antiparticle to the proton, the antiproton, in 1955. In 1995, physicists detected the first atoms of antihydrogen at CERN. Since 2000, CERN has had an "antimatter factory," in which ultracold antihydrogen atoms are produced and studied. One of the many questions to be answered is whether antimatter responds to gravity in the same way that regular matter does.

An antiparticle can also annihilate if it meets its particle partner. In this **annihilation** process, sketched in Figure 37.32, the entire mass of both particles is converted into energy. Thus, from the combination of quantum theory and relativity emerges a new picture of the relationship between mass and energy: Mass and energy can be interconverted, and mass is just one more form of energy.

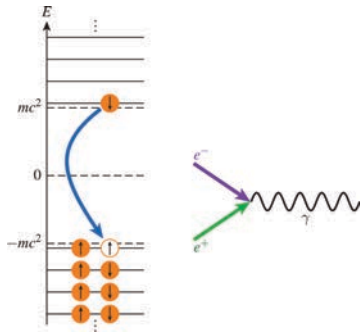

FIGURE 37.32
Electron-positron annihilation.

EXAMPLE 37.6 Matter Annihilation

Matter-antimatter annihilation is a popular energy source in science fiction books and movies. This idea conveniently ignores the fact that there is no source of antimatter anywhere on Earth or in our Solar System, or, most likely, anywhere in the entire universe. (We will investigate why this is so in Chapters 39 and 40 on subatomic physics.) All antimatter that could be used as an energy source would have to be created first, and at least as much energy would be required to do this as could be gained later from the annihilation. Nevertheless, it is interesting to figure out how much energy would be released in the annihilation process.

PROBLEM 1

How much energy would be released if you could let a soft drink can full of antiwater annihilate with regular water?

SOLUTION 1

A soft drink can holds 0.330 L of liquid. If this liquid is water, then its mass is 0.330 kg, because water has a density of $1000\ \text{kg/m}^3$ and so 1 L of water has a mass of 1 kg. Since the mass of an antiparticle (which makes up antimatter) is the same as the mass of the corresponding particle, the mass of the antiwater is also 0.330 kg. Therefore, we need to annihilate a total of 2×0.330 kg of mass (0.330 kg of antiwater and 0.330 kg of water).

The energy contained in this mass is obtained by multiplying the total mass by the square of the speed of light:

$$E = mc^2 = (0.660\ \text{kg})\left(3.00 \cdot 10^8 \text{m/s}\right)^2 = 5.94 \cdot 10^{16}\text{J}.$$

To see how much energy this is, let's consider a follow-up question.

PROBLEM 2

The largest nuclear power plants produce 1200 MW. How long would such a nuclear power plant have to operate in order to produce the same amount of energy as the soft drink can of antiwater?

SOLUTION 2

A 1200-MW power plant produces $1.2 \cdot 10^9 \mathrm{J}$ of usable energy each second. Thus, the number of seconds it takes to produce $E = 5.94 \cdot 10^9 \mathrm{J}$ is

$$\frac{5.94 \cdot 10^{16} \mathrm{J}}{1.2 \cdot 10^9 \, \mathrm{J/s}} = 4.95 \cdot 10^7 \mathrm{s}.$$

This is more than 1.5 years!

WHAT WE HAVE LEARNED EXAM STUDY GUIDE

- The absolute square of the wave function $\psi(x)$ is the probability density of finding a particle at some position. The wave function is normalized as

$$\int_{-\infty}^{\infty} |\psi(x)|^2 dx = \int_{-\infty}^{\infty} \psi^*(x)\psi(x)dx = 1.$$

- The operator for the particle's momentum is

$$\hat{\mathbf{p}}\psi(x) = -i\hbar\tfrac{d}{dx}\psi(x).$$

- The operator for the particle's kinetic energy is

$$\hat{\mathbf{K}}\psi(x) = \frac{1}{2m}\hat{\mathbf{p}}^2\psi(x) = \frac{1}{2m}\left(-i\hbar\frac{d}{dx}\right)^2\psi(x) = -$$

- The time-independent Schrödinger equation for a particle in a potential $U(x)$ is given by

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x).$$

- The wave function solution for a particle confined to an infinite potential well with walls at $x = 0$ and $x = a$ is

$$\psi(x) = \begin{cases} 0 & \text{for } x \\ \sqrt{\frac{2}{a}}\sin\left(\frac{n\pi x}{a}\right) \text{with } n = 1, 2, 3, \ldots & \text{for } 0 \\ 0 & \text{for } x \end{cases}$$

The corresponding energy eigenvalues are

$$E_n = \frac{\hbar^2 \pi^2}{2ma^2} n^2 \quad (\text{for } n = 1, 2, 3, \ldots).$$

- The solution for a finite potential well, with $E > U_1$,

$$U(x) = \begin{cases} \infty & \text{for } \ x < 0 \\ 0 & \text{for } \ 0 \leq x \leq a \\ U_1 & \text{for } \ x > a, \end{cases}$$

is

$$\psi(x) = \begin{cases} 0 & \text{for } x < 0 \\ \mathrm{D}\, \sin(\kappa x) & \text{for } \ 0 \leq x \leq a \\ F\, \cos(\kappa' x) + G\, \sin(\kappa' x) & \text{for } \ x > a, \end{cases}$$

$$\text{with } \kappa' = \sqrt{\kappa^2 - \frac{2mU_1}{\hbar^2}}.$$

Page 1189

- The solution for the same finite potential well, with $E < U_1$, is

$$\psi(x) = \begin{cases} 0 & \text{for } x < 0 \\ \mathrm{D}\, \sin(\kappa x) & \text{for } \ 0 \leq x \leq a \\ F e^{-\gamma x} & \text{for } \ x > a, \end{cases}$$

$$\text{with } \gamma^2 = \frac{2m(U_1 - E)}{\hbar^2} = \frac{2mU_1}{\hbar^2} - \kappa^2.$$

- For a potential step of the form

$$U(x) = \begin{cases} \infty & \text{for } \ x < 0 \\ 0 & \text{for } \ 0 \leq x \leq a \\ U_1 & \text{for } \ a \leq x \leq b \\ 0 & \text{for } \ x \geq b, \end{cases}$$

the wave function is

$$\psi(x) = \begin{cases} 0 & \text{for } x < 0 \\ D\sin(\kappa x) & \text{for } 0 \le x \le a \\ Fe^{-\gamma x} & \text{for } a < x < b \\ G\sin(\kappa x + \varphi) & \text{for } x \ge b. \end{cases}$$

The probability that a particle with energy less than the barrier height will tunnel through the barrier is

$$\Pi_\mathrm{t} = \frac{|\psi(b)|^2}{|\psi(a)|^2} = \frac{\left|Fe^{-\gamma b}\right|^2}{\left|Fe^{-\gamma a}\right|^2} = \left|e^{-\gamma(b-a)}\right|^2 = e^{-2\gamma(b-a)}$$

which depends exponentially on the barrier width.

- The wave function solutions for the harmonic oscillator potential $U(x) = \frac{1}{2}kx^2 = \frac{1}{2}m\omega_0^2x^2$ are

$$\psi_n(x) = \frac{1}{\sqrt{\sigma}\pi^{1/4}}\frac{1}{\sqrt{n!2^n}}H_n(x/\sigma)e^{-x^2/2\sigma^2},$$

where H_n is a Hermite polynomial and

$$\sigma = \sqrt{\frac{\hbar}{m\omega_0}}.$$

The corresponding energy eigenvalues are equally spaced:

$$E_n = \left(n + \tfrac{1}{2}\right)\hbar\omega_0 \quad (\text{for } n = 0, 1, 2, \ldots).$$

- The quantum mechanical expectation value of a quantity is found by integrating, over the entire space, ψ^* times the result obtained when the corresponding operator acts on ψ^*. The position expectation value is

$$\langle x \rangle = \int_{-\infty}^{\infty} \psi^*(x) x \psi(x)\, dx,$$

and the momentum expectation value is

$$\langle p \rangle = \int_{-\infty}^{\infty} \psi^*(x) \hat{\mathbf{p}} \psi(x) dx = -i\hbar \int_{-\infty}^{\infty} \psi^*(x) \frac{d}{dx} \psi(x)\, c$$

- The ground-state ($n = 0$) oscillator wave function has the minimum product of the uncertainties in position and momentum allowed by the uncertainty principle.
- The correspondence principle states that if the energy difference, ΔE, between neighboring quantum energy states becomes small relative to the total energy, E, that is, if $\Delta E \ll E$, quantum solution approaches its classical limit.
- The time-dependent Schrödinger equation is

$$-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\Psi(x,t) + U(x)\Psi(x,t) = i\hbar\frac{\partial}{\partial t}\Psi\left(\overrightarrow{r},t\right)$$

  with the solution $\Psi(x,t) = \psi(x)e^{-i\omega t}$.
- The Hamiltonian operator is

$$\widehat{\mathbf{H}} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + U(x) = \widehat{\mathbf{K}} + U(x).$$

  It is linear, so a linear combination of two solutions to the Schrödinger equation is also a solution.
- The two-particle wave function for (noninteracting) bosons is the symmetrized product of the one-particle wave functions:

$$\Psi^{\mathrm{B}}(x_1, x_2) = \frac{1}{\sqrt{2}}\left(\psi_a(x_1) \cdot \psi_b(x_2) + \psi_a(x_2) \cdot \psi_b(x_1\right.$$

- The two-particle wave function for (noninteracting) fermions is the antisymmetrized product of the one-particle wave functions:

$$\Psi^{\mathrm{F}}(x_1, x_2) = \frac{1}{\sqrt{2}}(\psi_a(x_1) \cdot \psi_b(x_2) - \psi_a(x_2) \cdot \psi_b(x_1$$

- Quantum computing defines a qubit as

$$|\psi\rangle = c_1 |1\rangle + c_0 |0\rangle.$$

  The superposition of qubits gives a quantum computer the (still only theoretical!) ability to evaluate many calculations simultaneously, providing a great advantage over conventional digital computing.
- The Dirac equation,

$$\left(\gamma^0 mc^2 + \sum_{i=1}^{3} \gamma^i \widehat{p}_i c\right) \Psi\left(\overrightarrow{r}, t\right) = i\hbar \frac{\partial}{\partial t} \Psi_0\left(\overrightarrow{r}\right),$$

  is the generalization of the time-dependent Schrödinger equation for the relativistically correct relationship between energy and momentum. It leads to negative energy states and antiparticles.

Answers to Self-Test Opportunities

37.1 Use $e^{\pm i\theta} = \cos\theta \pm i\,\sin\theta$ (Euler).

$$\begin{aligned}\psi(x) &= Ae^{i\kappa x} + Be^{-i\kappa x} \\ &= A(\,\cos(\kappa x) + i\,\sin(\kappa x)) + B(\cos(\kappa x) - i\,\sin(\kappa x)) \\ &= (A+B)\cos(\kappa x) + i(A-B)\sin(\kappa x) \\ &= C\,\cos(\kappa x) + D\,\sin(\kappa x) \quad \text{where} \\ C = A+B &\text{ and } D = i(A-B).\end{aligned}$$

37.2 Adding a constant energy, c, everywhere in space leaves the wave function solutions unchanged. However, all energies are shifted up by the constant c.

37.3 The wave function is the product of three one-dimensional wave functions, $\psi(x,y,z) = \psi_1(x)\cdot\psi_2(y)\cdot\psi_3(z)$:

$$\psi_1(x) = \begin{cases} 0 & \text{for } x < \\ \sqrt{2/a}\,\sin(n_x\pi x/a) \text{ with } n_x = 1,2,3,\ldots & \text{for } 0 \le \\ 0 & \text{for } x > \end{cases}$$

$$\psi_2(y) = \begin{cases} 0 & \text{for } y < \\ \sqrt{2/b}\,\sin(n_y\pi y/b) \text{with } n_y = 1,2,3,\ldots & \text{for } 0 \le \\ 0 & \text{for } y > \end{cases}$$

$$\psi_3(z) = \begin{cases} 0 & \text{for } z < \\ \sqrt{2/c}\,\sin(n_z\pi z/c) \text{with } n_z = 1,2,3,\ldots & \text{for } 0 \le \\ 0 & \text{for } z > \end{cases}$$

$$E_{n_x,n_y,n_z} = \frac{\hbar^2\pi^2}{2ma^2}n_x^2 + \frac{\hbar^2\pi^2}{2mb^2}n_y^2 + \frac{\hbar^2\pi^2}{2mc^2}n_z^2.$$

37.4 A continuous wave function at point b requires that

$$Fe^{-\gamma b} = G\,\sin(\kappa b + \phi), \qquad \textbf{(i)}$$

and a continuous derivative of the wave function at the same point requires that

$$-\gamma F e^{-\gamma b} = \kappa G\,\cos(\kappa b + \phi). \qquad \textbf{(ii)}$$

Divide equation (i) by equation (ii) to obtain $\tan(\kappa b + \phi) = \dfrac{\kappa}{-\gamma}$.

Solve this for the phase shift, ϕ: $\phi = \tan^{-1}\left(\dfrac{\kappa}{-\gamma}\right) - \kappa b$.

To get the amplitude, G, it is easiest to divide equation (ii) by κ then square both sides of equation (i) and equation (ii). This results in

$$F^2 e^{-2\gamma b} = G^2\,\sin^2(\kappa b + \phi)$$
$$(\gamma/\kappa)^2 F^2 e^{-2\gamma b} = G^2\,\cos^2(\kappa b + \phi).$$

Now add these two equations, which yields

$$\left(1 + (\gamma/\kappa)^2\right) F^2 e^{-2\gamma b} = G^2.$$

Taking the square root gives us the expression for G: $G = \sqrt{1 + (\gamma/\kappa)^2}\,F e^{-\gamma b}$.

37.5 Start with the definition and insert the wave function:

$$\langle p\rangle = \int_{-\infty}^{\infty} \psi^*(x)\hat{\mathrm{p}}\psi(x)dx = -i\hbar \int_{-\infty}^{\infty} \psi^*(x)\frac{d}{dx}\psi(x)dx$$

$$\psi_0(x) = Ae^{-x^2/2\sigma^2}$$

$$\frac{d}{dx}\psi_0(x) = \frac{Ax}{\sigma^2}e^{-x^2/2\sigma^2}$$

$$= \int_{-\infty}^{\infty}\left(Ae^{-x^2/2\sigma^2}\right)\left(\frac{Ax}{\sigma^2}e^{-x^2/2\sigma^2}\right)dx = \frac{A}{\sigma^2}\int_{-\infty}^{\infty} ex^{-x^2/2\sigma^2}dx =$$

37.6 For the harmonic oscillator, we find

$$E_n = (n+\tfrac{1}{2})\hbar\omega_0 \quad (\text{for } \; n = 0, 1, 2, \ldots).$$

The average kinetic energies are

$$\langle K_0\rangle = E_0/2 = \frac{\hbar\omega_0}{4}$$

$$\langle K_1\rangle = E_1/2 = \frac{3\hbar\omega_0}{4}$$

$$\langle K_2\rangle = E_2/2 = \frac{5\hbar\omega_0}{4}$$

$$\langle K_3\rangle = E_3/2 = \frac{7\hbar\omega_0}{4}.$$

PROBLEM-SOLVING GUIDELINES

1. Quantum mechanics dominates all of modern physics, and many different systems have been and continue to be investigated. However, most of these systems do not have straightforward analytic solutions and require the use of computers. On the introductory level, most problems can be mapped to (in)finite potential wells or harmonic oscillator potentials.

2. Wave functions are often determined by boundary conditions and symmetries. Be sure to exploit these in your solution attempts.

3. Quantum mechanics and classical mechanics are not totally different from each other. Classical mechanics is the limit of quantum mechanics when the fact that $\hbar$ is nonzero can be neglected. Be sure that your quantum solutions do not violate classical mechanics in that limit.

4. Typically, you will find discrete energies for quantum solutions. Fixed energy differences between neighboring states point to oscillator potentials, whereas linearly increasing energy differences point to infinite potential wells.

Multiple-Choice Questions

37.1 The wavelength of an electron in an infinite potential well is $\alpha/2$, where α is the width of the well. Which state is the electron in?

a) $n = 3$

b) $n = 6$

c) $n = 4$

d) $n = 2$

37.2 For which of the following states will the particle never be found in the exact center of a square infinite potential well?

a) the ground state

b) the first excited state

c) the second excited state

d) any of the above

e) none of the above

37.3 The probability of finding an electron at a particular location in a hydrogen atom is directly proportional to

a) its energy.

b) its momentum.

c) its wave function.

d) the square of its wave function.

e) the product of the position coordinate and the square of the wave function.

f) none of the above.

37.4 Is the superposition of two wave functions, which are solutions to the time-independent Schrödinger equation for the

same potential energy, also a solution to the Schrödinger equation?

a) no

b) yes

c) depends on the value of the potential energy

d) only if $\frac{d^2\psi(x)}{dx^2} = 0$

37.5 Let k be the wave number of a particle moving in one dimension with velocity v. If the velocity of the particle is doubled, to $2v$, then the magnitude of the wave number is

a) κ

b) 2κ

c) $\kappa/2$.

d) none of these.

37.6 An electron is in a square infinite potential well of width a: $U(x) = \infty$, for $x < 0$ and $x > a$. If the electron is in the first excited state, $\psi(x) = A \sin(2\pi x/a)$, at what position(s) is the probability function a maximum?

a) 0

b) $a/4$

c) $a/2$

d) $3a/4$

e) both $a/4$ and $3a/4$

37.7 Which of the following statements is (are) true?

a) The energy of electrons is always discrete.

b) The energy of a bound electron is continuous.

c) The energy of a free electron is discrete.

d) The energy of an electron is discrete when it is bound to an ion.

37.8 Which of the following statements is (are) true?

a) In a one-dimensional quantum harmonic oscillator, the energy levels are evenly spaced.

b) In a one-dimensional infinite potential well, the energy levels are evenly spaced.

c) The minimum total energy possible for a classical harmonic oscillator is zero.

d) The correspondence principle states that because the minimum possible total energy for the classical simple harmonic oscillator is zero, the expected value for the fundamental state $(n = 0)$ of the one-dimensional quantum harmonic oscillator should also be zero.

e) The $(n = 0)$ state of a one-dimensional quantum harmonic oscillator is the state with the minimum possible uncertainty, $\Delta x \Delta p$.

37.9 Simple harmonic oscillation occurs when the potential energy function is equal to $\frac{1}{2}kx^2$, where κ is a constant. What happens to the ground-state energy level if κ is increased?

a) It increases.

b) It remain the same.

c) It decreases.

37.10 A particle with energy $E = 5$ eV approaches a barrier of height $U = 8$ eV. Quantum mechanically there is a nonzero probability that the particle will tunnel through the barrier. If the barrier height is slowly decreased, the probability that the particle will deflect off the barrier will

a) decrease.

b) increase.

c) not change.

CONCEPTUAL Questions

37.11 Is the following statement true or false? The larger the amplitude of a Schrödinger wave function, the larger its kinetic energy. Explain your answer.

37.12 For a particle trapped in a square infinite potential well of length L, what happens to the probability that the particle is found between 0 and $L/2$ as the particle's energy increases?

37.13 Think about what happens to wave functions for a particle in a square infinite potential well as the quantum number n approaches infinity. Does the probability distribution in that limit obey the correspondence principle? Explain.

37.14 Show by symmetry arguments that the expectation value of the momentum for an even-n state of a one-dimensional harmonic oscillator is zero.

37.15 Is it possible for the expectation value of the position of an electron to correspond to a position where the electron's probability function, $\Pi(x)$, is zero? If it is possible, give a specific example.

37.16 Sketch the two lowest-energy wave functions for an electron in an infinite potential well that is 20 nm wide and a finite potential well that is 1 eV deep and is also 20 nm wide. Using your sketches, can you determine whether the energy levels in the finite potential well are lower, the same, or higher than in the infinite potential well?

37.17 In the cores of white dwarf stars, carbon nuclei are thought to be locked into very ordered lattices because the temperature is very low, $\sim 10^4$ K. Consider a one-dimensional lattice in which the atoms are separated by 20 fm $\left(1\text{ fm} = 1 \cdot 10^{-15}\text{m}\right)$. Approximate the Coulomb potentials of the two outside atoms as following a quadratic relationship, and assume that the atoms' vibrational motions are small. What energy state would the central carbon atom be in at this temperature? (Use $E = \frac{3}{2}k_\text{B}T$.

37.18 For a square finite potential well, you have seen solutions for particle energies greater than and less than the well depth. Show that these solutions are equal outside the potential well if the particle energy is equal to the well depth. Explain your answer and the possible difficulty with it.

37.19 Consider the energies allowed for bound states of a half-harmonic oscillator, having the potential

$$U(x) = \begin{cases} \frac{1}{2}m\omega_0^2 & \text{for } x > 0 \\ & \text{for } x \leq 0. \end{cases}$$

Using simple arguments based on the characteristics of normalized wave functions, what are the energies allowed for bound states in this potential?

37.20 Suppose $\psi(x)$ is a properly normalized wave function describing the state of an electron. Consider a second wave function, $\psi_{\text{new}}(x) = e^{i\phi}\psi(x)$, for some real number ϕ. How does the probability density associated with ψ_{new} compare to that associated with ψ?

37.21 A particle of mass m is in the potential $U(x) = U_0 \cosh(x/a)$, where U_0 and a are constants. Show that the ground-state energy of the particle can be *estimated* as

$$E_0 \cong U_0 + \frac{1}{2}\hbar\left(\frac{U_0}{ma^2}\right)^2.$$

37.22 The time-independent Schrödinger equation for a nonrelativistic free particle of mass m is obtained from the energy relationship $E = p^2/(2m)$ by replacing E and p with appropriate derivative operators, as suggested by the de Broglie relations. Using this procedure, derive a quantum wave equation for a

relativistic particle of mass m, for which the energy relation is $E^2 - p^2c^2 = m^2c^4$, *without* taking any square root of this relation.

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 37.1

37.23 A neutron has a kinetic energy of 10.0 MeV What size object would have to be used to observe neutron diffraction effects? Is there anything in nature of this size that could serve as a target to demonstrate the wave nature of 10.0 MeV neutrons?

37.24 Given the complex function $f(x) = (8 + 3i) + (7 - 2i)x$ of the real variable x, what is $|f(x)|^2$?

Section 37.3

37.25 Determine the two lowest energies of the wave function of an electron in a box of width $2.0 \cdot 10^{-9}$ m.

37.26 Determine the three lowest energies of the wave function of a proton in a box of width $1.0 \cdot 10^{-10}$ m.

37.27 What is the ratio of the energy difference between the ground state and the first excited state for a square infinite potential well of length L and that for a square infinite potential well of length $2L$? That is, find $(E_2 - E_1)_L / (E_2 - E_1)_{2L}$.

• **37.28** An electron is confined in a one-dimensional infinite potential well of width 1.0 nm. Calculate (a) the energy difference between the second excited state and the ground state, and (b) the wavelength of light emitted when an electron makes this transition.

• **37.29** Find the wave function for a particle in an infinite square well centered at the origin, with the walls at $\pm a/2$.

• **37.30** In Example 37.1, we calculated the energy of the wave function with the lowest quantum number for an electron confined to a one-dimensional box of width 2.00 Å However, atoms are *three-dimensional* entities with a typical diameter of $1.00 \text{ Å} = 10^{-10}$ m. It would seem then that the better approximation would be an electron trapped in a three-dimensional infinite potential well (a potential cube with sides of 1.00 Å).

a) Derive an expression for the wave function and the corresponding energies of an electron in a three-dimensional rectangular infinite potential well.

b) Calculate the lowest energy allowed for the electron in this case.

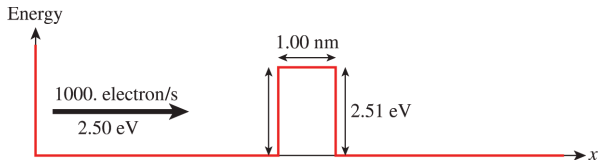
Section 37.4

37.31 An electron is confined to a potential well shaped as shown in Figure 37.10. The width of the well is $1.0 \cdot 10^{-9}$m, and $U_1 = 2.0$ eV. Is the $n = 3$ state bound in this well?

37.32 If a proton of kinetic energy 18.0 MeV encounters a rectangular potential energy barrier of height 29.8 MeV and width $1.00 \cdot 10^{-15}$m, what is the probability that the proton will tunnel through the barrier?

• **37.33** Suppose the kinetic energy of the neutron described in Example 37.3 is increased by 15%. By what factor does the neutron's probability of tunneling through the barrier increase?

• **37.34** A beam of electrons moving in the positive x-direction encounters a potential barrier that is 2.51 eV high and 1.00 nm wide. Each electron has a kinetic energy of 2.50 eV, and the electrons arrive at the barrier at a rate of 1000. electrons/s. What is the rate I_T (in electrons/s) at which electrons pass through the barrier, on average? What is the rate I_R (in electrons/s) at which electrons bounce back from the barrier, on average? Determine and compare the wavelengths of the electrons before and after they pass through the barrier.



•**37.35** Consider an electron approaching a potential barrier 2.00 nm wide and 7.00 eV high. What is the energy of the electron if it has a 10.0% probability of tunneling through this barrier?

• **37.36** Consider an electron in a three-dimensional box—with infinite potential walls—of dimensions
1.00 nm × 2.00 nm × 3.00 nm. Find the quantum numbers n_x, n_y, and n_z, and the energies (in eV) of the six lowest energy levels. Are any of these levels degenerate, that is, do any distinct quantum states have identical energies?

• **37.37** In a scanning tunneling microscope, the probability that an electron from the probe will tunnel through a 0.100-nm gap is

0.100%. Calculate the work function of the probe.

•• **37.38** Consider a square potential, $U(x) = 0$ for $x < -\alpha$, $U(x) = -U_0$ for $-\alpha \leq x \leq \alpha$, where U_0 is a positive constant, and $U(x) = 0$ for $x > \alpha$. For $E > 0$, the solutions of the time-independent Schrödinger equation in the three regions will be the following:

For $x < -\alpha$, $\psi(x) = e^{i\kappa x} + Re^{-i\kappa x}$, where $\kappa^2 = 2mE/\hbar^2$ and R is the amplitude of a reflected wave.

For $-\alpha \leq x \leq a$, $\psi(x) = Ae^{i\kappa' x} + Be^{-i\kappa' x}$, and $(\kappa')^2 = 2m(E + U_0)/\hbar^2$.

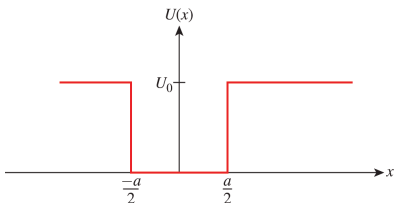
For $x > \alpha$, $\psi(x) = Te^{i\kappa x}$ where T is the amplitude of the transmitted wave.

Match $\psi(x)$ and $d\psi(x)/dx$ at $-\alpha$ and α and find an expression for R. What is the condition for which $R = 0$ (that is, there is no reflected wave)?

•• **37.39**

a) Determine the wave function and the energy levels for the bound states of an electron in the symmetrical one-dimensional potential well of finite depth shown in the figure.

b) If the penetration distance η into the classically forbidden region is defined as the distance at which the wave function decreases to $1/e$ of its value at the edge of the well, determine an expression for this penetration distance.



c) The electrons in a typical GaAs-GaAlAs quantum-well laser diode are confined within a one-dimensional potential well like the one shown in the figure, of width 1 nm and depth 0.300 eV.

Numerical solutions to the Schrödinger equation show that there is only one possible bound state for the electrons in this case, with energy of 0.125 eV. Calculate the penetration distance for these electrons.

Section 37.5

37.40 An oxygen molecule has a vibrational mode that behaves approximately like a simple harmonic oscillator with frequency $2.99 \cdot 10^{14}\text{rad/s}$. Calculate the energy of the ground state and the first two excited states.

37.41 An electron in a harmonic oscillator potential emits a photon with a wavelength of 360 nm as it undergoes a $3 \rightarrow 1$ quantum jump. What is the wavelength of the photon emitted in a $3 \rightarrow 2$ quantum jump? (*Hint:* The energy of the photon is equal to the energy difference between the initial and the final state of the electron.)

37.42 An experimental measurement of the energy levels of a hydrogen molecule, H_2, shows that they are evenly spaced and separated by about 9.10^{-20}J. A reasonable model of one of the hydrogen atoms would then seem to be that of a particle in a simple harmonic oscillator potential. Assuming that the hydrogen atom is attached by a spring with a spring constant *k* to the other atom in the molecule, what is the spring constant *k*?

•37.43 Calculate the ground-state energy for an electron confined to a cubic potential well with sides equal to twice the Bohr radius ($R = 0.0529\text{ nm}$). Determine the spring constant that would give this same ground-state energy for a harmonic oscillator.

• 37.44 A particle in a harmonic oscillator potential has the initial wave function $\Psi(x,0) = A\left[\psi_0(x) + \psi_1(x)\right]$. Normalize $\Psi(x,0)$.

• 37.45 The ground-state wave function for a harmonic oscillator is given by $\psi_0(x) = A_2 e^{-x^2/2b^2}$.

a) Determine the normalization constant, A_2.

b) Determine the probability that a quantum harmonic oscillator in the $n = 0$ state will be found in the classically forbidden region.

Section 37.6

37.46 A particle is in a square infinite potential well of width L and is in the $n = 3$ state. What is the probability that, when observed, the particle is found to be in the rightmost 10.0% of the well?

•37.47 An electron is confined between $x = 0$ and $x = L$ The wave function of the electron is $\psi(x) = A\sin(2\pi x/L)$. The wave function is zero for the regions $x < 0$ and $x > L$.

a) Determine the normalization constant, A.

b) What is the probability of finding the electron in the region $0 \leq x \leq L/3$?

37.48 Find the probability of finding an electron trapped in a one-dimensional infinite well of width 2.00 nm in the $n = 2$ state between 0.800 and 0.900 nm (assume that the left edge of the well is at $x = 0$ and the right edge is at $x = 2.00$ nm

• 37.49 An electron is trapped in a one-dimensional infinite potential well that is $L = 300.$ pm wide. What is the probability that the electron in the first excited state will be detected in an interval between $x = 0.500\ L$ and $x = 0.750\ L$

Section 37.8

• **37.50** Find the uncertainty of x for the wave function $\Psi(x,t) = Ae^{-\lambda x^2}e^{-i\omega t}$.

•**37.51** Write a wave function $\Psi\left(\overrightarrow{r},t\right)$ for a non relativistic free particle of mass m moving in three dimensions with momentum $\overrightarrow{p}$, including the correct time dependence as required by the Schrödinger equation. What is the probability density associated with this wave?

• **37.52** Suppose a quantum particle is in a stationary state with a wave function $\Psi(x,t)$. The calculation of $\langle x\rangle$, the expectation value of the particle's position, is shown in the text. Calculate $d\langle x\rangle/dt$ (**not** $\langle dx/dt\rangle$)

•• **37.53** Although quantum systems are frequently characterized by their stationary states, a quantum particle is not required to be in such a state unless its energy has been measured. The actual state of the particle is determined by its initial conditions. Suppose a particle of mass m in a one-dimensional potential well with infinite walls (a box) of width a is actually in a state with the wave function

$$\Psi(x,t) = \frac{1}{\sqrt{2}}[\Psi_1(x,t) + \Psi_2(x,t)],$$

where Ψ_1 denotes the stationary state with quantum number $n = 1$ and Ψ_2 denotes the state with $n = 2$ Calculate the probability density distribution for the position x of the particle in this state.

Section 37.10

37.54 In Chapter 40, you will see that a nuclear-fusion reaction between two protons (creating a deuteron, a positron, and a neutrino) releases 0.42 meV of energy. Nuclear fusion is what causes the stars to shine, and if we can harness it, we can solve the world's energy problems. Compare the energy released in this fusion reaction with what would be released by the annihilation of a proton and an antiproton.

37.55 Particle-antiparticle pairs are occasionally created out of empty space. Considering energy-time uncertainty, how long would such pairs be expected to exist at most if they consist of

a) an electron and a positron?

b) a proton and an antiproton?

37.56 A positron and an electron annihilate, producing two 2.0-meV gamma rays moving in opposite directions. Calculate the kinetic energy of the electron when the kinetic energy of the positron is twice that of the electron.

Additional Exercises

37.57 Calculate the energy of the first excited state of a proton in a one-dimensional infinite potential well of width $\alpha = 1.00$ nm.

37.58 Electrons in a scanning tunneling microscope encounter a potential barrier that has a height of $U = 4.0$ eV above their total energy. By what factor does the tunneling current change if the tip moves a net distance of 0.10 nm farther from the surface?

37.59 An electron is confined in a three-dimensional cubic space of L^3 with infinite potentials.

a) Write down the normalized solution of the wave function for the ground state.

b) How many energy states are available between the ground state and the second excited state? (Take the electron's spin into account.)

37.60 A mass-and-spring harmonic oscillator used for classroom demonstrations has the angular frequency $\omega_0 = 4.45\ \text{s}^{-1}$. If this oscillator has a total (kinetic plus potential) energy $E = 1.00$ J, what is its corresponding quantum number, n?

37.61 The neutrons in a parallel beam, each having kinetic energy $\frac{1}{40}$eV (which approximately corresponds to room temperature), are directed through two slits 0.50 mm apart. How far apart will the peaks of the interference pattern be on a screen 1.5 m away?

37.62 Find the ground-state energy (in eV) of an electron in a one-dimensional box, if the box is of length $L = 0.100$ nm.

37.63 An approximately one-dimensional potential well can be formed by surrounding a layer of GaAs with layers of $\text{Al}_x\text{Ga}_{1-x}\text{As}$. The GaAs layers can be fabricated in thicknesses that are integral multiples of the single-layer thickness, 0.28 nm. Some electrons in the GaAs layer behave as if they were trapped in a box. For simplicity, treat the box as a one-dimensional infinite potential well and ignore the interactions between the electrons and the Ga and As atoms (such interactions are often accounted for by replacing the actual electron mass with an effective electron mass). Calculate the energy of the ground state in this well for these cases:

a) 2 GaAs layers

b) 5 GaAs layers

37.64 Consider a water molecule in the vapor state in a room $4.00\ \text{m} \times 10.0\ \text{m} \times 10.0\ \text{m}$.

a) What is the ground-state energy of this molecule, treating it as a simple particle in a box?

b) Compare this energy to the average thermal energy of such a molecule, taking the temperature to be 300. K

c) What can you conclude from the two numbers you just calculated?

37.65 A neutron moves between rigid walls 8.4 fm apart. What is the energy of its $n = 1$ state?

• **37.66** A surface is examined using a scanning tunneling microscope (STM). For the range of the gap, L, between the tip of the probe and the sample surface, assume that the electron wave function for the atoms under investigation falls off exponentially as $|\psi| = e^{-(10.0\ \text{nm}^{-1})a}$. The tunneling current through the tip of the probe is proportional to the tunneling probability. In this situation, what is the ratio of the current when the tip is 0.400 nm above a surface feature to the current when the tip is 0.420 nm above the surface?

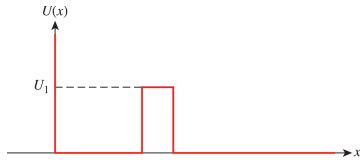
• **37.67** An electron is trapped in a one-dimensional infinite well of width 2.00 nm. It starts in the $n = 4$ state, and then goes into the $n = 2$ state, emitting radiation with energy corresponding to the energy difference between the two states. What is the wavelength of the radiation?

• **37.68** Two long, straight wires that lie along the same line have a separation at their tips of 2.00 nm The potential energy of an electron in this gap is about 1.00 eV higher than it is in the conduction band of the two wires. Conduction-band electrons have enough energy to contribute to the current flowing in the wire.

What is the probability that a conduction electron from one wire will be found in the other wire after arriving at the gap?

•37.69 Consider an electron that is confined to a one-dimensional infinite potential well of width $a = 0.10$ nm, and another electron that is confined to a three-dimensional (cubic) infinite potential well with sides of length $a = 0.10$ nm. Let the electron confined to the cube be in its ground state. Determine the difference in energy ground state of the two electrons and the excited state of the one-dimensional electron that minimizes the difference in energy with the three-dimensional electron.

• **37.70** An electron with an energy of 129 keV is trapped in a potential well defined by an infinite potential at $x < 0$ and a potential barrier of finite height U_1 extending from $x = 529.2$ fm to $x = 2116.8$ fm $\left(1 \text{ fm} = 1.0^{-15}\text{m}\right)$, as shown in the figure. It is found that the electron can be detected beyond the barrier with a probability of 10%. Calculate the height of the potential barrier.



• **37.71** Consider an electron that is confined to the xy-plane by a two-dimensional rectangular infinite potential well. The width of the well is w in the x-direction and $2w$ in the y-direction. What is the lowest energy that is shared by more than one distinct state, that is, two different states having the same energy?

MULTI-VERSION EXERCISES

37.72 A 5.15-MeV alpha particle $\left(\text{mass} = 3.7274\ \text{GeV}/c^2\right)$ inside a heavy nucleus encounters a barrier whose average height is 5.5 MeV and whose width is 11.7 fm $\left(1\ \text{fm} = 1.0^{-15}\text{m}\right)$. What is the probability that the alpha particle will tunnel through the barrier? (*Hint:* A potentially useful value is $\hbar c = 197.327\ \text{MeV fm}$.

37.73 A 6.31-MeV alpha particle $\left(\text{mass} = 3.7274\ \text{GeV}/c^2\right)$ inside a heavy nucleus encounters a barrier whose average height is 15.7 MeV and whose width is 13.7 fm $\left(1\ \text{fm} = 1.0^{-15}\text{m}\right)$. What is the value of the decay constant, $\gamma\left(\text{in fm}^{-1}\right)$? (*Hint:* A potentially useful value is $\hbar c = 197.327\ \text{MeV fm}$.

37.74 An alpha particle $\left(\text{mass} = 3.7274\ \text{GeV}/c^2\right)$ inside a heavy nucleus encounters a barrier whose average height is 15.7 MeV and whose width is 15.5 fm $\left(1\ \text{fm} = 1.0^{-15}\text{m}\right)$. The decay constant, γ is measured to be $1.257\ \text{fm}^{-1}$. What is the kinetic energy of the alpha particle? (*Hint:* A potentially useful value is $\hbar c = 197.327\ \text{MeV fm}$.

37.75 A 8.59-MeV alpha particle $\left(\text{mass} = 3.7274\ \text{GeV}/c^2\right)$ inside a heavy nucleus encounters a barrier whose average height is 15.9 MeV The tunneling probability is measured to be $1.042 \cdot 10^{-18}$. What is the width of the barrier? (*Hint:* A potentially useful value is $\hbar c = 197.327\ \text{MeV fm}$.

37.76 An electron with a mass of $9.109 \cdot 10^{-31}$ kg is trapped inside a one-dimensional infinite potential well of width 13.5 nm. What is the energy difference between the $n = 5$ and the $n = 1$ states?

37.77 A proton with a mass of $1.673 \cdot 10^{-27}$ kg is trapped inside a one-dimensional infinite potential well of width 23.9 nm. What is

the quantum number, n of the state that has an energy difference of $1.08 \cdot 10^{-3}$meV with the $n = 2$ state?

37.78 A particle is trapped inside a one-dimensional infinite potential well of width 19.3 nm. The energy difference between the $n = 2$ and the $n = 1$ states is $2.639 \cdot 10^{-25}$ J. What is the mass of the particle?

Lasers were first developed less than 50 years ago, but they have become common in many areas of daily life. They are used in Blu-ray, DVD, and CD players, in bar-code readers in stores, even in light shows at rock concerts and other events. They also have important scientific applications, for example, in astronomy. Observatories fire lasers into the sky (Figure 38.1) and see how the light is distorted by atmospheric disturbance.

Computers then feed this information back to adaptive mirrors that have movable sections that correct for atmospheric motion, producing steady, sharp images.

FIGURE 38.1 A sodium laser (nearly vertical yellow line) is fired into the night sky to provide a laser guide for the adaptive optics of the telescopes of the Teide Observatory in Tenerife, Spain.

carlos martin diaz/Shutterstock

Lasers work by producing photons of light as electrons move between energy levels in atoms, a topic we will study in this chapter. The concept of atomic energy levels was part of the Bohr model of the atom, which was one of the earliest attempts at applying quantum ideas to atomic structure. However, despite some outstanding successes, the Bohr model did not fully explain how particles function together within atoms; that explanation requires application of the quantum wave mechanics of Chapter 37. We will present an overview of this application, skipping over many of the mathematical details, and then show how the results underlie the operation of X-ray tubes and lasers.

Chapters 36 and 37 surveyed the phenomena that can be explained by the quantization hypothesis, and we solved some simple systems by following the laws imposed by quantum mechanics. With this introductory understanding of quantum mechanics, we have the tools to understand atoms.

WHAT WE WILL LEARN

- The narrow lines observed in the spectra of some atoms result from the transitions of electrons from one state to another.
- The Bohr model of the atom, which is based on a quantization condition for the angular momentum, was an early success in explaining the observed line spectra of hydrogen. The electrons' orbital radii and the atom's energy levels obtained with the Bohr model are physically correct. However, the Bohr model does not obtain the correct values of the quantum numbers and is thus intrinsically flawed.
- To go beyond the Bohr model and find for the correct electron wave functions of the hydrogen atom, we have to solve the Schrödinger equation for the electrons in the Coulomb potential due to the nucleus.
- The complete solution of the Schrödinger equation for the hydrogen atom is the product of the angular part and the radial part. The quantum numbers from these solutions are the radial quantum number, $n = 1, 2, 3, \ldots$; the orbital angular momentum quantum number, $\ell = 0, 1 \ldots, n - 1$; and the magnetic quantum number, $m = -\ell, \ldots, \ell$.
- The wave functions for other atoms can be determined in a manner similar to that used for the hydrogen wave functions. The Pauli Exclusion Principle requires that each possible state be occupied by at most two electrons, one with spin down and one with spin up.
- Lasers work on the basis of population inversion, in which electrons are lifted into a metastable state and subsequently stimulated to emit photons when they make transitions from the metastable state to the ground state.

38.1 Spectral Lines

Chapter 32 showed that the index of refraction of light in a prism depends on the wavelength. Figure 38.2 shows how white light (coming in from the left) is split into different wavelength components by a prism, as a result of the dependence of the index of refraction on wavelength.

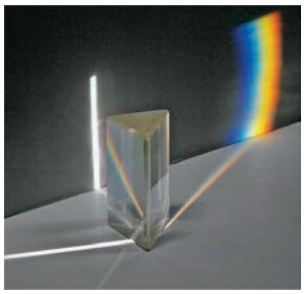

FIGURE 38.2 A prism decomposes white light into different colors (wavelengths).

W. Bauer and G. D. Westfall

A **spectrometer** can be constructed using a prism. This instrument displays the spectral components of light emitted by all kinds of objects. Figure 38.3 shows a kind of spectrometer often used in introductory physics laboratories. One arm of the spectrometer points toward a light source and provides a narrowly focused thin beam of light, which strikes the central prism and is then spectrally decomposed. The other spectrometer arm contains the ocular lenses and is used for observations. It rotates around a central pivot axis located under the center of the prism. With the spectrometer, we can measure the angle between the two arms and thus determine the angle of deflection of each color. The index of refraction of the prism is known, and thus Snell's Law can be applied to precisely determine the wavelengths of the light.

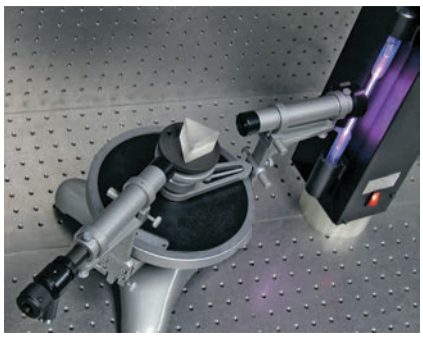

FIGURE 38.3 Spectrometer with prism.

W. Bauer and G. D. Westfall

In the late 19th century, spectrometers were used in many laboratories to study gases. Researchers trapped a gas in an electric discharge tube and then sent a current through the tube, causing the gas to emit light. (The black box in the right part of Figure 38.3

holds the purple-glowing electric discharge tube with its power supply.) Incidentally, this way of generating light is the basis for neon lights.

A spectrometer pointed at the Sun will spectrally decompose light into a spectrum like the one shown in Figure 38.2—that is, an array of different colors. Measuring the intensity, or spectral emittance, of the different colors of the Sun's light makes it possible to measure the temperature of the Sun's surface, on the assumption that the Sun emits a blackbody spectrum. An expensive spectrometer is not needed to see that the Sun emits a broad spectrum of all colors; a child's toy prism can do the job.

However, if you pointed a spectrometer at a discharge tube filled with pure hydrogen and looked at the spectrum emitted by this gas, you might be very surprised. Instead of a broad continuous spectrum, you would see a few thin lines of particular colors. At most there are four lines: red (wavelength 656 nm, also historically called H-alpha), teal blue (wavelength 486 nm, H-beta), deep blue (434 nm, H-gamma), and finally violet (410 nm, H-delta). Other discrete lines appear in the hydrogen spectrum, but they lie outside the range of wavelengths accessible by the unaided human eye. Still, it is possible to determine the wavelengths of these other spectral lines, and this was done to very good precision in the 19th century. The lower part of Figure 38.4 shows where the hydrogen lines are located as a function of their wavelengths, λ. Shown are the four visible lines in their characteristic colors. In addition, the invisible lines are indicated with thin white lines. These lines fall into distinct groups, named after their discoverers: the Lyman, Balmer, Paschen, and Brackett series. (Other series, not shown, were discovered at wavelengths above 2000 nm.)

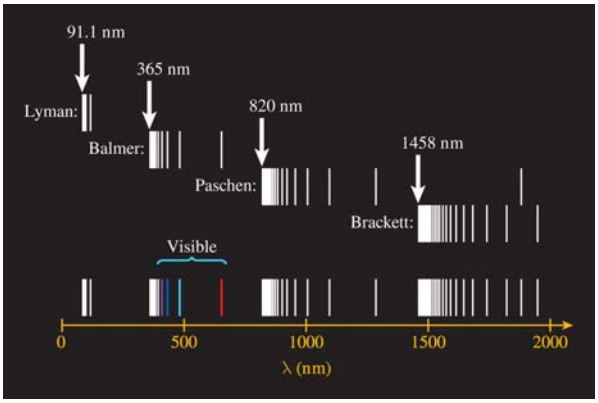

FIGURE 38.4 Calculated spectral lines of hydrogen.

Purely from studying patterns in the values for the wavelengths, the Swiss mathematician and hobbyist physicist Johann Balmer (1825–1898) found in 1885 an empirical formula that predicted the wavelengths in the Balmer group of the hydrogen spectrum:

$$\lambda = (364.56\ \text{nm})\frac{n^2}{n^2 - 4} \quad (\text{for } n = 3, 4, 5, \ldots). \tag{38.1}$$

Three years later, the Swedish physicist Johannes Rydberg (1854–1919) was able to generalize the Balmer formula to include all other line series (Lyman, Paschen, Brackett,

etc.) in the hydrogen spectrum. The **Rydberg formula** for the wavelengths in the hydrogen spectrum is

$$\frac{1}{\lambda} = R_H\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right), \quad \text{with } n_1 < n_2. \tag{38.2}$$

The numbers n_1 and n_2 are simple integers; R_H is the **Rydberg constant** for hydrogen and has the dimension of inverse length. The value of R_H is

$$R_\mathrm{H} = 1.097373 \cdot 10^7\ \mathrm{m}^{-1}.$$

For $n_1 = 1$ and $n_2 = 2, 3, 4, \ldots, \infty$, we obtain the wavelengths of the Lyman series; for $n_1 = 2$ and $n_2 = 3, 4, 5, \ldots, \infty$, we obtain the Balmer series; and so on.

EXAMPLE 38.1 Spectral Lines

PROBLEM

Figure 38.4 gives the wavelength of the leftmost line in each of the first four series in the hydrogen spectrum. What are the wavelengths for the rightmost lines in these series?

SOLUTION

The wavelengths of the lines in the hydrogen spectrum are described by the Rydberg formula (equation 38.2):

$$\frac{1}{\lambda} = R_{\mathrm{H}}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right).$$

Because $n_1 < n_2$, the term $1/n_1^2$ is always greater than $1/n_2^2$. For a given fixed value of n_1, an increasing value of n_2 means that a smaller number, $1/n_2^2$, is subtracted from $1/n_2^1$ and thus $1/\lambda$ increases. Therefore, the wavelength decreases monotonically with increasing n_2.

Now that we understand this dependence, we can see that the leftmost and therefore smallest wavelength in each series must correspond to the largest value of n_2, which is $n_2 \approx \infty$. This is also the reason why the lines become so densely spaced at this end of the series: There are an infinite number of values of n_2 with almost exactly the same wavelength.

Conversely, the rightmost and therefore largest value of the wavelength in each series must correspond to the smallest possible value of n_2 in that series. Since we have the condition $n_1 < n_2$, this smallest possible value is $n_{2,\min} = n_1 + 1$. Using this relation, we find for the maximum wavelength in each series:

Lyman series:

$$n_1 = 1,\ n_{2,\min} = 1 + 1 + 2 \Rightarrow \frac{1}{\lambda_{\max}} = R_{\mathrm{H}}\left(1 - \frac{1}{4}\right) \Rightarrow \lambda_{\max} = 121.5\ \mathrm{nm}$$

Balmer series:

$$n_1 = 2,\ n_{2,\min} = 2 + 1 = 3 \Rightarrow \frac{1}{\lambda_{\max}} = R_{\mathrm{H}}\left(\frac{1}{4} - \frac{1}{9}\right) \Rightarrow \lambda_{\max} = 656\ \mathrm{nm}$$

Paschen series:

$$n_1 = 3,\ n_{2,\min} = 3 + 1 = 4 \Rightarrow \frac{1}{\lambda_{\max}} = R_{\mathrm{H}}\left(\frac{1}{9} - \frac{1}{16}\right) = \lambda_{\max} = 1875\ \mathrm{nm}$$

Brackett series:

$$n_1 = 4,\ n_{2,\min} = 4 + 1 = 5 \Rightarrow \frac{1}{\lambda_{\max}} = R_{\mathrm{H}}\left(\frac{1}{16} - \frac{1}{25}\right) \Rightarrow \lambda_{\max} = 4050\ \mathrm{nm}.$$

DISCUSSION

The maximum wavelength in the Balmer series corresponds to the red H-alpha line in the visible spectrum and is thus probably the most prominent line in the entire hydrogen spectrum. You can see that the highest values of the wavelengths in each of the first two series are lower than the lowest value in the next higher series. However, this changes with the Paschen series. Its longest wavelength line has a wavelength of 1875 nm, which is greater than all but a few wavelengths in the Brackett series, which has its minimum wavelength at a value of 1458 nm. The lines with the highest wavelengths in the Lyman, Balmer, and Paschen series are shown in Figure 38.4, whereas the highest wavelength of the Brackett series lies far outside the range of wavelengths displayed.

Self-Test Opportunity 38.1

Derive the values for the minimum wavelengths in the four series shown in Figure 38.4.

Concept Check 38.1

The number of lines in the Brackett series that have wavelengths greater than the maximum wavelength in the Paschen series is

a) 1.

b) 2.

c) 4.

d) 8.

e) ∞.

Self-Test Opportunity 38.2

Derive the formula originally given by Balmer for the wavelengths of the Balmer series (equation 38.1) from the more general Rydberg formula (equation 38.2).

Before we go on, let's emphasize the main point: Hydrogen gas can emit light when excited, but the light cannot have any wavelength but only the well-defined wavelengths described by the Rydberg formula. Chapters 36 and 37, which discussed all kinds of quantized phenomena, lead us to look for an explanation for the discreteness of the hydrogen spectrum within quantum mechanics. The next section covers Bohr's quantum description, which is valuable for its insight, its historical significance, and its limited success. The rigorous quantum mechanical analysis of the hydrogen atom will be presented in Section 38.3

Other elements in their gaseous state also show similar **line spectra** with discrete lines. In particular, some elements (such as lithium and sodium) have hydrogen-like

spectra in their gaseous state. In general, however, the line spectra of other atoms are more complicated than the simplest case of the hydrogen atom. The characteristic line spectra often serve as atomic “fingerprints” for detecting the presence of specific chemical elements. Astronomers use this technique when they want to determine the elemental composition of stars, for example.

38.2 Bohr's Model of the Atom

An atom consists of a nucleus, which contains positively charged protons and uncharged neutrons, surrounded by negatively charged electrons that are bound to it by Coulomb interactions. In an electrically neutral atom, the number of protons is equal to the number of electrons. The ionization of an atom—that is, the removal of one or more electrons—causes the remaining ion to be positively charged. The typical size of an atom is on the order of $d \approx 10^{-10}$ m, and the typical size of the atomic nucleus is smaller than that by a factor of 10,000. Hydrogen—the most abundant element in the universe—is also the simplest atom in the universe, consisting of only one proton in the central nucleus with one electron orbiting it.

It is not unusual nowadays for children to learn most of these basic facts about atoms in elementary school. However, at the beginning of the 20th century, the atom was unknown territory, and it was not at all clear what its basic structure was. For example, one possible model of an atom was the "plum pudding" model. In this model, the entire atom was filled with positive charge, and the electrons were equally distributed over the entire atomic volume like raisins in a plum pudding. However, the 1909 scattering experiments of Ernest Rutherford, Hans Geiger, and Ernest Marsden brought clarity and led to the currently accepted model. The physics of the atomic nucleus will be discussed in Chapters 39 and 40.

Page 1199

After Rutherford's experiments, physicists believed that electrons orbit the nucleus, not unlike the way in which the Earth and the other planets orbit the Sun. Let's quantify what this means for the simplest atom, hydrogen. Chapter 9 showed that motion in a circular orbit requires a constant centripetal acceleration. Because the gravitational force acting on the electron due to the nucleus is so weak, the centripetal force is provided by the Coulomb force (see Chapter 21). This leads us to

$$k\frac{e^2}{r^2} = \mu\frac{v^2}{r}, \tag{38.3}$$

where $k = 8.98755 \cdot 10^9 \text{N m}^2/\text{C}^2$ is the Coulomb constant. This equation simply restates Newton's Second Law, with the force given by the Coulomb force and the acceleration as the centripetal acceleration.

A remark on the notation μ for the mass is in order. Up to now, we have been using m for the mass of the electron. However, the electron in a hydrogen atom is not moving around the proton; instead, both are moving around a common center of mass. We can incorporate this effect by introducing the **reduced mass,** μ:

$$\mu = \frac{mM}{m+M}, \tag{38.4}$$

where $m = 9.10938291(40) \cdot 10^{-31}\,\mathrm{Kg}$ is the electron mass and $M = 1.672621777(74) \cdot 10^{-27}\,\mathrm{kg}$ is the proton mass. This reduced mass has the numerical value $\mu = 9.10442 \cdot 10^{-31}\,\mathrm{kg}$. Because the proton mass is 1836 times the electron mass, the term $M/(M+m)$ is very close to 1, and thus $\mu \approx m$ to 1 part in 2000. Thus, we could still use the notation m for the mass in this case, and it would be close enough for most purposes. However, we will use the reduced mass μ from now on. An advantage to using μ in our formulations is that historically, a quantum number m was introduced in the solution to the hydrogen problem, and we want to avoid confusion.

This classical picture of a miniature planetary system of electrons in orbit around a central nucleus, which plays the role that the Sun does in the Solar System, has immense appeal and gives rise to a symmetry between the macro-cosmos and the micro-cosmos that just rings true. Right away, though, it runs into a fatal conceptual flaw: An accelerated charge radiates away energy. An electron moving on a classical circular orbit and experiencing constant centripetal acceleration would quickly lose energy and spiral into the nucleus, thus destroying the atom. Niels Bohr addressed this flaw in 1913.

Quantization of Orbital Angular Momentum

In 1913, the Danish physicist Niels Bohr (1885–1962) made an *ad hoc* assumption that the angular momentum of the electron in its orbit around the nucleus can assume only discrete values. Chapter 10 introduced the angular momentum vector of a point particle as, $\overrightarrow{L} = \overrightarrow{r} \times \overrightarrow{p}$. Bohr's idea was to require that the only possible stable electron orbits should be those whose angular momentum is an integer multiple of $\hbar$ (Planck's constant divided by 2π):

$$L = \left| \overrightarrow{r} \times \overrightarrow{p} \right| = r\mu v = n\hbar \quad (\text{for } n = 1, 2, 3, \ldots). \tag{38.5}$$

Why impose this condition? Dimensionally it works out, because both angular momentum and Planck's constant have units of $\text{Kg m}^2\,\text{s}^{-1} = \text{J s}$. However, of course, this fact alone is not sufficient. In the following discussion, we show that the quantization of angular momentum also leads to the quantization of energy. In addition, if the electron's energy is quantized, then the electron cannot radiate arbitrarily small amounts of energy and spiral into the nucleus.

Let's first work out the consequences and predictions of the Bohr postulate and then discuss its meaning and the validity of the model. To begin the calculations for the **Bohr model of the hydrogen atom**, we start with equation 38.3 for the centripetal force and multiply both sides by the factor μr^3. This leads to

$$k\frac{e^2}{r^2} = \mu\frac{v^2}{r} \Rightarrow r\mu k e^2 = \mu^2 v^2 r^2.$$

Page 1200

On the right-hand side, we can see that $\mu^2 v^2 r^2$ is the square of the angular momentum. From Bohr's quantization condition (equation 38.5), this is equal to $n^2\hbar^2$. Therefore,

$$r\mu k e^2 = \mu^2 v^2 r^2 = n^2\hbar^2.$$

Solving this for the orbital radius, *r*, results in

$$r = \frac{\hbar^2}{\mu k e^2} n^2 \equiv a_0 n^2. \tag{38.6}$$

This equation gives the allowed radii in the Bohr model of the hydrogen atom. They are proportional to the square of the quantum number *n*, and the proportionality constant, a_0, is called the **Bohr radius:**

$$a_0 = \frac{\hbar^2}{\mu k e^2} = \frac{\left(1.05457 \cdot 10^{-34}\ \text{J s}\right)^2}{\left(9.10442 \cdot 10^{-31}\ \text{kg}\right)\left(8.98755 \cdot 10^{9}\ \text{N m}^2/\text{C}^2\right)\left(1.60218 \cdot 10^{-19}\ \text{C}\right)^2}$$

$$a_0 = 5.295 \cdot 10^{-11}\ \text{m} = 0.05295\ \text{nm} = 0.5295\ \text{Å}.$$

The value of the Bohr radius is given here in nanometers (nm) as well as angstroms (Å), with $1\text{Å} = 10^{-10}\text{m} = 0.1\text{ nm}$. Inserting this result for the Bohr radius back into equation 38.3, we find for the speed v:

$$v = \sqrt{\frac{ke^2}{\mu a_0 n^2}} = \frac{1}{n}\sqrt{\frac{\left(8.988 \cdot 10^9\,\text{N m}^2/\text{C}^2\right)\left(1.602 \cdot 10^{-19}\,\text{C}\right)^2}{\left(9.104 \cdot 10^{-31}\,\text{kg}\right)\left(5.295 \cdot 10^{-11}\,\text{m}\right)}} = \frac{1}{n}2.188 \cdot 10^6\text{m}$$

This speed is 0.73% of the speed of light for $n = 1$ and decreases monotonically for the higher orbits. Therefore, the nonrelativistic approximation that we are using is justified. The total energy of the electron in orbit is the sum of its potential and kinetic energies:

$$E = \tfrac{1}{2}\mu v^2 - k\frac{e^2}{r} = -\tfrac{1}{2}k\frac{e^2}{r} = -\tfrac{1}{2}k\frac{e^2}{a_0 n^2} = -E_0\frac{1}{n^2}. \qquad \textbf{(38.7)}$$

The second step of this equation uses the general result for satellite motion (see Chapter 12) that the kinetic energy has exactly half of the magnitude of the potential energy, so the total energy is half of the potential energy. (This relation is often referred to as the *virial theorem*.) The constant E_0 can be calculated by inserting the values of the constants:

$$E_0 = \frac{ke^2}{2a_0} = \frac{\left(8.988 \cdot 10^9\,\text{N m}^2/\text{C}^2\right)\left(1.602 \cdot 10^{-19}\,\text{C}\right)^2}{2\left(5.295 \cdot 10^{-11}\,\text{m}\right)} = 2.18 \cdot 10^{-18}\,\text{J} = 13.6\,\text{eV}$$

Thus, the allowed energies for electrons in orbit around the nucleus of the hydrogen atom are $E(n=1) = -13.6\,\text{eV}, E(n=2) = -3.40\,\text{eV}, E(n=3) = -1.51\,\text{eV},$ and so on, approaching zero energy from below as $n \to \infty$. Combining equations 38.6 and 38.7 gives $E = -E_0 a_0/r$. Figure 38.5 shows E plotted versus r and indicates that only certain values of E and r, corresponding to n being an integer in equations 38.6 and 38.7, are allowed.

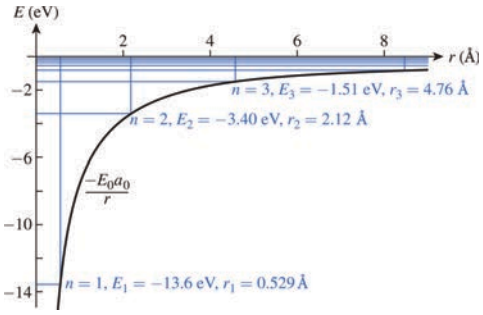

FIGURE 38.5 Energies and radii for allowed electron orbits in the Bohr model of hydrogen.

In many textbooks, the Bohr radius is defined in terms of the mass of the electron, m_e, rather than the reduced mass, μ, of the electron in the hydrogen atom:

$$a_{0,m_\mathrm{e}} = \frac{\hbar^2}{m_\mathrm{e} k e^2}.$$

The Bohr radius has the value $a_{0,m_\mathrm{e}} = 5.292 \cdot 10^{-11}$ m using this definition.

Spectral Lines in the Bohr Model

In the Bohr model, an electron cannot radiate away small amounts of energy and thus spiral into the nucleus, because of the quantization of angular momentum. However, transitions between states are still allowed. Bohr postulated that an electron in a higher energy state with quantum number n_2 could "jump" to a lower energy state with quantum number n_1, and the atom would emit a photon with energy equal to the difference in the energies between the two states. The photon energy is related to its frequency via Planck's relation, $E = hf : E_{n_2} = E_{n_1} + hf$. For light, the frequency is related to the wavelength via $f = c/\lambda$, where c is the speed of light, giving

$$E_{n_2} = E_{n_1} + \frac{hc}{\lambda}. \tag{38.8}$$

The formula for the energies (equation 38.7) then gives

$$\begin{aligned} -\frac{ke^2}{2a_0}\frac{1}{n_2^2} &= -\frac{ke^2}{2a_0}\frac{1}{n_1^2} + \frac{hc}{\lambda} \Rightarrow \\ \frac{1}{\lambda} &= \frac{ke^2}{2hca_0}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right). \end{aligned}$$

This equation is structurally identical to equation 38.2. Furthermore, the product of the constants in this equation evaluates to

$$\frac{ke^2}{2hca_0} = \frac{\left(8.988 \cdot 10^9\ \mathrm{N\,m^2/C^2}\right)\left(1.602 \cdot 10^{-19}\ \mathrm{C}\right)^2}{2\left(6.626 \cdot 10^{-34}\ \mathrm{J\,s}\right)\left(2.998 \cdot 10^8\ \mathrm{m/s}\right)\left(5.295 \cdot 10^{-11}\ \mathrm{m}\right)} = 1.097 \cdot 10^7\ \mathrm{m}^-$$

This agrees with the value of the Rydberg constant, which was determined from the experimental data, to four significant figures. That is, we can write

$$R_\mathrm{H} = \frac{ke^2}{2hca_0}.$$

Given $a_0 = \hbar^2/\mu ke^2$, the Rydberg constant can also be written as

$$R_\mathrm{H} = \frac{ke^2}{2hc(\hbar^2/\mu ke^2)} = \frac{\mu k^2 e^4}{4\pi c\hbar^3}.$$

In other words, the Bohr model is able to explain the structure of the hydrogen line spectrum and can be used to derive the experimentally found value of the Rydberg constant from the fundamental constants of the electron mass m (contained in the reduced mass, μ), charge quantum e, Planck's constant h (equal to $2\pi\hbar$), the speed of light c, and Coulomb's constant k. This was properly celebrated as an astounding success and lent considerable credence to the seemingly *ad hoc* assumption of quantized angular momentum of the electron in its orbit around the central nucleus. Transitions between energy levels can be depicted in an **energy-level diagram**, as is done in Figure 38.6 for the Balmer series.

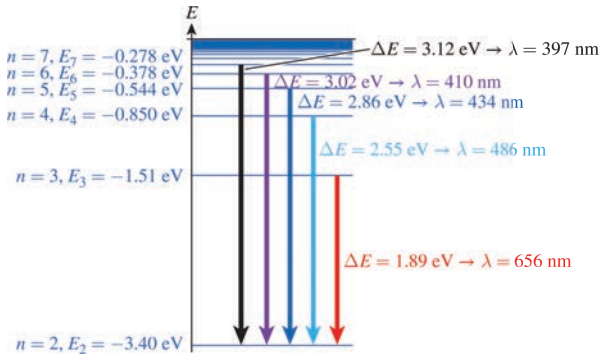

FIGURE 38.6 The first few electron transitions corresponding to the Balmer series in hydrogen.

However, at its heart, the Bohr model assumes that the electron is a classical point particle. The model was refined several times, but after Louis de Broglie postulated matter waves in 1923 (see Chapter 36) and Schrödinger published his wave equation in 1926 (see Chapter 37), it became clear that the Bohr model had to be replaced by a quantum mechanical theory of the hydrogen atom. In addition to the conceptual problems associated with a classical point particle, the Bohr model was also flawed in that it postulated an orbital angular momentum of $\hbar$ for the lowest energy state—the ground state—of hydrogen, in contradiction to experimental evidence that points to an orbital angular momentum of zero for this state. Nevertheless, the Bohr model was a very instructive first attempt at solving the hydrogen problem, and its impressive success in explaining line spectra hints that the real solution to this problem must somehow be close to what the Bohr model postulates.

SOLVED PROBLEM 38.1 Paschen Series for Doubly Ionized Lithium

We learned that the Lyman, Balmer, Paschen, Brackett, and other series in the hydrogen spectrum correspond to transitions in the hydrogen atom, in which the atom's (single) electron "jumps" between two discrete energy states. We can observe the equivalent line spectra for one-electron ions of other atoms. Doubly ionized lithium is such an ion.

PROBLEM

What is the wavelength of the second line of the Paschen series of doubly ionized lithium?

SOLUTION

THINK

Lithium has an atomic number of $Z = 3$. A doubly ionized lithium ion has two fewer electrons than the neutral atom. This leaves one electron in the Coulomb potential due to the nucleus, and we obtain hydrogen-like wave functions. The only difference from the case of the hydrogen atom is that we have $-kZe^2/r = -3ke^2/r$ for the Coulomb potential in this case. Thus, the formulas for the line spectra of the hydrogen atom still hold, but we need to find the appropriate Rydberg constant for this case.

SKETCH

Though the Bohr model of the hydrogen atom has fatal shortcomings, it is still useful to sketch the Bohr radii (Figure 38.7) to help clarify which transition is responsible for the spectral line.

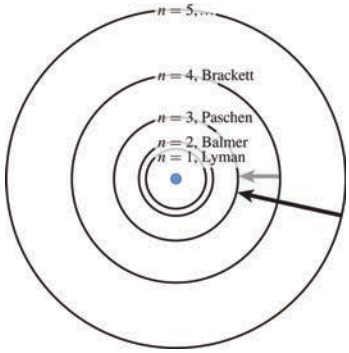

FIGURE 38.7 Transition responsible for the second line of the Paschen series (in black).

RESEARCH

The wavelengths for hydrogen-like line spectra are given by equation 38.2:

$$\frac{1}{\lambda} = R_{\mathrm{H}}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right), \quad \text{with } n_1 < n_2.$$

For the Rydberg constant, R_{H}, we had correctly obtained from the Bohr model

$$R_{\mathrm{H}} = \frac{\mu k^2 e^4}{4\pi c\hbar^3},$$

where μ is the reduced mass of the electron (which for this lithium ion is even closer to the exact electron mass than in the hydrogen atom, where it deviated by only 1 part in 2000 from the real value).

In this case, we need to replace ke^2 by $3ke^2$ to obtain the Rydberg constant for the doubly ionized lithium ion. It is 9 times bigger $\left(\left(3ke^2\right)^2 = 9\left(ke^2\right)^2 = 9k^2e^4\right)$ than the value of $R_{\mathrm{H}} = 1.097373 \cdot 10^7\ \mathrm{m}^{-1}$ for the hydrogen atom.

Finally, from Figure 38.7, we see that $n_1 = 3$ for the Paschen series and that the second line in that series must have $n_2 = 5$.

SIMPLIFY

Inserting $9R_{\mathrm{H}}$ instead of R_{H} and $n_1 = 3$ and $n_2 = 5$ into the formula for the wavelengths of the spectral lines, we obtain

$$\frac{1}{\lambda} = 9R_{\mathrm{H}}\left(\frac{1}{9} - \frac{1}{25}\right)$$

or

$$\lambda = \left(9R_{\mathrm{H}}\left(\frac{1}{9} - \frac{1}{25}\right)\right)^{-1}.$$

CALCULATE

Now it is time to put in the numbers:

$$\lambda = \left(9\left(1.097373 \cdot 10^7\ \mathrm{m}^{-1}\right)\left(\frac{1}{9} - \frac{1}{25}\right)\right)^{-1} = 1.423855 \cdot 10^{-7}\ \mathrm{m}.$$

ROUND

Within the assumptions stated, our result is exact in the sense that we used only the measured value of the Rydberg constant and integer values for the quantum numbers. However, the reduced mass of the electron is not exactly the same for the doubly ionized lithium ion as it is for the hydrogen atom, so we have a deviation on the order of 1 part in 2000, and it is prudent to round our result to three or at most four digits. Our final answer is thus

$$\lambda = 1.424 \cdot 10^{-7}\ \mathrm{m} = 142.4\ \mathrm{nm}.$$

DOUBLE-CHECK

Figure 38.4 shows that the Paschen lines in the hydrogen spectrum start at 820 nm. The second line in that series thus must have a wavelength greater than 820 nm. From our research above, it is clear that the wavelength for the second line in the Paschen series for the lithium ion should be smaller by a factor of 9 than this value, which it is. So we have additional confidence that our result is realistic.

38.3 Hydrogen Electron Wave Function

To improve on the Bohr model of the hydrogen atom, we have to return to what we learned about quantum mechanics in Chapter 37 and solve the Schrödinger equation for the electron in a Coulomb potential. To find the bound states of the electron, we need to solve the time-independent Schrödinger equation and find the energy eigenvalues, E_n. We hope our solution will resemble equation 38.7, $E_n = -13.6/n^2\ \text{eV}$, because this prediction of the Bohr model was found to be in agreement with experimental data.

A word of caution before we start on this task: Part of the mathematics involved in solving this problem is tedious and perhaps as advanced as any we will present. This is the bad news. The good news is that this problem is very instructive, providing a glimpse of many deep features of quantum mechanics and of ways to illuminate them. The math will not be worked out in all its details, and sometimes the outcome of a calculation will simply be stated. Do not become discouraged as we study this essential quantum system. It will not only help you understand the hydrogen atom, but also give insight into the entire periodic table of the elements.

The potential in the Schrödinger equation is the Coulomb potential, $U\left(\vec{r}\right) = -ke^2/r$. Note that this potential depends only on the radial distance to the origin (where the nucleus is located), and not on the angular direction of the electron relative to the nucleus. The hydrogen atom is an object in the real world and thus exists in three-dimensional space. According to Chapter 37, the Schrödinger equation in three-dimensional space must be written as

$$-\frac{\hbar^2}{2\mu}\frac{\partial^2\psi}{\partial x^2} - \frac{\hbar^2}{2\mu}\frac{\partial^2\psi}{\partial y^2} - \frac{\hbar^2}{2\mu}\frac{\partial^2\psi}{\partial z^2} + U\psi = -\frac{\hbar^2}{2\mu}\nabla^2\psi + U\psi = E\psi.$$

The Laplacian operator, ∇^2, in Cartesian coordinates is $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$. This operator appeared in Chapter 37 in the section on antimatter. It is a seemingly straightforward generalization of the second derivative d^2/dx^2, which appears in the one-dimensional Schrödinger equation.

Now we need to choose a coordinate system. The potential energy term U depends only on the radial coordinate r, so it is advantageous to use spherical coordinates, r, θ, ϕ, as shown in Figure 38.8. Then the Schrödinger equation reads

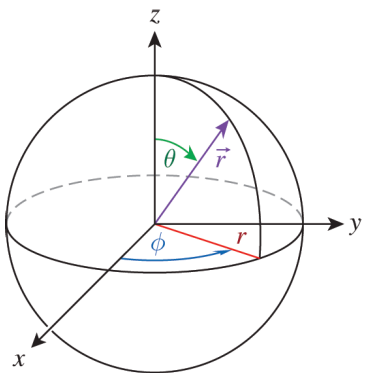

FIGURE 38.8 Definition of the spherical coordinates.

$$-\frac{\hbar^2}{2\mu}\nabla^2\psi(r,\theta,\phi) - k\frac{e^2}{r}\psi(r,\theta,\phi) = E\psi(r,\theta,\phi), \tag{38.9}$$

where the Coulomb potential is used for the potential U.

With spherical coordinates, however, there is a price to pay: The Laplacian operator looks much more complicated:

$$\nabla^2\psi = \frac{1}{r}\frac{\partial^2}{\partial r^2}(r\psi) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}\psi\right) + \frac{1}{r^2\sin^2\theta}\frac{\partial^2}{\partial\phi^2}\psi. \tag{38.10}$$

Is this worth the effort? The answer is certainly yes if the wave function does not depend on the angular coordinates but only on the radial one. Therefore, we try this method first and look for spherically symmetric solutions.

Spherically Symmetric Solutions

Motivated by the Bohr model's success, we first investigate whether there are spherically symmetric solutions. If these exist, they can only be a function of the radial coordinate, *r*. Let's work with this assumption and see where it leads us. The Laplacian operator simplifies greatly because the derivatives with respect to θ and ϕ vanish, leaving us with

$$\nabla^2\psi(r) = \frac{1}{r}\frac{\partial^2}{\partial r^2}(r\psi(r)) = \frac{1}{r}\frac{d^2}{dr^2}(r\psi(r)).$$

Notice that we replaced the partial derivative by the conventional derivative, because the wave function in this case depends on only one variable, *r*. Thus, for the Schrödinger equation, we now have

$$-\frac{\hbar^2}{2\mu}\frac{1}{r}\frac{d^2}{dr^2}(r\psi(r)) - k\frac{e^2}{r}\psi(r) = E\psi(r). \qquad \textbf{(38.11)}$$

The solution of this differential equation is tedious, but the result is very interesting. We find that, similar to the particle in a box or the harmonic oscillator, the energy can assume only certain values of E_n, given by

$$E_n = -\frac{\mu k^2 e^4}{2\hbar^2}\frac{1}{n^2} \quad (for\, n = 1, 2, 3, \ldots).$$

This is exactly the form of the energy eigenvalues we obtained for the Bohr model (equation 38.7) with $E_0 = \mu k^2 e^4/2\hbar^2 = 13.6\,\text{eV}$, an energy unit sometimes called a *rydberg*.

The wave functions that correspond to the lowest values of the quantum number *n* are

$$\begin{aligned}
\psi_1(r) &= A_1 e^{-r/a_0} \\
\psi_2(r) &= A_2\left(1 - \frac{r}{2a_0}\right)e^{-r/2a_0} \\
\psi_3(r) &= A_3\left(1 - \frac{2r}{3a_0} + \frac{2r^2}{27a_0^2}\right)e^{-r/3a_0},
\end{aligned} \qquad \textbf{(38.12)}$$

where the subscript on ψ represents the corresponding value of *n*. Here A_1, A_2, and A_3 are normalization constants that can be determined from the condition that the integral of the absolute square of the wave function is 1:

$$\int |\psi_n(r)|^2 d^3r = \int_0^\infty 4\pi r^2 |\psi_n(r)|^2 dr = 1.$$

Figure 38.9a shows these solutions, and Figure 38.9b shows their probability densities, weighted with the factor r^2 to account for the effect of the volume element increasing with rising radius. The solutions for the three lowest values of the radial quantum number *n* are shown as a function of the radial coordinate divided by the Bohr

radius, a_0. Vertical lines indicate the locations of the semiclassical Bohr orbits that correspond to these values of n. For $n = 1$, the maximum of the probability density for the wave function corresponds to the Bohr orbit, whereas this is not the case for $n > 1$.

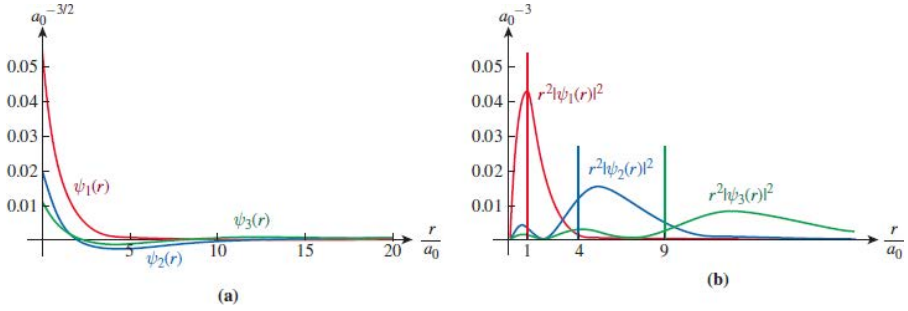

FIGURE 38.9 Spherically symmetric solutions to the Schrödinger equation for the three lowest values of the radial quantum number for the hydrogen atom. (a) Wave functions; (b) weighted probability densities. The vertical lines in (b) represent the Bohr model's predictions.

EXAMPLE 38.2 Normalization of the Hydrogen Wave Function

PROBLEM

The hydrogen wave function corresponding to $n = 1$, has the form given in equation 38.12: $\psi_1(r) = A_1 e^{-r/a_0}$. Using the condition that the integral of the absolute square of the wave function is 1, determine A_1.

SOLUTION

The condition that the integral of the absolute square of the wave function is 1 gives us

$$\int |\psi_n(r)|^2 d^3r = \int_0^\infty 4\pi r^2 |\psi_n(r)|^2 dr = 1.$$

Putting in the given wave function leads to

$$\int_0^\infty 4\pi r^2 \left| A_1 e^{-r/a_0} \right|^2 dr = 4\pi A_1^2 \int_0^\infty r^2 e^{-2r/a_0}\, dr.$$

The definite integral can be expressed as $\int_0^\infty x^2 e^{-cx}\, dx = 2/c^3$. Taking $c = 2/a_0$, we get

$$4\pi A_1^2 \int_0^\infty r^2 e^{-2r/a_0}\, dr = 4\pi A_1^2 \left[2\left(\frac{a_0}{2}\right)^3 \right] = \pi a_0^3 A_1^2 = 1.$$

We can solve this equation for A_1:

$$A_1 = \frac{1}{\sqrt{\pi a_0^3}} = \frac{1}{\sqrt{\pi} a_0^{3/2}}.$$

Thus, the hydrogen wave function corresponding to $n = 1$ is

$$\psi_1(r) = \frac{1}{\sqrt{\pi} a_0^{3/2}} e^{-r/a_0}.$$

Angular Momentum

Chapter 37 introduced quantum operators for the momentum and kinetic energy, where the classical value of the momentum is replaced by a constant times the derivative in coordinate space, $-i\hbar d/dx$. In three-dimensional space, the momentum operator is a vector, for which each individual component is a partial derivative in its respective direction. In Cartesian coordinates, this operator is written as

$$\widehat{\mathbf{p}}\psi(x,y,z) = -i\hbar\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right)\psi(x,y,z) \equiv -i\hbar\overrightarrow{\nabla}\psi(x,y,z).$$

This derivative operator is called the *gradient*, for which we use the common shorthand notation, $\overrightarrow{\nabla}$. In spherical coordinates, the gradient is given by

$$\overrightarrow{\nabla}\psi(r,\theta,\phi) = \left(\frac{\partial}{\partial r}, \frac{1}{r}, \frac{\partial}{\partial \theta}, \frac{1}{r\sin\theta}\frac{\partial}{\partial \phi}\right)\psi(r,\theta,\phi).$$

Then the equation for the momentum operator becomes

$$\widehat{\mathbf{p}}\psi(x,y,z) = -i\hbar\overrightarrow{\nabla}\psi(r,\theta,\phi) = -i\hbar\left(\frac{\partial}{\partial r}, \frac{1}{r}\frac{\partial}{\partial \theta}, \frac{1}{r\sin\theta}\frac{\partial}{\partial \phi}\right)\psi(r,\theta,\phi).$$

Now we can write the angular momentum operator by simply replacing the momentum vector by the gradient operator:

$$\widehat{\mathbf{L}}\psi = -i\hbar\overrightarrow{r}\times\overrightarrow{\nabla}\psi. \tag{38.13}$$

(Remember, classically the angular momentum is $\overrightarrow{L} = \overrightarrow{r}\times\overrightarrow{p}$.) According to the rules for quantum measurements, we can now calculate the expectation value of the angular momentum operator:

$$\langle L\rangle = \int \psi^*\widehat{\mathbf{L}}\psi d^3r = -i\hbar\int \psi^*\overrightarrow{r}\times\overrightarrow{\nabla}\psi d^3r. \tag{38.14}$$

It is particularly interesting to look at the outcome of this measurement of the angular momentum for the case of spherically symmetric wave functions, that is, wave functions that depend only on the radial coordinate r, and not on any angular coordinate, θ or ϕ. Then we obtain

$$\langle L\rangle = \int \psi^*(r)\hat{L}\psi(r)d^3r = -i\hbar\int \psi^*(r)\overrightarrow{r}\times\overrightarrow{\nabla}\psi(r)d^3r = 0. \tag{38.15}$$

DERIVATION 38.1 Angular Momentum Expectation Value

To show that equation 38.15 is true, we use the gradient operator in spherical coordinates. Applying it to the spherically symmetric wave function results in

$$\vec{\nabla}\psi(r) = \left(\frac{\partial}{\partial r}, \frac{1}{r}, \frac{\partial}{\partial \theta}, \frac{1}{r\sin\theta}\frac{\partial}{\partial \phi}\right)\psi(r) = \hat{r}\frac{\partial}{\partial r}\psi(r),$$

because the partial derivatives in the θ and ϕ directions are both zero when the wave function does not depend on either of these angular coordinates. We have again used the notation $\hat{r}$ for the unit vector in the radial direction. In terms of this unit vector, we can write the vector $\vec{r}$ as $\vec{r} = r\hat{r}$. Now the vector product in the integral of equation 38.15 simplifies to

$$-i\hbar\int \psi^*(r)\vec{r}\times\vec{\nabla}\psi(r)d^3r = -i\hbar\int \psi^*(r)r\hat{r}\times\hat{r}\frac{\partial}{\partial r}\psi(r)d^3r.$$

For any vector, the vector product with itself has the value zero. Thus, $\hat{r}\times\hat{r} = 0$, and the entire integral has the value zero.

This is a very general result that holds for any spherically symmetric wave function: A wave function that does not depend on the angular coordinate θ or ϕ must have an expectation value of zero for the angular momentum.

The spherically symmetric solutions for the hydrogen atom, $\psi_n(r)$, obtained in the previous subsection, depend only on the radius, so all have angular momentum zero. It is not permissible to interpret the quantum number n as one of angular momentum, as the Bohr model did, despite the fact that the energy eigenvalues of the quantum mechanical spherically symmetric solutions reproduce exactly the discrete energy values of the Bohr model. This fact implies that *the Bohr model is fatally flawed:* We cannot start with a classical particle in orbit around a central nucleus, demand quantization of angular momentum, and then obtain consistent results. Despite its astounding success in explaining the hydrogen line spectra in great detail and to great precision, the Bohr model is wrong, and its success was accidental.

Full Solution

Does the Schrödinger equation for hydrogen have solutions that are not spherically symmetric and that have nonzero angular momentum? The answer is yes. We will only sketch out how to get to these solutions. Typically, the mathematics needed to arrive at them is lengthy and complicated. However, it is also instructive and something to look forward to in a more advanced course, where this topic will be covered in greater detail. In the following discussion, we introduce many different functions. Keep in mind that these are not meant to be memorized. The goal here is for you to understand the general features of the solutions, not their exact form. Even the most seasoned professionals in the field do not know all the functions by heart and look them up in tables when they are needed.

Separation of Variables

We start with a technique we used successfully in finding solutions for the time-dependent Schrödinger equation in one spatial dimension: the separation of variables. To achieve this, we assume that the full wave function can be written as a product of three functions, each of which is a function of only one variable:

$$\psi(r,\theta,\phi) = f(r)g(\theta)h(\phi). \tag{38.16}$$

We insert this trial solution into the Schrödinger equation (38.9) to find

$$-\frac{\hbar^2}{2\mu}\nabla^2(f(r)g(\theta)h(\phi)) - k\frac{e^2}{r}(f(r)g(\theta)h(\phi)) = E(f(r)g(\theta)h(\phi)).$$

Now we evaluate the action of the Laplacian operator (in spherical coordinates, equation 38.10) on this product of functions:

$$\begin{aligned}
\nabla^2(f(r)g(\theta)h(\phi)) &= \frac{1}{r}\frac{\partial^2}{\partial r^2}(r(f(r)g(\theta)h(\phi))) \\
&\quad + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}(f(r)g(\theta)h(\phi))\right) \\
&\quad + \frac{1}{r^2\sin^2\theta}\frac{\partial^2}{\partial\phi^2}(f(r)g(\theta)h(\phi)) \\
&= g(\theta)h(\phi)\frac{1}{r}\frac{\partial^2}{\partial r^2}(rf(r)) \\
&\quad + \frac{f(r)h(\phi)}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}g(\theta)\right) \\
&\quad + \frac{f(r)g(\theta)}{r^2\sin^2\theta}\frac{\partial^2}{\partial\phi^2}h(\phi).
\end{aligned}$$

Inserting this result into the Schrödinger equation and multiplying both sides of the equation by the product $-2\mu r^2/\hbar^2 f(r)g(\theta)h(\phi)$, we arrive at

$$\begin{aligned}
&\frac{r}{f(r)}\frac{\partial^2}{\partial r^2}(rf(r)) + \frac{1}{g(\theta)\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}g(\theta)\right) \\
&+\frac{1}{h(\phi)\sin^2\theta}\frac{\partial^2}{\partial\phi^2}h(\phi) + \frac{2\mu r^2}{\hbar^2}\left(E + k\frac{e^2}{r}\right) = 0.
\end{aligned}$$

Now we can see that some terms depend only on the radial variable *r*, and not on the angular variables θ and *ø*, while other terms depend on θ and/or *ø*, but not on *r*. We rearrange the preceding equation to get all *r*-dependent terms on the left-hand side and all others on the right-hand side:

$$\begin{aligned}
&\frac{r}{f(r)}\frac{\partial^2}{\partial r^2}(rf(r)) + \frac{2\mu r^2}{\hbar^2}\left(E + k\frac{e^2}{r}\right) = \\
&-\frac{1}{g(\theta)\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}g(\theta)\right) - \frac{1}{h(\phi)\sin^2\theta}\frac{\partial^2}{\partial\phi^2}h(\phi).
\end{aligned} \tag{38.17}$$

$$g(\theta)\sin\theta\ \partial\theta\ \left[\cdots\ \partial\theta\ \cdots\right] \qquad h(\phi)\sin^2\theta\ \partial\phi^2\ \cdots$$

This equation can be true only if each side is equal to the same constant. We make a choice that may look strange at first and call this constant $\ell(\ell+1)$.

Radial Part

Using the integration constant $\ell(\ell+1)$ gives us the radial equation (left-hand side of equation 38.17):

$$\frac{r}{f(r)}\frac{d^2}{dr^2}(rf(r)) + \frac{2\mu r^2}{\hbar^2}\left(E + k\frac{e^2}{r}\right) = \ell(\ell+1).$$

(Again, we replaced the partial derivatives with conventional ones because the function f depends on only one variable.) If we multiply this equation by $-f(r)\hbar^2/2\mu r^2$, it has the form

$$-\frac{\hbar^2}{2\mu}\frac{1}{r}\frac{d^2}{dr^2}(rf(r)) - k\frac{e^2}{r}f(r) + \frac{\ell(\ell+1)\hbar^2}{2\mu r^2}f(r) = Ef(r). \qquad \textbf{(38.18)}$$

Comparing this equation with the Schrödinger equation for the spherically symmetric solution (equation 38.11), we see that the only difference is the term $\ell(\ell+1)\hbar^2/2\mu r^2$, which plays the role of an additional potential, in addition to the Coulomb potential. (For $\ell = 0$, we recover the spherically symmetric solution.) What is this additional potential term?

An argument from the orbital motion of a classical particle in a central potential may help. To work out our classical argument, let's start with energy conservation, $\frac{1}{2}\mu v^2 + U(r) = E$. (Remember, this is the classical equivalent of the Schrödinger equation.) Now we can split the velocity into radial and tangential parts and get $\frac{1}{2}\mu v^2 = \frac{1}{2}\mu v_r^2 + \frac{1}{2}\mu v_t^2 = \frac{1}{2}\mu v_r^2 + \frac{1}{2}\mu(\omega r)^2$. Further note that the angular momentum for the case of a point particle in circular motion is $L = \mu r v_t = \mu r^2\omega$. This definition also holds for all motion in a central potential, not just circular motion, and the angular momentum is a conserved quantity. Thus, we can write $\frac{1}{2}\mu(\omega r)^2 = \frac{1}{2}L^2/\mu r^2$. Therefore, our classical equation for energy conservation in this case is $\frac{1}{2}\mu v_r^2 + U(r) + L^2/2\mu r^2 = E$.

The $\ell(\ell+1)\hbar^2/2\mu r^2$ term now seems plausible as a term originating from conservation of angular momentum, if we are allowed to substitute the quantum mechanical $\ell(\ell+1)\hbar^2$ for the classical L^2. Later we will see that these solution functions are also the eigenfunctions for the quantum mechanical operator corresponding to L^2 with eigenvalue $\ell(\ell+1)\hbar^2$; so this substitution works out just as advertised. Now you can begin to understand the seemingly arbitrary choice for the integration constant, $\ell(\ell+1)$. The $\ell(\ell+1)\hbar^2/2\mu r^2$ term represents the quantum mechanical angular momentum barrier in the rotating system, and we will soon see that ℓ is an integer. We say "barrier" because this term is positive and increases as r decreases, just like a potential energy barrier. Figure 38.10 shows the effective potential from equation 38.18 for various values of ℓ.

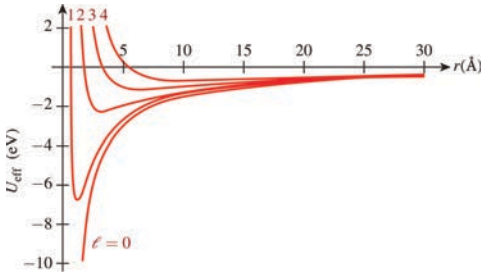

FIGURE 38.10 Effective potential for (from bottom to top) angular momentum quantum numbers $\ell = 0, 1, 2, 3,$ and 4.

What are the solutions to the differential equation for the radial function, equation 38.18? In general, they are products of exponential functions and polynomials. For very large *r,* the exponential function dominates the asymptotic behavior of the solutions. The solutions depend on two quantum numbers. First is the quantum number *n,* which was present in the spherically symmetric solutions presented earlier. Second is the quantum number ℓ, just introduced for the separation of variables, which we motivated as the quantum number of angular momentum. (The next section will give further evidence for this assignment.) For the sake of completeness, we write out the solutions for the radial functions, but you are not expected to memorize them:

$$f_{n\ell}(r) = \sqrt{\frac{4(n-\ell-1)!}{a_0^3 n^4 (n+1)!}} e^{-r/na_0} \left(\frac{2r}{na_0}\right)^{\ell} L_{n-\ell-1}^{2\ell+1}\left(\frac{2r}{na_0}\right). \qquad \textbf{(38.19)}$$

These solutions exist only for integers $n > \ell$ and $\ell \geq 0$. Therefore, for a given value of *n,* the quantum number ℓ can have the values

$$0 \leq \ell \leq n - 1.$$

The factor $L_{n-\ell-1}^{2\ell+1}(2r/na_0)$ in equation 38.19 is an associated Laguerre polynomial. These polynomials have been tabulated in reference books, where you can look them up. Their exact form is not important here, but we note the following general considerations. The product $(2r/na_0)^{\ell} L_{n-\ell-1}^{2\ell+1}(2r/na_0)$ is a polynomial of rank $n - 1$ for any value of ℓ. This polynomial has $n - \ell - 1$ positive roots and ℓ roots at $r = 0$. An example for $n = 3$ is shown in Figure 38.11, with the positive roots of the three possible polynomials indicated by the colored arrows.

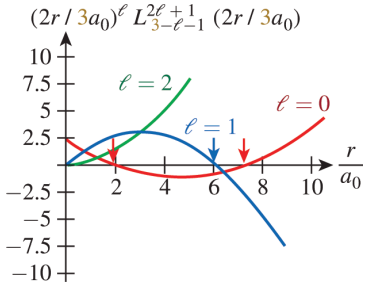

FIGURE 38.11 Polynomial terms in the radial wave function for $n = 3$.

Instead of examining equation 38.19 further in abstract terms, it is perhaps more instructive to write the radial solutions for the lowest values of n and ℓ:

$$
\begin{aligned}
f_{10}(r) &= 2a_0^{-3/2}e^{-r/a_0} \\
f_{20}(r) &= \frac{1}{\sqrt{2}}a_0^{-3/2}\left(1-\frac{r}{2a_0}\right)e^{-r/2a_0} \\
f_{21}(r) &= \frac{1}{2\sqrt{6}}a_0^{-3/2}\left(\frac{r}{a_0}\right)e^{-r/2a_0} \\
f_{30}(r) &= \frac{2}{3\sqrt{3}}a_0^{-3/2}\left(1-\frac{2r}{3a_0}+\frac{2r^2}{27a_0^2}\right)e^{-r/3a_0} \\
f_{31}(r) &= \frac{8}{27\sqrt{6}}a_0^{-3/2}\left(\frac{r}{a_0}-\frac{r^2}{6a_0^2}\right)e^{-r/3a_0} \\
f_{32}(r) &= \frac{4}{81\sqrt{30}}a_0^{-3/2}\left(\frac{r^2}{a_0^2}\right)e^{-r/3a_0}.
\end{aligned}
$$

Comparing these solutions to the spherically symmetric ones (equation 38.12) shows that for each value of n, the solutions with $\ell = 0$ correspond to the spherically symmetric solutions.

Because the lowest values of n correspond to the lowest values of the energy, the radial functions listed here are overwhelmingly the most important for the hydrogen atom.

If we plot the radial functions for the lowest allowed values of the quantum numbers n and ℓ, an interesting picture emerges. Figure 38.12a shows the six wave functions listed above. It is important to note that the solutions for a radial quantum number n are polynomials of rank $n-1$, multiplied by an exponentially decreasing term that assures that the wave functions approach zero for very large values of the radius r. All wave functions with $\ell > 0$ have a value of 0 at $r = 0$; only those with $\ell = 0$ assume a finite nonzero value at $r = 0$. (In the figure, it may appear that the $\ell = 0$ solutions diverge as they approach $r = 0$, but this is misleading. If the scale were expanded, we would see them turn over, because the exponential function has a value of 1 at $r = 0$.)

Figure 38.12b shows the probability of finding an electron in a state with quantum numbers n and ℓ at a distance r from the nucleus of the hydrogen atom. The wave function f_{10}— the only wave function for $n = 1$—is red, and the two possible wave

functions for $n = 2$ (f_{20} and f_{21}) are blue. The three possible wave functions for $n = 3$, which are f_{30}, f_{31}, and f_{32}, are shown in green. For the group of wave functions with a given value of n, all weighted probability densities plotted in Figure 38.12b peak at a similar distance from the origin. They form a **shell.** This appearance of shells is a universal phenomenon in atomic and nuclear physics and is a unique quantum effect. We will return to the concept of shells repeatedly in our discussions of these subjects.

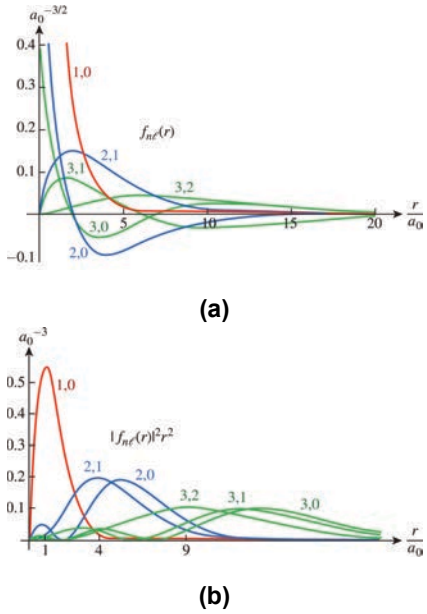

FIGURE 38.12 (a) Radial wave functions for the lowest values of the quantum numbers n and ℓ; (b) corresponding weighted probability densities.

An interesting side note: The radial wave functions $f_{n,n-1}$ all peak at values of r that correspond to the radii predicted by the Bohr model for the corresponding quantum number n.

Angular Part

Let's return to the Schrödinger equation in spherical coordinates (equation 38.17). If the left-hand side is equal to $\ell(\ell+1)$, so is the right-hand side:

$$\ell(\ell+1) = -\frac{1}{g(\theta)\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}g(\theta)\right) - \frac{1}{h(\phi)\sin^2\theta}\frac{\partial^2}{\partial\phi^2}h(\phi). \quad \textbf{(38.20)}$$

This equation is still a function of the two variables θ and $\boldsymbol{\phi}$. We can rearrange the terms and obtain an equation in which all θ-dependent terms are on the left-hand side and all $\boldsymbol{\phi}$-dependent terms are on the right-hand side. This is accomplished by multiplying both sides of equation 38.20 by $\sin^2\theta$ and then moving the first term on the right to the left:

$$\ell(\ell+1)\sin^2\theta + \frac{\sin\theta}{g(\theta)}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}g(\theta)\right) = -\frac{1}{h(\phi)}\frac{\partial^2}{\partial\phi^2}h(\phi).$$

Again, we have separated the variables, and for this equation to be true, both sides need to be equal to the same constant. Let us call this constant m^2. (Remember, we are using μ for the mass of the electron, not m.)

The two resulting ordinary differential equations for the angular variables are

$$\frac{d^2}{d\phi^2}h(\phi) = -m^2h(\phi) \quad \textbf{(38.21)}$$

$$\ell(\ell+1)\sin^2\theta + \frac{\sin\theta}{g(\theta)}\frac{d}{d\theta}\left(\sin\theta\frac{d}{d\theta}g(\theta)\right) = m^2. \quad \textbf{(38.22)}$$

Note that the form of differential equation 38.21 is exactly the same as that for a simple harmonic oscillator, which we studied extensively in Chapter 14. Perhaps you can therefore guess the solution to equation 38.21 right away: It is a linear combination of $\sin(m\phi)$ and $\cos(m\phi)$. Alternatively, using the conventional complex notation, it is

$$h(\phi) = Ae^{im\phi}. \quad \textbf{(38.23)}$$

Here A is a normalization constant, which we can deal with later when we consider the overall normalization of the wave function. What is more important is that the same wave function must be obtained when 2π is added to the angle ϕ, because this addition corresponds to one complete 360° rotation in the xy-plane. This implies that

$$e^{im\phi} = e^{im(\phi+2\pi)} \Rightarrow e^{2\pi im} = 1 \Rightarrow m = 0, \pm1, \pm2, \ldots.$$

Thus, we have found that our integration constant m must be an integer.

The solution to equation 38.22 for θ is not so easy to obtain, so we simply state it here:

$$g(\theta) = BP_\ell^m(\cos\theta) = B(-1)^{|m|}\sin^{|m|}\theta\left(\frac{d}{d(\cos\theta)}\right)^{|m|} P_\ell(\cos\theta). \quad \textbf{(38.24)}$$

Here B is another normalization constant. Just like the constant A, we ignore it for now. The functions P_ℓ^m are called *associated Legendre functions*, and the functions P_ℓ are *Legendre polynomials*:

$$P_\ell(x) \equiv \frac{1}{2^\ell \ell!}\left(\frac{d}{dx}\right)^\ell (x^2-1)^\ell \quad \text{and} \quad P_\ell^m(x) = (-1)^m(1-x^2)^{m/2}\left(\frac{d}{dx}\right)^m P_\ell(x)$$

for integer nonnegative values of ℓ. The first few Legendre polynomials are

$$\begin{aligned}
P_0(x) &= 1 \\
P_1(x) &= \tfrac{1}{2}\frac{d}{dx}(x^2-1) = x \\
P_2(x) &= \tfrac{1}{8}\frac{d^2}{dx^2}(x^2-1)^2 = \tfrac{1}{2}(3x^2-1) \\
P_3(x) &= \tfrac{1}{48}\frac{d^3}{dx^3}(x^2-1)^3 = \tfrac{1}{2}(5x^3-3x) \\
P_4(x) &= \tfrac{1}{384}\frac{d^4}{dx^4}(x^2-1)^4 = \tfrac{1}{8}(35x^4-30x^2+3) \\
P_5(x) &= \tfrac{1}{3840}\frac{d^5}{dx^5}(x^2-1)^5 = \tfrac{1}{8}(63x^5-70x^3+15x).
\end{aligned}$$

These are shown in Figure 38.13.

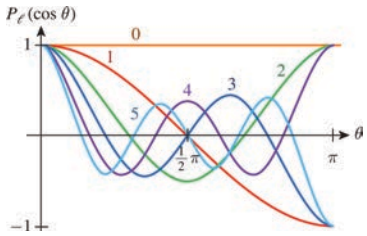

FIGURE 38.13 Legendre polynomials for $\ell = 0, 1, 2, 3, 4,$ and 5.

You can see that a Legendre polynomial P_ℓ is a polynomial of rank ℓ. If you take the nth-derivative of a polynomial of rank ℓ with $n > \ell$, you obtain zero. This means that an upper limit exists for the integer $|m|$:

$$|m| \leq \ell \Rightarrow -\ell \leq m \leq \ell.$$

Therefore, for any value of ℓ, there are $2\ell + 1$ possible values of m. The associated Legendre functions $P_\ell^m(\cos\theta)$ with the lowest values of ℓ are

	$\boxed{m=0}$	$\boxed{m=1}$	$\boxed{m=2}$	$\boxed{m=3}$
$\boxed{\ell=0}$	1			
$\boxed{\ell=1}$	$\cos\theta$	$-\sin\theta$		
$\boxed{\ell=2}$	$\frac{1}{2}\left(3\cos^2\theta - 1\right)$	$-3\cos\theta\sin\theta$	$3\sin^2\theta$	
$\boxed{\ell=3}$	$\frac{1}{2}\left(5\cos^3\theta - 3\cos\theta\right)$	$-\frac{3}{2}\sin\theta\left(5\cos^2\theta - 1\right)$	$15\cos\theta\sin^2\theta$	$-15\sin^3\theta.$

The expressions for negative values of m do not have to be written separately, because only the absolute value of the quantum number m appears in the defining equation 38.24.

The products of the functions, $g(\theta)h(\phi)$, properly normalized, are called the **spherical harmonics,** Y_ℓ^m:

$$Y_\ell^m(\theta,\phi) = \sqrt{\frac{(\ell - |m|)!}{(\ell + |m|)!}\frac{(2\ell+1)}{4\pi}}P_\ell^m(\cos\theta)e^{im\phi}. \qquad \textbf{(38.25)}$$

The spherical harmonics describe the angular dependence of the electron wave functions for the hydrogen atom. They have a complex phase factor $e^{im\phi}$, but are otherwise real valued. Figure 38.14 plots the absolute values of the spherical harmonics. These absolute values are symmetric under rotation about the z-axis, but in general, for $m \neq 0$, this is not the case for the real part or for the imaginary part.

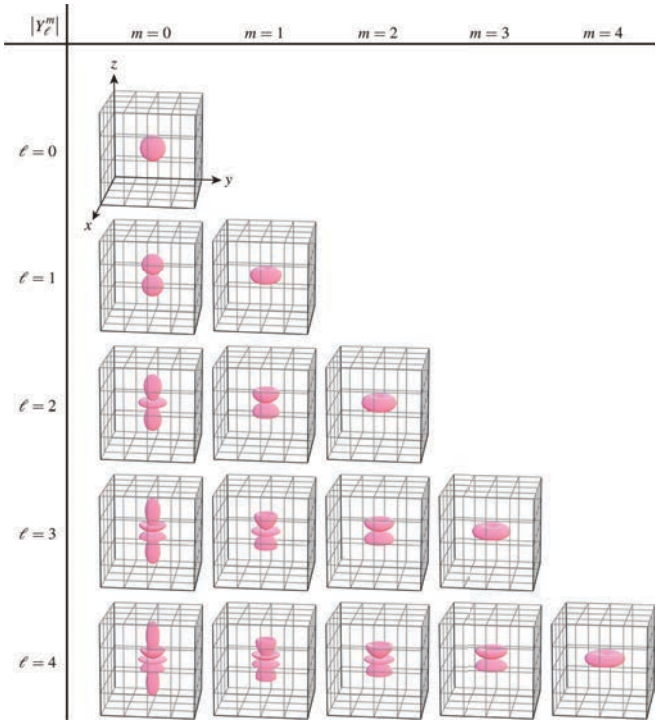

FIGURE 38.14 Absolute value of the spherical harmonics for the lowest values of the angular momentum quantum numbers. Each box extends from -1 to 1 in each Cartesian direction.

What else is special about the spherical harmonics? It can be shown (we will not do this here) that they are also eigenfunctions of the operator for the square of the angular momentum, $\widehat{\mathbf{L}}^2$, with eigenvalues $\ell(\ell+1)\hbar^2$, and of the operator for the projection of the angular momentum on the z-axis, $\widehat{\mathbf{L}}_z$, with eigenvalue $m\hbar$:

$$\widehat{\mathbf{L}}^2 Y_\ell^m(\theta,\phi) = \ell(\ell+1)\hbar^2 Y_\ell^m(\theta,\phi) \tag{38.26}$$

$$\widehat{\mathbf{L}}_z Y_\ell^m(\theta,\phi) = m\hbar Y_\ell^m(\theta,\phi). \tag{38.27}$$

Thus, the quantum number ℓ is a measure of the absolute value of the total orbital angular momentum—that is, the length of the angular momentum vector—and the quantum number m measures the length of the projection of the angular momentum vector along the z-axis.

You might now be able to guess what the operators $\widehat{\mathbf{L}}^2$ and $\widehat{\mathbf{L}}_z$ look like in spherical coordinates. They are

$$\widehat{\mathbf{L}}^2 = -\hbar^2 \frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}\right) - \hbar^2 \frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\phi^2}$$

and

$$\widehat{\mathbf{L}}_z = -i\hbar\frac{\partial}{\partial\phi}.$$

Comparing these two expressions to equations 38.20 and 38.21 shows why equations 38.26 and 38.27 must be true. The construction of the spherical harmonics as solutions to the angular part of a rotationally invariant Schrödinger equation means that they must be eigenfunctions to the operators for the square of the angular momentum and for the projection of the angular momentum on the symmetry axis.

Complete Solution

Let's collect the parts of our complete solution. We have separated the variables and constructed the solutions as products of the radial part of the wave function (equation 38.19) and the angular part (equation 38.25):

$$\psi_{n\ell m}(r,\theta,\phi) = f_{n\ell}(r)Y_{\ell m}(\theta,\phi). \tag{38.28}$$

The quantum numbers of these solutions are the **radial quantum number,** $n = 1, 2, 3, \ldots$; the **orbital angular momentum quantum number,** $\ell = 0, 1, \ldots, n-1$; and the **magnetic quantum number,** $m = -\ell, \ldots, \ell$. The energy eigenvalue corresponding to a particular eigenfunction that is a solution depends only on the radial quantum number:

$$E_n = -\frac{1}{n^2}E_0 = -\frac{1}{n^2}\frac{\mu k^2 e^4}{2\hbar^2}. \tag{38.29}$$

The solutions for a given value of the radial quantum number n all peak at a similar distance from the center, approximately given by the radius of the corresponding semiclassical Bohr orbit, $r_n = n^2 a_0 = n^2\hbar^2/\mu k e^2$. (For the wave functions with the maximum possible angular momentum quantum number, $\ell = n-1$, this is an exact statement.) Thus, the wave functions for a given radial quantum number n form a shell. The shells are sometimes (especially in chemistry) labeled with capital letters according to their radial quantum number:

	K	L	M	N	O	P	Q	$\ldots$
$n =$	1	2	3	4	5	6	7	$\ldots.$

Therefore, the lowest energy shell is the *K*-shell, and the shells with successively higher radial quantum number n follow alphabetically.

Within a given shell, all wave functions have the same energy. Traditionally, they are labeled with letters according to their orbital angular momentum quantum number:

	s	p	d	f	g	h	i	k	$\ldots$
$\ell =$	0	1	2	3	4	5	6	7	$\ldots.$

Here the first two angular momentum states receive the letters s (monopole) and p (dipole), and from $\ell = 2$ (quadrupole) on, the angular momentum states follow the alphabet successively, starting with the letter d, but skipping e and j. (Why this ordering? This is how the nomenclature was developed historically.) Thus, a $4d$ state implies that the radial quantum number is 4 and the orbital angular momentum quantum number is 2. The energies and level assignments are shown in Figure 38.15.

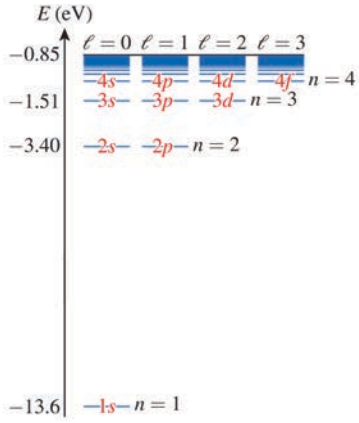

FIGURE 38.15 Wave function quantum numbers, energies, and label assignments.

We can also plot the solution wave functions. We have the choice of displaying the wave function, its real or imaginary part, or its absolute value. All wave functions with $m = 0$ are real, and we can easily plot these wave functions—for example, in slices through space. Figure 38.16 shows the wave functions $\psi_{n\ell m}$ for the lowest values of the quantum numbers n and ℓ with $m = 0$ in a slice through coordinate space, in the xz-plane with $y = 0$. Blue shades imply positive values of the wave function, and red shades indicate negative values. Yellow represents values close to zero; a scale is given on the right side. In each case, a region between $\pm 30a_0$ is shown in each direction, x and z. As you can see, all s-states ($\ell = 0$ states) appear as concentric circles in the contour plots, because they are all spherically symmetric. The states with nonzero angular momentum show beautiful patterns of alternating regions of positive and negative values.

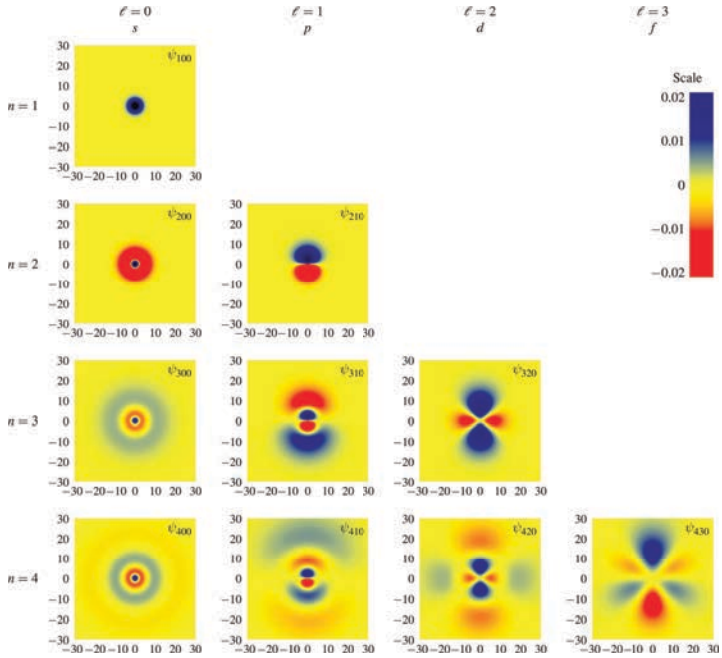

FIGURE 38.16 Hydrogen atom electron wave functions in the *xz*-plane for $y = 0, \psi_{n\ell m}(x, 0, z)$. The coordinates in the *xz*-plane are displayed in multiples of the classical Bohr radius, a_0. The scale on the right indicates how the colors in the plots represent the value of $\psi_{n\ell m}$.

We can see regularities in the patterns that emerge. As n increases, an outer shell becomes populated, while the structure of the inner shell wave function with the same angular momentum quantum number gets preserved and squeezed down, with a spherical node (yellow rings) separating it from the neighboring shells. All *p*-waves show twofold symmetries, as expected from dipolar shapes. In the same way, the *d*-waves exhibit fourfold quadrupole structure, and the *f*-waves show a characteristic sixfold symmetry.

Finally, we list the wave functions for the innermost shells—those with the lowest values for the radial quantum numbers and thus the lowest energies. In the $n = 1$ shell, there is only one possible wave function, and it is in an *s*-state:

$$\psi_{100}(r, \theta, \phi) = \frac{1}{\sqrt{\pi} a_0^{3/2}} e^{-r/a_0}. \qquad \textbf{(38.30)}$$

Self-Test Opportunity 38.3

Referring to the explicit form of the solution, sketch a plot of $\psi_{211}(r, \theta, \phi)$ similar to those in Figure 38.16.

Note that the value of the energy eigenvalue that corresponds to this wave function is the lowest possible, $E_1 = -13.6\,\text{eV}$. An electron that resides in this state cannot radiate away a photon to go to a lower energy state. Therefore, the state with this energy is the ground state of the electron in the hydrogen atom, and equation 38.30 is the ground-state wave function. You can compare equation 38.30 with the results of Example 38.2.

How many wave functions are possible in the $n = 5$ shell?

a) 9

b) 14

c) 16

d) 21

e) 25

In the $n = 2$ shell, one wave function in the s-state is possible, plus three p-waves, for a total of four wave functions, all of them corresponding to an energy eigenvalue of $E_2 = -3.40\,\text{eV}$:

$$\psi_{200}(r,\theta,\phi) = \frac{1}{2\sqrt{2\pi}a_0^{3/2}} e^{-r/2a_0}\left(1 - \frac{r}{2a_0}\right)$$

$$\psi_{210}(r,\theta,\phi) = \frac{1}{2\sqrt{2\pi}a_0^{3/2}} e^{-r/2a_0}\left(\frac{r}{2a_0}\right)\cos\theta$$

$$\psi_{21\pm1}(r,\theta,\phi) = \mp\frac{1}{4\sqrt{\pi}a_0^{3/2}} e^{-r/2a_0}\left(\frac{r}{2a_0}\right)\sin\theta e^{\pm i\phi}.$$

Self-Test Opportunity 38.4

Verify that equation 38.30 is indeed the ground-state hydrogen wave function by inserting it into the Schrödinger equation. For added difficulty, try the same exercise for one of the wave functions with $n = 2$.

In the $n = 3$ shell, there is one wave function in the s-subshell, three wave functions in the p-subshell, and five in the d-subshell, for a total of $1 + 3 + 5 = 9$ wave functions, all with energy $E_3 = -1.51\,\text{eV}$:

$$\psi_{300}(r,\theta,\phi) = \frac{1}{3\sqrt{3\pi}a_0^{3/2}} e^{-r/3a_0}\left(1 - \frac{2r}{3a_0} + \frac{2r^2}{27a_0^2}\right)$$

$$\psi_{310}(r,\theta,\phi) = \frac{2\sqrt{2}}{27\sqrt{\pi}a_0^{3/2}} e^{-r/3a_0}\left(\frac{r}{a_0} - \frac{r^2}{6a_0^2}\right)\cos\theta$$

$$\psi_{31\pm1}(r,\theta,\phi) = \mp\frac{2}{27\sqrt{\pi}a_0^{3/2}} e^{-r/3a_0}\left(\frac{r}{a_0} - \frac{r^2}{6a_0^2}\right)\sin\theta e^{\pm i\phi}$$

$$\psi_{320}(r,\theta,\phi) = \frac{1}{81\sqrt{6\pi}a_0^{3/2}} e^{-r/3a_0}\left(\frac{r^2}{a_0^2}\right)\left(3\cos^2\theta - 1\right)$$

$$\psi_{32\pm1}(r,\theta,\phi) = \mp\frac{1}{81\sqrt{\pi}a_0^{3/2}} e^{-r/3a_0}\left(\frac{r^2}{a_0^2}\right)\cos\theta\sin\theta e^{\pm i\phi}$$

$$\psi_{32\pm2}(r,\theta,\phi) = \frac{1}{162\sqrt{\pi}a_0^{3/2}} e^{-r/3a_0}\left(\frac{r^2}{a_0^2}\right)\sin^2\theta e^{\pm 2i\phi}.$$

In general, we can have $2\ell + 1$ wave functions with different m values for a given orbital angular momentum ℓ. In addition, since we can have $n - 1$ different orbital angular momentum states for a given radial quantum number *n,* the total number *N*(*n*) of possible wave functions in a given shell with radial quantum number *n* is

$$N(n) = \sum_{\ell=0}^{n-1}(2\ell + 1) = n^2. \qquad \textbf{(38.31)}$$

Does the procedure of separation of variables ensure that we have found *all* solutions? We will not prove this, but the answer is yes, because the set of solutions that we have found forms a complete basis for all functions in this space. We will not elaborate on this statement, which is covered in an advanced course on quantum physics.

We add a postscript to the discussion of the hydrogen atom. This system is surely the best-studied system in all of quantum physics, and one of the few for which an exact solution is possible. The differential equations that result, as well as their solutions, show an incredible amount of structure. It is perhaps surprising that this arguably simplest real quantum system exhibits such richness, and perhaps even more surprising that we can construct a mathematical description that captures this complexity—which is visible, for example, in the plots of Figure 38.16. The fact that the natural world arranges itself in this way and then can be captured by our mathematical constructions seems absolutely miraculous. We hope that the somewhat tedious mathematical derivations did not obscure the beauty that underlies this physical system and the theory that describes it.

38.4 Other Atoms

Now that we have a good understanding of the wave functions, energies, and possible transitions between levels for the hydrogen atom, we can ask if we can explain other atoms as well. What do we need to change in our formalism to explain other atoms? First, the charge Z of the nucleus changes. For hydrogen, $Z = 1$, but for higher values of Z, the potential needs to change to

$$U(r) = k\frac{Ze^2}{r}.$$

To be electrically neutral, an atom with Z protons must have Z electrons. These electrons will reside in the lowest energy states available to them. It is easy to see into which state the first electron can be put: It is the 1*s* state. We can generalize equation 38.29 for the hydrogen atom to see that the energy of this first electron is

$$E_1 = -\frac{\mu k^2 Z^2 e^4}{2\hbar^2}. \qquad \textbf{(38.32)}$$

We arrive at this result by simply replacing e^2 by Ze^2 in the Schrödinger equation. It is a useful exercise to examine the mathematics for the hydrogen atom and convince yourself that equation 38.32 indeed holds. (In equation 38.32, the value of μ is the reduced mass, calculated using equation 38.4 with M the mass of the nucleus.)

Where do we place the second electron? The answer to this is not so straightforward, because any given electron will interact with all other electrons of the same atom, which partially shield the charge Z of the nucleus. This problem cannot be solved with the exact analytical methods developed earlier. It needs approximation methods that are beyond the scope of this book. However, we can gain some qualitative understanding with the tools at our disposal.

The general idea of radial shells and subshells with fixed angular momentum quantum numbers, which we developed for the hydrogen atom, remains valid for other atoms. The partial screening of the Coulomb potential of the nucleus acts differently on different levels. The states with $\ell = 0$ have probability distributions that are peaked at the origin. For these states, there is a low probability that another electron lies closer to the origin, partially shielding the nuclear charge. For states with larger values of the angular momentum quantum number, however, shielding plays a more important role. This leads to the distribution of energy levels sketched in Figure 38.17. At first glance, this figure looks similar to Figure 38.15, which showed the plot for the hydrogen atom. Here, however, the energy scale is different by a factor of Z^2. The locations of energy levels in the absence of shielding are shown by the dashed blue lines, while the proper locations of the levels are indicated by the solid blue lines. For a few levels, small black arrows show the shifts. What is the main difference between Figure 38.17 and Figure 38.15? In Figure 38.17, different angular momentum quantum numbers ℓ for the same values of the main quantum number n result in different energy values, whereas they all have the same value for the hydrogen atom. This is due to the other electrons partially shielding the nuclear charge in atoms with more than one electron. If we sort the levels by increasing energy, starting with the lowest one, we find that the progression is 1*s*, 2*s*, 2*p*, 3*s*, 3*p*, 4*s*, 3*d*, 4*p*, 5*s*, 4*d*, 5*p*, 6*s*, ...

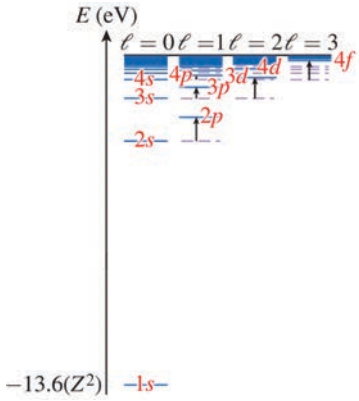

FIGURE 38.17 Energy levels in atoms with several electrons.

Electrons have a spin quantum number $\frac{1}{2}$. Thus, $2\left(\frac{1}{2}\right) + 1 = 2$ electrons can occupy each wave function with its set of fixed quantum numbers—one electron with spin up and the other with spin down. This fact is due to the Pauli Exclusion Principle. From that principle and Figure 38.17, we can determine in which order the electrons are distributed over the energy levels, as we fill each level in Figure 38.17 with two electrons successively.

Appendix D contains the ground-state electron configurations for all elements. These are written in the conventional shorthand notation with the number of electrons in a given level as a superscript right after the notation for the level. For example, fluorine $(Z = 9)$ is listed with the ground-state electron configuration of $1s^2 2s^2 2p^5$. This means that two electrons occupy each of the 1*s* and 2*s* levels, and the remaining five electrons are in the 2*p* state. The electron configuration of aluminum $(Z = 13)$ is listed as $[\text{Ne}]3s^2 3p$. This means that the occupation of the 1*s,* 2*s,* and 2*p* levels in aluminum is the same as in neon (that is, they are fully occupied) and aluminum has two additional electrons in the 3*s* state, plus one additional electron in the 3*p* state.

When all electrons of a given atom are in the lowest possible energy states available to them, the atom is in its ground state. Note that as *Z* increases, electrons sometimes fill an *s* state in a higher *n* shell rather than a state with lower *n* and higher angular momentum. (For example, see $Z = 19, 37,$ and 55.) This occurs because the angular momentum barrier has made the lower *n* state correspond to a higher electron energy.

Concept Check 38.3

Element 111 was discovered in 1994 and named roentgenium in 2004. It exists for only a few seconds before it decays. The electron configuration of roentgenium has not been determined yet. What would you predict it to be?

a) $[\text{Xe}]4f^{14}5d^{10}6s^{2}6p^{6}$

b) $[\text{Rn}]4f^{14}5d^{10}6s^{2}6p^{6}$

c) $[\text{Rn}]5f^{14}6d^{9}7s^{2}$

d) $[\text{Xe}]5f^{14}6d^{9}7s^{2}$

Just as in the hydrogen atom, electrons in other atoms can be excited into higher energy states by absorbing photons. However, the resulting line spectra are generally much more complicated than that of the hydrogen atom. It is considerably easier to answer the question of how much energy it takes to remove the least strongly bound electron from an atom. The process of removing an electron from an atom is called **ionization,** so we want to know the single-electron **ionization energy.** To lift the least strongly bound electron from its state with energy lower than zero to an energy just above zero, the ionization energy is the same as the magnitude of the energy of the level occupied by the least strongly bound electron. Figure 38.18 presents this ionization energy for every known atom (except for astatine, $Z = 85$, for which the ionization energy has not been measured yet). Can we explain the regularities of the ionization energies shown in this figure?

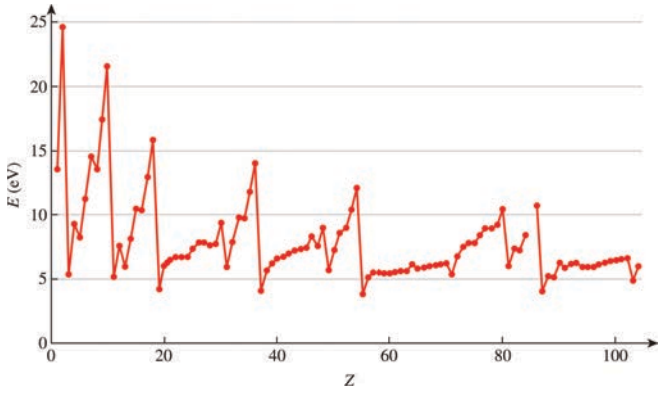

FIGURE 38.18 Single-electron ionization energies for all elements.

Let's start with hydrogen. The single electron of hydrogen resides in the 1*s* state in the ground state. Its energy is -13.6 eV, so it takes $+13.6$ eV to liberate this single electron.

Helium: Helium has two electrons, and they can both be accommodated in the 1*s* state. With $Z = 2$, the nuclear Coulomb potential is twice as strong as that of the hydrogen atom. The presence of the other electron partially screens this potential, but the second electron in the helium atom is still bound more strongly than the single electron in

hydrogen. Experimentally, we find a very large value of 24.6 eV for the ionization energy of helium, the largest value for any element. What does this mean for the chemical properties of helium? It is very difficult to remove an electron from helium and add it to any other atom to form a chemical bond. Conversely, it is also not possible to add another electron to the $n = 1$ shell in helium, because it is already completely filled with two electrons. An additional electron would have to be added to the $n = 2$ shell and thus be much more weakly bound to helium. Therefore, helium is chemically completely inert and is called a **noble gas.**

Lithium: Because $Z = 3$, lithium atoms have three electrons. The first two reside in the 1*s* state and completely fill the $n = 1$ level, just as in helium. The third electron needs to go in the next higher state, the 2*s* state. From Figure 38.12b, we see that the radial wave function of the 2*s* state is localized farther away from the center of the atom. We then expect the third electron to be less strongly bound, and indeed, we find an ionization energy of only 5.39 eV for lithium. Consequently, lithium acts as an excellent electron donor in chemical reactions.

Beryllium: This element has four protons and four electrons. The fourth electron fits into the 2*s* state, filling this angular momentum subshell completely. However, remember that for $n = 2$, we have angular momentum quantum numbers of 0 and 1. Thus, beryllium is not a closed-shell atom like helium. The ionization energy of beryllium is 9.32 eV, much higher than that of lithium, but also much lower than that of helium.

Boron through neon: Starting with boron, electrons populate the 2*p* subshell, which can hold $2(2\ell + 1) = 2(2 \cdot 1 + 1) = 6$ electrons. The first electron put into the 2*p* subshell is alone in this subshell. Again examining Figure 38.12b for guidance, we see that the 2*s* and 2*p* states have similar average distances of the radial wave functions from the center. Therefore, the ionization energy of boron $(Z = 5)$ is slightly lower than that of beryllium, but not nearly as low as that of lithium. Adding more electrons to the 2*p* subshell increases the ionization energy successively. Thus, it is increasingly difficult to remove an electron from the elements carbon, nitrogen, oxygen, and fluorine, and they are not good electron donors in chemical reactions. However, they become better electron receptors as more electrons are added to the 2*p* subshell. In particular, fluorine, with only one electron missing from an otherwise closed $n = 2$ shell, is chemically very aggressive. Neon $(Z = 10)$ completes the 2*p* subshell as well as the $n = 2$ shell. Neon thus has chemical properties very similar to those of helium—it is also chemically inert and is a noble gas. Because the radial wave functions in the $n = 2$ shell are on average farther from the atom's center than those in the $n = 1$ shell, the electrons in this shell should experience less attraction to the central nucleus and thus have lower ionization energies. Comparing the values for helium (24.6 eV) and neon (21.6 eV) confirms this expectation.

Some systematic trends in the progression of ionization energies are becoming evident. What looks like a wild and irregular zigzag curve in Figure 38.18 begins to exhibit structure. It is this structure that underlies the **periodic table of chemical elements** (Figure 38.19). In the periodic table, elements that are filling the $n = 1$ shell are in the first row, and those that are filling the $n = 2$ shell are in the second row. When an electron is added to a new shell, this corresponds to a new row in the periodic table. In each row, the electrons are added one by one, going from left to right. The elements with completely filled subshells, meaning that any additional electron would have to be placed into the next higher major shell, end up in the rightmost column; those that start a new shell are in the leftmost column.

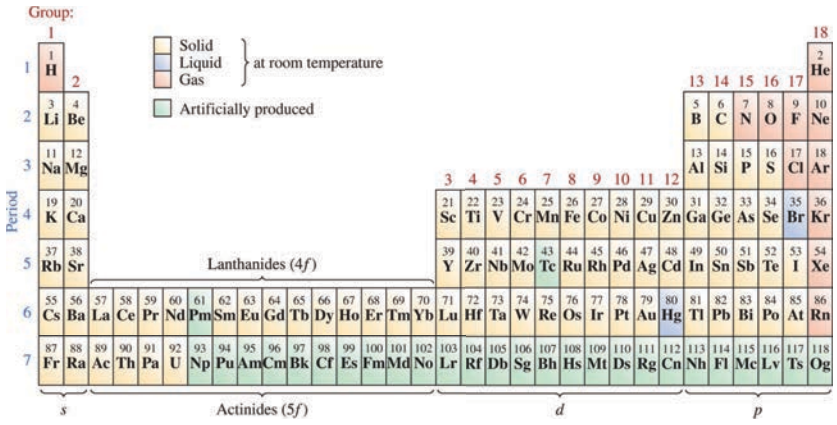

FIGURE 38.19 Periodic table of the elements.

The first two rows in the periodic table are identical to the first two major shells, but in general, a given row in the periodic table is not identical to a major shell. In the third row, the 3*d* electrons are missing. Because their energy levels are higher than those of the 4*s* electrons, the 4*s* electrons are added before them. Because the 4*s* electrons start a new row, the elements scandium through zinc, in which electrons fill the 3*d* subshell, are members of the fourth row of the periodic table, not the third.

Elements in a given column have a similar electron configuration in their outermost shell. The completely filled inner shells have very little influence on an atom's interactions with other atoms or photons. The electrons in the outermost shells of atoms, called the **valence electrons,** primarily determine chemical behavior. Therefore, elements in a given column are chemically similar in many ways.

Note that the lowest row in Figure 38.19 consists mostly of artificially produced atoms. Atoms with atomic numbers larger than 92 (uranium) are not stable and thus not found in nature. They can be created in the lab and exist for some time before they decay. As a general rule of thumb, the higher the atomic number is, the shorter the time the artificially produced atom exists before it decays. Elements 113 (Nihonium), 115 (Moscovium), 116 (Livermorium), 117 (Tennessine), and 118 (Oganesson) were discovered only in the first decade of the 21st century, and each exists for only a few milliseconds to seconds before decay. (Chapter 40 investigates the reasons for the short lifetimes of atoms with high atomic numbers.)

Using the arrangement of the elements in the periodic table, we can display the ionization energies for all elements up to $Z = 104$ in a three-dimensional representation (Figure 38.20). In general, the ionization energy decreases as n increases in the radial shells. Also, the ionization energy increases from left to right in the periodic table, as more electrons are added to a given angular momentum subshell. This trend indicates how we can gain great insights into chemistry from an understanding of the quantum mechanical wave functions of electrons in a central Coulomb potential. It seems miraculous that a general understanding of atoms with many electrons can be gained from the solution for the comparatively simple hydrogen atom with only one electron. Nevertheless, judging from experimental data on the ionization energies, the general principle works.

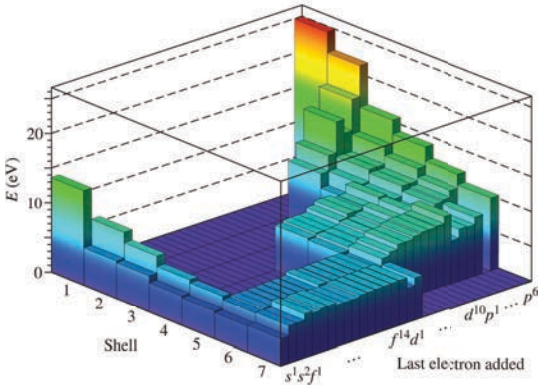

FIGURE 38.20 Ionization energies for the elements up to $Z = 104$ (rutherfordium) in the periodic table.

Note that the Pauli Exclusion Principle, which we discussed in Chapter 37, is absolutely crucial for understanding multi-electron atoms. If it were not true, all atoms would look a lot like hydrogen, and our world as we know it could not exist.

Concept Check 38.4

Element 118 was discovered in 2006 and exists for approximately 1 millisecond before it decays. Only a few atoms of this element have been produced. The ionization energy for element 118 has not been measured yet. What would you predict it to be?

a) approximately 0 eV (the atom is unstable)

b) approximately 2 eV

c) approximately 5 eV

d) approximately 10 eV

e) approximately 20 eV

EXAMPLE 38.3 Ionization Energy of the Helium Atom

As mentioned in the text, the ionization energy of helium has been measured to be 24.6 eV. A helium atom $(Z = 2)$ has two electrons in the $n = 1$ shell. These two electrons are in the ground state but interact with each other.

PROBLEM

Estimate the ionization energy of helium.

SOLUTION

The ground-state energy of electrons, if they do not interact with each other, is given by equation 38.32:

$$E_1 = -\frac{\mu k^2 z^2 e^4}{2\hbar^2}.$$

The reduced mass is closer to the mass of the electron because the mass of the helium nucleus is approximately four times more than the mass of a proton. The ground-state energy for one of the electrons in the helium atom is

$$E_1 = -\frac{\mu k^2 z^2 e^4}{2\hbar^2} = -z^2 \frac{\mu k^2 e^4}{2\hbar^2} = -z^2(13.6\text{ eV}) = -4(13.6\text{ eV}) = -54.4\text{ eV}.$$

We can estimate the energy of the interaction between the two electrons by remembering that the two electrons repel each other because they are both negatively charged. Thus, the electrons will try to be as far apart as possible. The Bohr model assumes that the electrons are in an orbit with a fixed radius, so they will be on opposite sides of the orbit, which means they are separated by its diameter. The radius of the orbit is given by equation 38.6 with e^2 replaced by Ze^2:

$$r = \frac{\hbar^2}{\mu k z e^2} = \frac{a_0}{z} = a_0/2.$$

The electric potential energy of the two electrons separated by a distance d is given in Chapter 23 as $U = ke^2/d$. This energy is positive, which means it lowers the energy required to ionize the helium atom. The electric potential energy is

$$U = \frac{ke^2}{d} = \frac{ke^2}{2(a_0/2)} = \frac{\left(8.99 \cdot 10^9\text{ N m}^2/\text{C}^2\right)\left(1.602 \cdot 10^{-19}\text{ C}\right)^2}{\left(5.295 \cdot 10^{-11}\text{ m}\right)} = 4.36 \cdot 10^{-1}$$

The difference between the ground-state energy and the electric potential energy between the two electrons is 27.2 eV, which is close to the measured ionization energy of 24.6 eV.

DISCUSSION

This analysis is oversimplified. The actual interaction between the two electrons is more complicated. However, our simple analysis gives some insight into the magnitude of the energies involved.

X-Ray Production

Arguably the discovery of X-rays by Wilhelm Conrad Röntgen (1845–1923) in 1895 was one of the events that kicked off the modern physics era. X-rays are penetrating radiation consisting of high-energy photons. Typical photon energies for diagnostic medical X-rays are between 25 keV and 140 keV, with mammograms using a typical maximum energy of 25 keV and dental X-rays using a typical maximum energy of 60 keV. X-rays for baggage screening at airports have energies up to 160 keV. All of these X-rays can be produced by X-ray tubes (Figure 38.21).

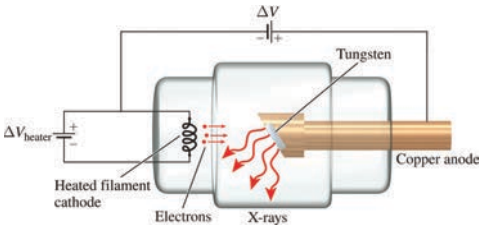

FIGURE 38.21 Schematic diagram of an X-ray tube.

How does an X-ray tube work? The physical principle is straightforward: A metal filament is heated and emits electrons from its surface. These electrons are then accelerated across an electrostatic potential difference, $\triangle V$. They hit the surface of the anode, which is typically made of metal, conventionally tungsten. As the electrons hit the surface of the metal, they can produce X-rays in two different ways. One is *bremsstrahlung* (German for "braking radiation"). As the electrons penetrate the surface of the metal, they experience a strong deceleration, which in turn causes the emission of photons. This process generates a continuous distribution of photons sketched by the dashed line in Figure 38.22. Note that this distribution terminates at a maximum energy, which is the total kinetic energy gained by the electron from the process of acceleration through the electrostatic potential, $E_{\max} = e \triangle V$, and is converted to a single photon of energy $hf_{\max} = hc/\lambda_{\min}$. The low-energy X-rays cannot penetrate through the walls of the X-ray tube. Therefore, the X-ray continuum is cut off at lower energies as well, as indicated in the figure.

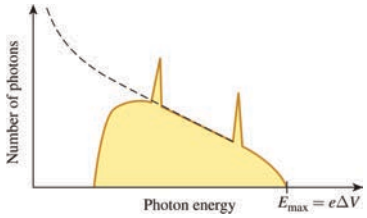

FIGURE 38.22 Sketch of an X-ray spectrum with a *bremsstrahlung* continuum plus sharp peaks due to electron transitions between atomic shells.

Concept Check 38.5

In the X-ray spectrum in Figure 38.22, suppose one of the peaks corresponds to a *K*-shell transition and the other to an *L*-shell transition. Which of the following is true?

a) The peak with the higher photon energy corresponds to the *K*-shell transition.

b) The peak with the higher photon energy corresponds to the *L*-shell transition.

c) Either peak could correspond to either transition, depending on the electrostatic potential difference applied in the X-ray tube.

d) The peaks cannot be identified, without knowing what material was used for the anode.

The other process by which X-rays are produced occurs when the accelerated electrons collide with electrons in the atoms of the anode and knock them out of their atomic shells. If a strongly bound electron from one of the inner shells gets knocked out, then an electron from the outer shells can make a transition into that inner shell and emit a photon of a fixed energy. This process is exactly the same as the one that leads to the spectral lines of hydrogen, which was discussed extensively in Section 38.2. However, the most important difference is that atoms with $Z > 1$ have electrons that are bound more strongly, and the corresponding photon energies are much larger than in the hydrogen line spectrum. The resulting discrete lines appear superimposed as spikes above the *bremsstrahlung* continuum, as sketched for two transitions in Figure 38.22. Since the photon energy is given as the difference between the energies of the initial and final states of the electron, these discrete peaks are characteristic of the anode material used.

These peaks are named according to the shell (*K* shell for $n = 1$, *L* shell for $n = 2$, ...) that the electron transitions into, with an index $(\alpha, \beta, \ldots)$ corresponding to the shell above, from which the electron transitions. A K_α X-ray corresponds to the transition from the $n = 2$ to the $n = 1$ shell.

We can even make predictions about the energies of the X-rays resulting from these transitions of electrons between atomic shells. According to equation 38.32, the energy of the innermost electron is $E_1 = -\mu k^2 Z^2 e^4 / 2\hbar^2 = -(13.6\,\text{eV})Z^2$. The transition energies should then be a factor of Z^2 bigger than those in the hydrogen atom. We can also take into account that for the outer shells the inner electrons partially screen the nuclear charge, which should result in an enhancement over the hydrogen case by a factor of $(Z - Z_{\text{screen}})^2$. The screening charge, Z_{screen}, depends only on the electron shell under consideration, not on the charge of the nucleus, *Z*. Therefore, we can predict that the X-ray energy corresponding to a particular transition in the atom should depend on the square of the nuclear charge. This means that a plot of the square root of the energy of the X-ray resulting from a particular transition should show a linear dependence on the nuclear charge. This type of plot was first produced by Henry Moseley (1887–1915) in 1913, and it contributed tremendously to convincing the scientific community of the validity of atomic models.

Figure 38.23 shows a plot of the type introduced by Moseley for the square root of the energy of the X-rays produced by of the K_α transition for all atoms from neon to uranium. The blue dashed line represents the experimental data, collected by the National Institute of Standards and Technology. The red line is based on the theory that

the dependence of the X-ray energy on the nuclear charge is given by $(Z - Z_{\text{screen}})^2$, with Z_{screen} independent of the nucleus in question. (For this plot, $Z_{\text{screen}} = 1$, because the other electron still in the K shell will partially screen the nuclear charge so that it seems to be 1 less than its actual value.) You can see that the theory is a good approximation to the experimental data, with small deviations only for the heaviest atoms.

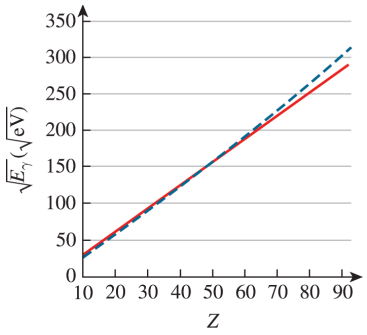

FIGURE 38.23 Moseley-type plot of the square root of the X-ray energy versus the nuclear charge. The blue dashed line represents the experimental data, and the red solid line gives the theoretical prediction.

38.5 Lasers

Originally, the word **laser** was an acronym for *Light* Amplification by *S*timulated *E*mission of *R*adiation. The word is now so commonly used that it is not written in all capital letters, as is the case for an acronym. Lasers, invented in 1960, are used today in all kinds of practical applications, such as Blu-ray, DVD and CD players and recorders, laser surgery, laser pointers, guidance systems, and precision measurement and survey systems. Lasers come in a large variety of sizes, power outputs, and beam colors and use many different materials. However, a few characteristics are common to practically all lasers. First, all lasers must have a medium (a gas, liquid, or solid) in which atoms can be excited to a higher energy state. Also, it must be possible to create a *population inversion*, in which more atoms are in the excited state than in the ground state. Second, a laser has to have a resonator cavity, usually simply a pair of parallel mirrors. Third, a laser has to have a means of pumping energy into the lasing medium.

We will examine the basic physics involved using a helium-neon (He-Ne) gas laser as an example. The lowest energy levels of helium and neon are sketched in Figure 38.24. The two valence electrons of helium reside in the lowest possible level, the 1*s* subshell, as discussed in Section 38.4. The ten electrons of neon fill the 1*s*, 2*s*, and 2*p* subshells. The valence electrons of neon in its ground state reside in the 2*p* subshell.

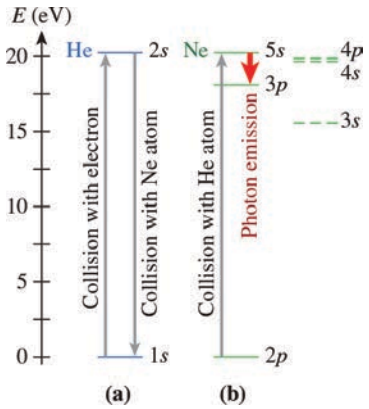

FIGURE 38.24 Energy levels relative to their respective ground states for (a) helium and (b) neon atoms.

Figure 38.24 shows the ground states of the two atoms (blue for helium, green for neon) as horizontal lines at zero energy. The lowest possible excited state for a single electron in helium is the 2*s* state, which lies at an energy of 20.61 eV above the ground state. Photons carry angular momentum $\ell = 1\hbar$, and the 1*s* and 2*s* states both have zero angular momentum, so it is not possible for a photon to cause a transition from the 1*s* to the 2*s* state or from the 2*s* to the 1*s* state.

Figure 38.24b shows the lowest energy levels of a single electron in neon atoms. (The other nine electrons remain in their respective shells: two each in the 1*s* and 2*s* angular

momentum states, and five in the 2*p* angular momentum state.) The states of highest interest for the present purpose (2*p,* 3*p,* and 5*s;* solid green lines) are in a separate column from those that are of lesser interest (3*s,* 4*s,* and 4*p;* dashed green lines). The energy difference between the 2*p* ground state and the 5*s* excited state in neon is 20.66 eV, very close to the 20.61 eV by which the 2*s* state lies above the 1*s* state in helium. The difference between these two energies is only 0.05 eV, which is very close to the average kinetic energy of gas molecules at room temperature (see Example 19.4). The energy of the 3*p* state in neon is 18.70 eV above the ground state. A transition from the 3*p* (angular momentum $\ell = 1\hbar$) to the 5*s* state (angular momentum 0) is thus possible by absorption of a photon of wavelength λ(see equation 38.8):

$$E_{5s} = E_{3p} + \frac{hc}{\lambda} \Rightarrow$$

$$\lambda = \frac{hc}{E_{5s} - E_{3p}} = \frac{1240\ \text{eV nm}}{(20.66 - 18.70)\ \text{eV}} = \frac{1240\ \text{eV nm}}{1.96\ \text{eV}} = 633\ \text{nm}.$$

Conversely, the transition from the 5*s* to the 3*p* state proceeds via the emission of a photon of wavelength 633 nm. This process causes the emission of red light, which is characteristic for this type of laser.

You may ask why the 5*s* state cannot emit a photon via a transition to the 4*p* state. In fact, this transition is also observed in practice and corresponds to a photon wavelength of 3390 nm. Another possible transition is between the 4*s* and 3*p* states, which causes the emission of a photon with wavelength of 1150 nm. In total, more than 10 laser transitions are known in this system, but for practical purposes the most useful one is the 5*s*-to-3*p* transition, because it is in the visible region.

Stimulated Emission and Population Inversion

Figure 38.25 illustrates the possible interaction processes of photons with atoms. The discussion of spectral lines in Sections 38.1 and 38.2 examined the connection between the transition between states of different energy in atoms and the emission and absorption of photons.

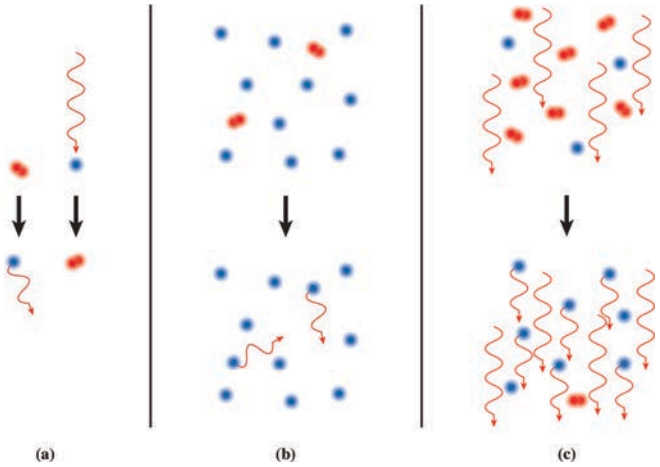

FIGURE 38.25 Interaction of photons (red sine waves) with atoms (blue dots for ground state, red dots for excited state). (a) Emission and absorption processes for an isolated atom. (b) Decay of excited atoms in a mixture of atoms in the ground and excited states. (c) Stimulated emission of photons from a population-inverted mixture of atoms in the excited and ground states.

Figure 38.25a depicts the emission of a photon from an atom in an excited state and the absorption of a photon with the appropriate energy to put the atom into the excited state. Figure 38.25b shows what happens if a large number of atoms are present in a system, a few of which are in the excited state. The excited atoms decay by emitting photons of fixed energy, but the direction of emission is random. Finally, Figure 38.25c shows the conditions for **stimulated emission:** A number of coherent photons, all with the same energy and moving in the same spatial direction, are sent into a system of atoms, in which the population of atoms in the state with higher energy is greater than the population with lower energy. Photons are bosons, so they prefer to occupy quantum states that are already occupied by other photons. Thus, the presence of a large number of coherent photons causes the preferred emission of photons into the same quantum state (same energy and same direction of motion) already occupied by the coherent photons.

For stimulated emission to occur, the coherent photons sent into the system must have the same energy as the emitted photons, which is the energy difference between the two states in the atom. Then each photon of coherent light sent into the system of atoms can also be absorbed by an atom in the lower energy state, lifting it into the higher energy state. If more atoms are in the lower energy state than in the higher energy state, the net effect is an overall reduction in the number of photons. Thus, light amplification through

stimulated emission can only be successful if the population of atoms in higher energy states is greater than the population in lower energy states.

Concept Check 38.6

What is the population ratio of the 5*s* state relative to the 3*p* state at a temperature of 5000 K?

a) $1.2 \cdot 10^{-33}$

b) $4.3 \cdot 10^{-23}$

c) 0.011

d) 0.51

e) 2.4

Chapter 19 showed that the probability of atoms (or molecules) in a gas having an energy E at a given temperature T is proportional to the exponential factor $e^{-E/k_{\mathrm{B}}T}$. Thus, the ratio of the population of the higher energy state to the population of the lower energy state is

$$\frac{n_{\text{higher}}}{n_{\text{lower}}} = e^{-\Delta E/k_{\mathrm{B}}T},$$

where $\triangle E$ is the energy difference between the higher and the lower energy states. Let's put in some typical numbers. Previously, we found that the energy difference between the 5*s* and 3*p* states in neon is $\Delta E = 1.96\,\mathrm{eV}$. At room temperature $(T = 300\,\mathrm{K})$, this means that for every atom found in the 3*p* state, there are only $e^{-1.96/(300 \cdot 8.617 \cdot 10^{-5})} = 1.2 \cdot 10^{-33}$ atoms in the 5*s* state. (Here the Boltzmann constant is expressed in the convenient units of electron-volts per kelvin: $k_{\mathrm{B}} = 8.617 \cdot 10^{-5}\,\mathrm{eV/K}$.)

Since a positive energy difference ΔE always implies that $e^{-\Delta E/K_{\mathrm{B}}T} < 1$, the population of the state with higher energy is always less than that of the state with lower energy, if the system of atoms is in thermal equilibrium.

Achieving the population inversion required for light amplification through stimulated emission requires systems for which **metastable states** exist—that is, states that have long lifetimes because a simple decay is forbidden. The energy-level diagrams of helium and neon in Figure 38.24 show that the 2*s* state in helium is just such a metastable state, because it cannot decay via emission of a single photon. This state can be populated through collisions of helium atoms with electrons, thereby "pumping" the excited state. This part of the laser works similarly to a simple neon sign, where gas atoms are excited via an electron discharge. The helium atoms can then transfer this energy to the neon atoms in the 5*s* state, which has approximately the same energy relative to neon's ground state, through collisions between excited helium atoms with neon atoms in the ground state. If enough energy is pumped into the system, population inversion between the 5*s* and 3*p* states in neon can be achieved by populating the 5*s* state faster than it can decay into the 3*p* state. The utilization of a metastable state to achieve population inversion is very common in all kinds of laser systems.

Figure 38.26 shows a demonstration model of a helium-neon laser. The discharge for pumping the lasing medium takes place in the gas cell. It is enclosed between a pair of parallel mirrors, which bounce the coherent photons back and forth many times to maximize the stimulated emission. The mirror on the right side is only 99% reflective; this allows the laser beam to exit from the cell.

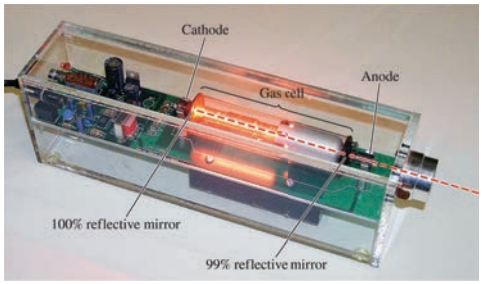

FIGURE 38.26 Demonstration model of a laser. The lasing medium, a mixture of helium and neon gas, is enclosed between two parallel mirrors. The laser beam itself is not visible but is indicated by the red dashed line.

W. Bauer and G. D. Westfall

EXAMPLE 38.4 Number of Photons from a Pulsed Ruby Laser

The lasing medium in a ruby laser consists mostly of alumina (Al_2O_3) and a small amount of chromium, which is responsible for the red color of the ruby. This laser emits a pulse of light ($\lambda = 694\,\text{nm}$) with a power of 3.00 kW over a period of 10.0 ns.

PROBLEM

How many chromium atoms undergo stimulated emission to produce this pulse?

SOLUTION

Each chromium atom that undergoes stimulated emission gives off one photon. The total energy of the pulse is equal to the number of photons, which is equal to the number of excited chromium atoms, times the energy of each photon. The total energy of the light contained in the pulse, E_{total}, is equal to the power P of the pulse times the time duration t of the pulse:

$$E_{\text{total}} = Pt = (3.00\,\text{kW})(10.0\,\text{ns}) = 3.0 \cdot 10^{-5}\,\text{J}.$$

The energy of each photon is

$$E = hf = h\frac{c}{\lambda} = \left(6.626 \cdot 10^{-34}\,\text{J s}\right)\frac{3.00 \cdot 10^{8}\,\text{m/s}}{694 \cdot 10^{-9}\,\text{m}} = 2.86 \cdot 10^{-19}\,\text{J}.$$

Thus, the number of chromium atoms, N, undergoing stimulated emission during the pulse is

$$N = \frac{E_{\text{total}}}{E} = \frac{3.00 \cdot 10^{-5}\,\text{J}}{2.86 \cdot 10^{-19}\,\text{J}} = 1.05 \cdot 10^{14}.$$

In comparison, the total number of atoms in the ruby is around 10^{23}.

Research and Lasers

Lasers come in a huge variety. Laser pointers emit light with a power of up to 5 mW and typically use semiconductor devices called *diodes*. Carbon-dioxide lasers, another type of gas laser, emit laser beams with wavelengths of 9.6 and 10.6 μm at a power of up to 100 kW. These lasers are used in industrial applications for cutting and welding. Other devices include chemical lasers, dye lasers, and solid-state lasers.

Current research on advanced lasers focuses on the generation of extremely short laser pulses of duration down to 43 attoseconds $\left(43.\,10^{-18}\,\mathrm{s}\right)$. At this timing resolution, it is possible to obtain information on the establishment of chemical bonds in real time.

Another focus of current research interest is free-electron lasers, in which the lasing medium is a relativistic electron beam. The electron beam passes through an alternating periodic magnetic field, which causes transverse "wiggles" in the motion of the electrons, generating coherent electromagnetic radiation. A laser beam generated in this way is tunable over a wide range of wavelengths, from millimeters to wavelengths in the visible range.

By using beams of electrons instead of atoms, it is possible to produce X-ray lasers, which have much higher-energy beams because each photon has a higher energy than in the case of optical lasers. This is also a very active area of research, in particular because of its potential medical and military applications.

The largest laser in the world was completed in 2009 and is housed at the National Ignition Facility (NIF; see Figures 38.27 and 38.28) at the Lawrence Livermore National Laboratory in California. Used to study nuclear fusion, it is a pulsed laser that produces 192 separate beams, consisting of short-lived laser pulses of total energy 2 MJ and duration 4 ns. Thus, the peak power of this laser is

$$P_{\max} = E/\Delta t = \left(2 \cdot 10^{6}\,\mathrm{J}\right)/\left(4 \cdot 10^{-9}\,\mathrm{s}\right) = 5 \cdot 10^{14}\,\mathrm{W} = 500\,\mathrm{TW}.$$

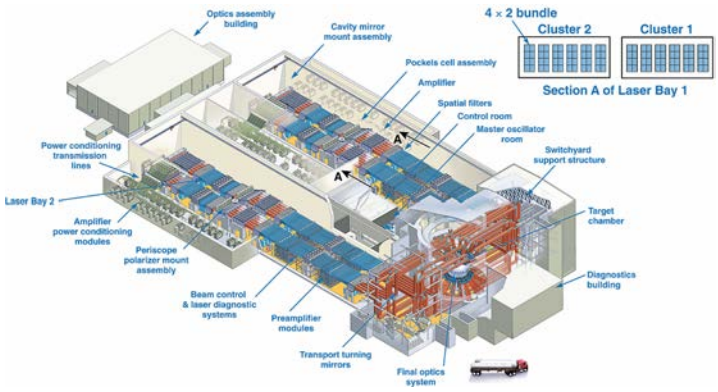

FIGURE 38.27 Cutaway diagram of the National Ignition Facility (NIF) laser system. The lasers are focused on the fusion pellets in the target chamber.

FIGURE 38.28 The Cluster 3 beam path in Laser Bay 2 of the NIF, which contains 6 bundles of 8 beams for a total of 48 beam lines. It was completed in October 2006, and all 6 bundles were operational by December 2006. Laser beams travel over 1000 feet before they reach the target chamber.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- The narrow lines observed in the spectra of atoms are due to the transitions of electrons from one state to another.
- The wavelengths of the photons emitted by an excited hydrogen atom are given by the Rydberg formula:

$$\frac{1}{\lambda} = R_{\mathrm{H}}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right), \quad \text{with } n_1 < n_2,$$

  where $R_{\mathrm{H}} = 1.097373 \cdot 10^7\ \mathrm{m}^{-1}$ is the Rydberg constant.
- The Bohr model of the atom was an early success in explaining the observed line spectra. It is based on the quantization condition for the angular momentum

$$L = \left|\overrightarrow{r} \times \overrightarrow{p}\right| = r\mu v = n\hbar \quad (\text{for } n = 1, 2, 3, \ldots).$$

- The orbital radii in the Bohr model are given by

$$r = \frac{\hbar^2}{\mu k e^2} n^2 = a_0 n^2.$$

  The Bohr radius is $a_0 = 5.295 \cdot 10^{-11}\mathrm{m} = 0.05295\ \mathrm{nm} = 0.5295\ \mathrm{\AA}$.
- To obtain the correct electron wave functions for the hydrogen atom, we need to solve the Schrödinger equation for the electron in the Coulomb potential of the nucleus:

$$-\frac{\hbar^2}{2\mu}\nabla^2\psi(r,\theta,\phi) - k\frac{e^2}{r}\psi(r,\theta,\phi) = E\psi(r,\theta,\phi).$$

- The full solution of this Schrödinger equation can be obtained by separation of variables: $\psi(r,\theta,\phi) = f(r)g(\theta)h(\phi)$.
- The angular parts of the solution are spherical harmonics, which are simultaneously eigenfunctions of the squared angular momentum operator, $\widehat{L}^2 Y_\ell^m(\theta,\phi) = \ell(\ell+1)\hbar^2 Y_\ell^m(\theta,\phi)$, and the operator for the z-projection of the angular momentum vector, $\widehat{L}_z Y_\ell^m(\theta,\phi) = m\hbar Y_\ell^m(\theta,\phi)$.
- The complete solution for the hydrogen eigenfunction is the product of the angular part and the radial part: $\psi_{n\ell m}(r,\theta,\phi) = f_{n\ell}(r)Y_{\ell m}(\theta,\phi)$.

- The quantum numbers of these solutions are the radial quantum number, $n = 1, 2, 3, \ldots$; the orbital angular momentum quantum number, $\ell = 0, 1, \ldots, n-1$; and the magnetic quantum number, $m = -\ell, \ldots \ell$. The energy eigenvalue corresponding to a particular eigenfunction that is a solution depends only on the radial quantum number and is the same as for the Bohr model:

$$E_n = -\frac{1}{n^2}E_0 = -\frac{1}{n^2}\frac{\mu k^2 e^4}{2\hbar^2}.$$

- The hydrogen ground-state wave function is

$$\psi_{100}(r,\theta,\phi) = \frac{1}{\sqrt{\pi}a_0^{3/2}}e^{-r/a_0}.$$

- The total number, $N(n)$, of possible wave functions in a given shell with radial quantum number n is

$$N(n) = \sum_{\ell=0}^{n-1}(2\ell+1) = n^2.$$

- The wave functions for other atoms can be determined in a manner similar to the hydrogen wave functions. The Pauli Exclusion Principle states that each possible state is occupied by at most two electrons, one with spin down and one with spin up.
- The order in which the angular momentum states are filled follows their energies and is 1*s*, 2*s*, 2*p*, 3*s*, 3*p*, 4*s*, 3*d*, 4*p*, 5*s*, 4*d*, 5*p*, 6*s*, ...
- Lasers work on the basis of population inversion. Electrons are lifted into a metastable state, followed by stimulated emission of photons with energy corresponding to the transition between the metastable state and the ground state.

ANSWERS TO SELF-TEST OPPORTUNITIES

38.1 We need to take the limit as $n_2 \to \infty$ and find $\frac{1}{\lambda} = R_{\mathrm{H}}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \xrightarrow[n_2 \to \infty]{} \frac{R_{\mathrm{H}}}{n_1^2}$. With $R_{\mathrm{H}} = 1.097373 \cdot 10^7\ \mathrm{m}^{-1}$, we find for the Lyman ($n_1 = 1$), Balmer (2), Paschen (3), and Brackett (4) series: $\lambda_{\min} = 91.1\ \mathrm{nm}, 365\ \mathrm{nm}, 820\ \mathrm{nm}, 1458\ \mathrm{nm}$.

38.2 For Balmer, $n_1 = 2, n_2 = n$: $\frac{1}{\lambda} = R_{\mathrm{H}}\left(\frac{1}{4} - \frac{1}{n^2}\right) = R_{\mathrm{H}}\left(\frac{n^2 - 4}{4n^2}\right)$. Therefore, the wavelengths in this series are $\lambda = \frac{4}{R_{\mathrm{H}}}\frac{n^2}{n^2 - 4} = (364.5\ \mathrm{nm})\frac{n^2}{n^2 - 4}$.

38.3 $\psi_{211}(x, 0, z)$ has a shape like $\psi_{210}(x, 0, z)$, but rotated 90° counterclockwise in the xz-plane.

38.4 Insert the wave function, $\psi_{100}(r, \theta, \phi) = \frac{1}{\sqrt{\pi} a_0^{3/2}} e^{-r/a_0}$, into the Schrödinger equation: $-\frac{\hbar^2}{2\mu}\frac{1}{r}\frac{d^2}{dr^2}(r\psi(r)) - K\frac{e^2}{r}\psi(r) = E\psi(r)$. First, take the derivative: $\frac{d}{dr}\left(r\frac{1}{\sqrt{\pi} a_0^{3/2}} e^{-r/a_0}\right) = \frac{1}{\sqrt{\pi} a_0^{3/2}} e^{-r/a_0}\left(1 - \frac{r}{a_0}\right)$; then take the second derivative: $\frac{d}{dr}\left(\frac{1}{\sqrt{\pi} a_0^{3/2}} e^{-r/a_0}\left(1 - \frac{r}{a_0}\right)\right) = -\frac{e^{-r/a_0}}{a_0 \sqrt{\pi} a_0^{3/2}}\left(2 - \frac{r}{a_0}\right)$. Insert back into the Schrödinger equation:

$$\left(-\frac{\hbar^2}{2\mu}\frac{1}{r}\right)\left[-\frac{e^{-r/a_0}}{a_0\sqrt{\pi} a_0^{3/2}}\left(2 - \frac{r}{a_0}\right)\right] - k\frac{e^2}{r}\left(\frac{1}{\sqrt{\pi} a_0^{3/2}} e^{-r/a_0}\right) = E\left(\frac{1}{\sqrt{\pi} a_0^{3/2}} e^{-r/a_0}\right).$$

Now cancel common factors and find $E = -\frac{\mu k^2 e^4}{2\hbar^2}$, which means that $\psi_{100}(r, \theta, \phi)$ is indeed a solution to the Schrödinger equation with the correct value for the energy.

PROBLEM-SOLVING GUIDELINES

1. For photons emitted or absorbed in atomic transitions, you can always calculate the energy as the difference between the final and initial electron energies. The Bohr model of the atom may be fundamentally flawed, but it is still useful in many calculations involving electron energies in hydrogen-like atoms.

2. The hydrogen atom is a quantum system, so all of the problem-solving guidelines presented in Chapters 36 and 37 apply to problems involving this system. In particular, the hydrogen wave functions for a given quantum state can be used to obtain expectation values of quantum operators via integration.

3. The Pauli Exclusion Principle is of fundamental importance in understanding how subshells get filled in many-electron atoms. Making sure that no two electrons occupy the same quantum state in the same atom at the same time avoids many simple errors.

MULTIPLE-CHOICE QUESTIONS

38.1 The wavelength of the fourth line in the Lyman series of the hydrogen spectrum is

a) 80.0 nm.

b) 85.0 nm.

c) 90.2 nm.

d) 94.9 nm.

38.2 The electron in a certain hydrogen atom is in the $n = 5$ state. Which of the following could be the ℓ and m values for the electron?

a) $5, -3$

b) $4, -5$

c) $3, -2$

d) $4, -6$

38.3 A muon has the same charge as an electron but a mass that is 207 times greater. The negatively charged muon can bind to a proton to form a new type of hydrogen atom. How does the binding energy, $E_{\mathrm{B}\mu}$, of the muon in the ground state of a muonic hydrogen atom compare with the binding energy, $E_{\mathrm{B}e}$, of an electron in the ground state of a conventional hydrogen atom?

a) $|E_{\mathrm{B}\mu}| \approx |E_{\mathrm{B}e}|$

b) $|E_{\mathrm{B}\mu}| \approx 100\,|E_{\mathrm{B}e}|$

c) $|E_{\mathrm{B}\mu}| \approx |E_{\mathrm{B}e}|/100$

d) $|E_{\mathrm{B}\mu}| \approx 200\,|E_{\mathrm{B}e}|$

e) $|E_{\mathrm{B}\mu}| \approx |E_{\mathrm{B}e}|/200$

38.4 Which of the following can be used to explain why you can't walk through walls?

a) Coulomb repulsive force

b) the strong nuclear force

c) gravity

d) Pauli Exclusion Principle

e) none of the above

38.5 How many antinodes are there in a system with the quantum number $n = 6$?

a) 12

b) 6

c) 3

d) 5

38.6 Transition metals can be defined as the elements in which the *d* subshells go from empty to full. How many transition metals are there in each period?

a) 2

b) 6

c) 10

d) 14

38.7 What is the shortest wavelength photon that can be emitted by singly ionized helium $\left(\mathrm{He}^{+}\right)$?

a) 0.00 nm

b) 22.8 nm

c) 46.0 nm

d) 91.0 nm

e) 365 nm

38.8 An electron made a transition between allowed states, emitting a photon. Which of the following physical constants is (are) needed to calculate the energy of the photon from the measured wavelength?

a) the Plank constant, h

b) the basic electric charge, e

c) the speed of light in vacuum, c

d) the Stefan-Boltzmann constant, σ

CONCEPTUAL QUESTIONS

38.9 The common depiction of an atom, with electrons tracing elliptical orbits centered on the nucleus, is an icon of the Atomic Age. Given what you know of the physics of atoms, what's wrong with this picture?

38.10 Given that the hydrogen atom has an infinite number of energy levels, why can't a hydrogen atom in the ground state absorb all possible wavelengths of light?

38.11 Compare the difference in energy levels for increasing n for an infinite square well, a quantum harmonic oscillator, and the hydrogen atom.

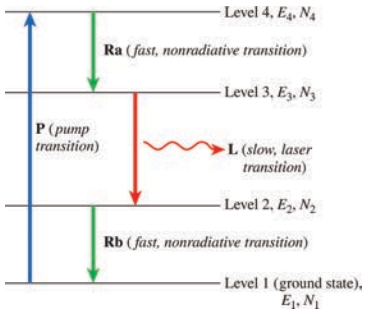
38.12 What would happen to the energy levels of a hydrogen atom if the Coulomb force doubled in strength? What would happen to the sizes of atoms?

38.13 Which model of the hydrogen atom—the Bohr model or the quantum mechanical model—predicts that the electron spends more time near the nucleus?

38.14 For $\ell < 4$, which values of ℓ and m correspond to wave functions that have their maximum probability in the xy-plane?

38.15 *Hund's rule,* a component of the *Aufbauprinzip* (construction principle), states that as one moves across the periodic table, with increasing atomic number, the available subshells are filled successively with one electron in each orbital, their spins all parallel; only when all orbitals in a subshell contain one electron are second electrons, with spins opposite to the first, placed in the orbitals. Explain why the ground-state electron configurations of successive elements should follow this pattern.

38.16 The energy-level diagram for a four-level laser is presented in the figure, which includes information about the relative times required for the various transitions involved in the operation of such a laser. Explain why the nonradiative transitions have to be fast (higher rate of transitions per second) compared to the slower laser transition.



38.17 The hydrogen atom wave function ψ_{200} is zero when $r = 2a_0$. Does this mean that the electron in that state can never be observed at a distance of $2a_0$ from the nucleus or that the electron can never be observed passing through the spherical surface defined by $r = 2a_0$? Is there a difference between those two descriptions?

38.18 A 10-eV electron collides with (but is not captured by) a hydrogen atom in its ground state. Calculate the wavelengths of all photons that might be emitted.

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 38.1

38.19 What is the shortest wavelength of light that a hydrogen atom will emit?

38.20 Determine the wavelength of the second line in the Paschen series.

38.21 The Pfund series results from emission/absorption of photons due to transitions of electrons in a hydrogen atom to/from the $n = 5$ energy level from/to higher energy levels. What are the shortest and longest wavelengths of lines in the Pfund series? Are any of these in the visible portion of the electromagnetic spectrum?

38.22 An electron in the second excited state of a hydrogen atom jumps to the ground state. What are the possible colors and wavelengths of the light emitted as a result of the jump?

Section 38.2

38.23 Calculate the energy of the fifth excited state of a hydrogen atom.

38.24 Hydrogen atoms are bombarded with 13.1-eV electrons. Determine the shortest wavelength of light the atoms will emit.

38.25 The Rydberg constant with a finite mass of the nucleus is given by $R_{\text{modified}} = R_{\text{H}}/(1 + m/M)$, where m and M are the masses of an electron and a nucleus, respectively. Calculate the modified value of the Rydberg constant for (a) a hydrogen atom, and (b) a positronium (in a positronium, the "nucleus" is a positron, which has the same mass as an electron).

38.26 A muon is a particle very similar to an electron. It has the same charge but its mass is $1.88 \cdot 10^{-28}$ kg.

a) Calculate the reduced mass for a hydrogen-like muonic atom consisting of a single proton and a muon.

b) Calculate the ionization energy for such an atom, assuming that the muon is initially in its ground state.

•**38.27** An excited hydrogen atom emits a photon with an energy of 1.133 eV. What were the initial and final states of the hydrogen atom before and after emitting the photon?

•**38.28** An 8.00-eV photon is absorbed by an electron in the $n = 2$ state of a hydrogen atom. Calculate the final speed of the electron.

•**38.29** Assume that Bohr's quantized energy levels apply to planetary orbits. Derive an equation similar to equation 38.6 that gives the allowed radii of those orbits, and estimate the principal quantum number for the Earth's orbit.

•**38.30** Prove that the period of an electron in the nth Bohr orbit is given by $T = n^3/(2cR_{\text{H}})$, with $n = 1, 2, 3, \ldots$.

Section 38.3

38.31 What are the largest and smallest possible values for the angular momentum L of an electron in the $n = 5$ shell?

38.32 Electrons with the same value of the quantum number n are said to occupy the same electron shell, *K, L, M, N,* or higher. Calculate the maximum allowed number of electrons for the (a) *K* shell, (b) *L* shell, and (c) *M* shell.

•**38.33** What is the angle between the total angular momentum vector and the *z*-axis for a hydrogen atom in the stationary state (3,2,1)?

•**38.34** A hydrogen atom is in its fifth excited state, with principal quantum number $n = 6$. The atom emits a photon with a wavelength of 410 nm. Determine the maximum possible orbital angular momentum of the electron after emission.

•**38.35** The radial wave function for hydrogen in the 1*s* state is given by $R_{1s} = A_1 e^{-r/a_0}$, where the normalization constant, A_1, was found in Example 38.2.

a) Calculate the probability density at $r = a_0/2$.

b) The 1*s* wave function has a maximum at $r = 0$ but the 1*s* radial probability density peaks at $r = a_0$. Explain this difference.

•**38.36** For the wave function $\psi_{100}(r)$ in equation 38.30, find the value of *r* for which the function $P(r) = 4\pi r^2 |\psi_{100}(r)|^2$ is a maximum.

•• **38.37** An electron in a hydrogen atom is in the 2*s* state. Calculate the probability of finding the electron within a Bohr radius ($a_0 = 0.05295$ nm) of the proton. The 2*s* wave function for hydrogen is

$$\psi_{2s}(r) = \frac{1}{4\sqrt{2\pi a_0^3}} \left(2 - \frac{r}{a_0}\right) e^{-r/2a_0}.$$

Evaluating the integral is a bit tedious, so you may want to consider using a program such as Mathcad or Mathematica or finding the integral online at http://integrals.wolfram.com/index.jsp.

Section 38.4

38.38 Calculate the energy needed to change a single ionized helium atom into a double ionized helium atom (that is, change it from He^+ into He^{2+}). Compare it to the energy needed to ionize the hydrogen atom. Assume that both atoms are in their ground state.

38.39 A He^+ ion consists of a nucleus (containing two protons and two neutrons) and a single electron. Find the Bohr radius for this system.

•38.40 Find the wavelengths of the three lowest-energy lines in the Paschen series of the spectrum of the He^+ ion.

•38.41 The binding energy of an extra electron added when As atoms are used to dope a Si crystal may be approximately calculated by considering the Bohr model of a hydrogen atom.

a) Express the ground energy of the hydrogen-like atoms in terms of the dielectric constant, the effective mass of an extra electron, and the ground-state energy of a hydrogen atom.

b) Calculate the binding energy of the extra electron in a Si crystal. The dielectric constant of Si is about 10.0, and the effective mass of extra electrons in a Si crystal is about 20.0% of that of free electrons.

•38.42 What is the wavelength of the first visible line in the spectrum of doubly ionized lithium? Begin by writing the formula for the energy levels of the electron in doubly ionized lithium—then consider energy-level differences that give energies in the appropriate (visible) range. Express the answer as "the transition from state n to state n' produces the first visible line, with wavelength X."

•38.43 Following the steps used in the text for the hydrogen atom, apply the Bohr model of the atom to derive an expression for

a) the radius of the nth orbit,

b) the speed of the electron in the nth orbit, and

c) the energy levels in a hydrogen-like ionized atom with charge number Z that has lost all of its electrons except for one. Compare the results with the corresponding ones for the hydrogen atom.

•38.44 Apply the results of Problem 38.43 to determine the maximum and minimum wavelengths of the spectral lines in the Lyman, Balmer, and Paschen series for a singly ionized helium atom (He^+).

Section 38.5

38.45 Consider an electron in a hydrogen atom. If you are able to excite the electron from the $n = 1$ shell to the $n = 2$ shell with laser light of a given wavelength, what wavelength of laser light will excite that electron again from the $n = 2$ to the $n = 3$ shell? Explain.

38.46 A low-power laser has a power of 0.50 mW and a beam diameter of 3.0 mm.

a) Calculate the average light intensity of the laser beam.

b) Compare the value from part (a) to the intensity of light from a 100-W light bulb viewed from 2.0 m.

38.47 A ruby in a laser consists mostly of alumina (Al_2O_3) and a small amount of chromium ions, responsible for its red color. A 3.00-kW ruby laser emits light pulses of duration 10.0 ns and wavelength 694 nm.

a) What is the energy of each of the photons in a pulse?

b) Determine the number of chromium atoms undergoing stimulated emission to produce a pulse.

38.48 You have both a green, 543-nm, 5.00-mW laser and a red, 633-nm, 4.00-mW laser. Which one will produce more photons per second, and why?

Additional Exercises

38.49 What is the shortest possible wavelength in the Lyman series in hydrogen?

38.50 How much energy is required to ionize a hydrogen atom when the electron is in the nth level?

38.51 By what percentage is the mass of the electron changed by using the reduced mass for the hydrogen atom? What would the reduced mass be if the proton had the same mass as the electron?

38.52 Show that the number of different electron states possible for a given value of n is $2n^2$.

38.53 Section 38.2 established that an electron, if observed in the ground state of hydrogen, is expected to have a speed of $0.0073c$. For what nuclear charge Z would an innermost electron have a speed of approximately $0.500c$, when considered classically?

38.54 A collection of hydrogen atoms have all been placed into the $n = 4$ excited state. What wavelengths of photons will be emitted by the hydrogen atoms as they transition back to the ground state?

38.55 Consider a muonic hydrogen atom, in which the electron is replaced by a muon of mass $105.66\ \text{MeV}/c^2$ that orbits the proton. What are the first three energy levels of the muon in this type of atom?

38.56 What is the ionization energy of a hydrogen atom excited to the $n = 2$ state?

38.57 He^+ is a helium atom with one electron missing. Treating this ion like a hydrogen atom, what are its first three energy levels?

38.58 What is the energy of a transition capable of producing light of wavelength 10.6 μm? (This is the wavelength of light associated with a commonly available infrared laser.)

38.59 What is the energy of the orbiting electron in a hydrogen atom with a radial quantum number of 45?

•**38.60** Find the energy difference between the ground state of hydrogen and the ground state of deuterium (hydrogen with an extra neutron in the nucleus).

•**38.61** An excited hydrogen atom, whose electron is in the $n = 4$ state, is motionless. When the electron drops to the ground state, does it set the atom in motion? If so, with what speed?

•**38.62** The radius of the $n = 1$ orbit in the hydrogen atom is $a_0 = 0.053\ \text{nm}$.

a) Compute the radius of the $n = 6$ orbit. How many times larger is this than the $n = 1$ radius?

b) If an electron in the $n = 6$ orbit drops to the $n = 1$ orbit (ground state), what are the frequency and the wavelength of the emitted radiation? What kind of radiation is emitted (visible, infrared, etc.)?

c) How would your answer to part (a) change if the atom was a singly ionized helium atom $\left(\text{He}^+\right)$ instead?

•**38.63** An electron in a hydrogen atom is in the ground state ($1s$). Calculate the probability of finding the electron within a Bohr radius $(a_0 = 0.05295\ \text{nm})$ of the proton.

The ground-state wave function for hydrogen is $\psi_{1s}(r) = A_{1s}e^{-r/a_0} = e^{-r/a_0}\sqrt{\pi a_0^3}$.

MULTI-VERSION EXERCISES

38.64 A beam of electrons is incident on a system of excited hydrogen atoms. What minimum speed must the electrons have to cause the emission of light due to the transition in the hydrogen atoms from $n = 2$ to $n = 1$? (In the collision of an electron with a hydrogen atom, you may neglect the recoil energy of the hydrogen atom, because it has a mass much greater than that of the electron.)

38.65 A beam of electrons with a speed of 676.01 km/s is incident on a system of excited hydrogen atoms. If an electron hits a hydrogen atom in the $n = 3$ state, what is the highest level n, to which this hydrogen atom can be excited in this collision? (In the collision of the electron with the hydrogen atom, you may neglect the recoil energy of the hydrogen atom, because it has a mass much greater than that of the electron.)

38.66 A beam of electrons with a speed of 378.92 km/s is incident on a system of excited hydrogen atoms. If an electron hits a hydrogen atom and excites it to the $n = 10$ state, what is the lowest level n in which this hydrogen atom could have been before the collision? (In the collision of the electron with the hydrogen atom, you may neglect the recoil energy of the hydrogen atom, because it has a mass much greater than that of the electron.)

38.67 Find the ratio of the number of hydrogen atoms in the $n = 3$ state to the number of hydrogen atoms in the $n = 7$ state at a temperature of 528.3 K.

38.68 At what temperature is the ratio of the number of hydrogen atoms in the $n = 3$ state to the number of hydrogen atoms in the $n = 8$ state equal to $5.1383 \cdot 10^5$?

Cosmology is the study of the largest things we know about: the universe and its time evolution. Principally a part of astronomy, cosmology seeks clues about the early universe from studying far-distant galaxies and clusters of galaxies. For example, the collision of two galaxies (Figure 39.1) indicates how galaxies might have grown and evolved billions of years ago. Strangely enough, some of the other major contributions to cosmology come from studying the smallest things we know about: elementary particles and their interactions. Understanding how matter and energy interact at the most basic level gives us some idea of what the earliest moments of the universe must have been like.

FIGURE 39.1 Two galaxies colliding as photographed by the Hubble Space Telescope.

NASA/ESA/STScI/AURA

This chapter examines the most basic components of matter, the elementary particles that make up atoms and even the particles within atoms. What is known about these basic units is based on quantum mechanics, but we will skip over most of the mathematics

involved and emphasize the basic concepts instead. Experimental evidence to back up these ideas is hard to come by, and usually requires analysis of debris formed when particles moving at speeds close to the speed of light are collided in enormous particle accelerators. There has been a continual increase in the energy needed for further research in this field. Today's particle colliders are among the largest and most powerful instruments ever built.

However, the study of the tiniest particles and the highest energies involves some of the most speculative areas of physics. Particle physicists have developed a model of the most basic particles and their interactions, usually referred to as the *standard model*. But even the standard model does not explain everything, and new ideas about how to extend or improve it seem to arise every day. This chapter will look at some of these theories that may become the standard model of the future.

WHAT WE WILL LEARN

- The quest to reduce systems to their components is a main theme in science and has its present culmination in particle physics. While it is equally valid to analyze complexity and emergent structure, this chapter focuses on reductionism in particle physics.
- Substructure is probed using scattering experiments. This chapter defines the concept of a scattering cross section.
- Elementary fermions have spin $\frac{1}{2}\hbar$ and consist of the six quarks (up, down, strange, charm, bottom, top), the electron, muon, and tau leptons, and the electron-, muon-, and tau-neutrinos. Each of these 12 fermions has an antiparticle. Quarks have a noninteger charge of $-\frac{1}{3}e$ or $+\frac{2}{3}e$ and cannot be observed in isolation.
- Elementary bosons are the mediators of the interactions between the fermions. These bosons include the photon (electromagnetic), *W* and *Z* bosons (electroweak), gluon (strong), and graviton (gravitational). The graviton is yet to be observed experimentally. Gluons can also interact with other gluons.
- Feynman diagrams represent the interactions of fundamental particles pictorially, and calculations can be based on these diagrams.
- A widely accepted model of particle interactions is the standard model. Extensions of the standard model, which itself is incomplete, are grand unified theories, supersymmetric theories, and string theories.
- Elementary quarks and antiquarks can combine to form particles, which can be observed in isolation. A quark and an antiquark can form a meson (pion, kaon, etc.). Three quarks can form a baryon (proton, neutron, delta baryon, lambda baryon, etc.).

- Particle physics and astrophysics intersect in the study of Big Bang cosmology, its inflationary phase and its electroweak and quark-gluon-plasma phase transitions, all of which happened in the first 3 minutes of the existence of the universe. This chapter also discusses the origin of the cosmic microwave background radiation.

39.1 Reductionism

At least since the times of the ancient Greek philosophers, a central theme has guided humanity's attempts to achieve a quantitative scientific understanding of the world around us. This central theme is **reductionism,** which assumes that a system can be understood in terms of its subsystems. Figure 39.2 illustrates reductionism in particle physics.

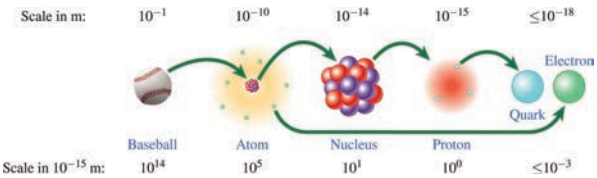

FIGURE 39.2 Reductionism in particle physics.

Lawrence Manning/CORBIS

Astronomers have established that the universe contains hundreds of billions of galaxies, which are each composed of hundreds of billions of star systems. These star systems can consist of a central star (or sometimes two or more stars), which is orbited by planets, which in turn are orbited by their moons.

Biologists are trying to understand the entire ecosystem as composed of populations of species. Individual organisms of these species contain specialized organs and cells, which have nuclei containing chromosomes consisting of DNA. The DNA, which contains the genetic code that governs all traits passed on from one generation to the next, is understood to be segmented into thousands of genes. Genes are made of usefully readable content, called *exons,* interspersed with unreadable (or at least unread) *introns*. The exons are made of "words"—called codons—each of which contains three amino acid base pairs: each pair consisting of adenine (A) and thymine (T) or cytosine (C) and guanine (G).

Arguably, physicists have led the charge toward reductionism. Physicists now know that matter is composed of molecules, which in turn are made of atoms. The word *atom* derives from the Greek

word *átomos* (ατομος, "individual, indivisible"). In particular, the Greek philosopher Democritus was the earliest prominent proponent of the atomistic theory of matter. The four elements of the Greek atomistic theory were earth, air, fire, and water, which were arranged in a two-by-two matrix of hot-cold and wet-dry opposites (see Figure 39.3), and which were thought to be immutable. Aristotle added to these four a fifth element, *quintessence,* which he thought to be the material of which the heavens were made.

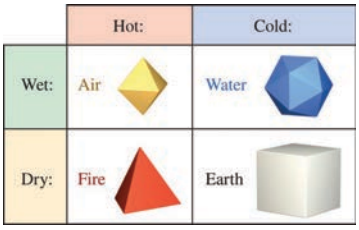

FIGURE 39.3 The four basic elements of ancient Greek philosophy, each shown with the regular polyhedron assigned to it by Plato.

The Greek atomistic theory was forgotten until the Renaissance. Then philosophers, physicists, and chemists created a new atomistic view of the world, and it proved to be incredibly successful and productive. By 1869, many different kinds of atoms had been identified as the elementary building blocks of the chemical elements. The Russian chemist Dimitri Mendeleev (1834–1907) took a giant step forward in that year by arranging the atoms of the elements in the periodic table. The current count of the different known elements is 118: the 112 elements from hydrogen through copernicium, plus the yet unnamed elements 113 through 118.

The idea of simplicity is intimately connected with reductionism. According to the rule known as *Occam's razor,* when an observation can be explained by several alternative theories, the simplest explanation is usually preferable. In addition, physical theories are often guided by the search for symmetry and abstract beauty, as well as the more practical demands of consistency and reproducibility. While physics is *the* basic science and is usually concerned with measurable facts, at the level discussed here it is also influenced by concepts from philosophy and even the arts.

The fact that so many kinds of atoms exist led many people to speculate at the end of the 19th century that atoms are not really the most basic fundamental building blocks of matter and that there must be an underlying, more fundamental structure. This more fundamental structure turned out to be a hierarchy of several layers. The rest of this chapter is devoted to peeling back these layers one at a time.

Nuclear physics and elementary particle physics are devoted to searching for this fundamental structure explaining the phenomena observed at the respective size scales. The reductionist quest to discover the most fundamental level is far from complete. For example, nuclear and particle physicists are currently engaged in this quest using the Large Hadron Collider (LHC, Figure 39.4) at CERN (straddling the Swiss-French border, near Geneva), which became operational in 2008.

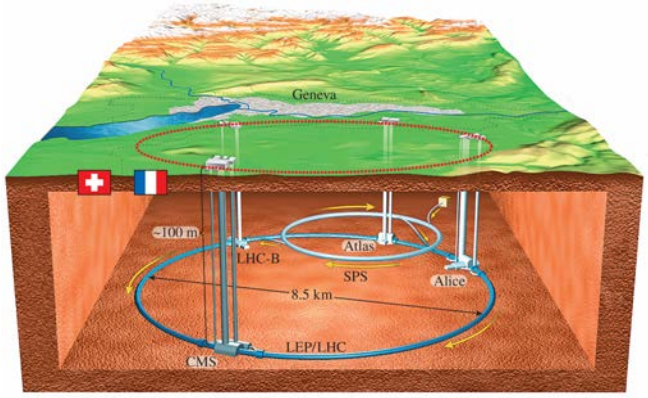

FIGURE 39.4 Schematic layout of the LHC accelerator and detector complex at CERN.

Cathedral-size caves located approximately 100 m underground house the largest particle detectors ever built. Figure 39.5 shows a construction photo of the partially finished ATLAS detector at CERN. Figure 39.6 shows a cutaway construction drawing of the ALICE detector that is also part of the LHC complex at CERN. At the LHC, physicists have discovered the Higgs boson (see Section 39.3) and hope to discover hints about the next more fundamental level in the hierarchy (if it exists!).

Complexity

The remainder of this chapter focuses on atomic nuclei, elementary particles, and smallest constituents, but reductionism is only one part of science research. Just as important is the complementary research goal: finding out how constituents on one level of the size hierarchy work together to create the structure observed on the next-larger level. This is the study of **complexity**—pattern formation, self-organization of systems, and emergence of order out of chaos. This aspect of science is much less mature than the reductionist thread that science has followed for the last few centuries. The study of complexity often relies on computer modeling and is thus not usually covered in introductory textbooks. Nevertheless, many stunning investigations of complex systems are currently ongoing.

Examples of complexity on the atomic scale include pattern formation in complex materials and the self-assembly of nanostructures. Physicists, biochemists, and microbiologists are forming interdisciplinary collaborations to try to understand the mechanism of protein folding in creating three-dimensional structure from the encoding of the genetic sequence in DNA; the interaction of cells in large multicellular organisms; the precise mechanism of evolution and propagation of genetic mutations; and the origins of life and of intelligence (biological, as well as artificial). In biology, the establishment of order in animal populations (examples are anthills and bird-flight formations) is under intense study. The complexities underlying the spread of epidemics need to be understood. Almost everything in nature shows complex patterns, and scientists seek to understand which universal principles govern their formation. In meteorology, the goal is to come closer to being able to describe and predict the complexity of weather patterns. Human interaction has many complex dimensions that can be modeled, such as traffic flow in cities, the rise and fall of social trends and fashions, and the movement of market indicators in economies. Even the universe as a whole shows fractal patterns in the distribution of its galaxy clusters and superclusters.

For many or perhaps most of these fields of research, training in just one discipline of science is not sufficient. Instead,

interdisciplinary teams composed of physical scientists, mathematicians, engineers, biologists, computer scientists, social scientists, and others need to work together to obtain a deeper understanding of these areas. In particular, as our ability to shape nature grows faster, the risk of unintended consequences from intervention in poorly understood systems increases, and that risk demands deeper exploration.

But first things first! Let's take things apart, before we put them back together. What is an elementary particle?

39.2 Probing Substructure

For a particle to be considered elementary, it cannot have a substructure of other particles. How is substructure discovered? Visual examination can reveal substructure of systems that are large enough, but as Chapter 38 showed, atomic radii are on the order of 10^{-10}m and thus too small to see. The only means available to explore dimensions that are smaller than this scale is to shoot small particles at atomic targets and observe how the particles are deflected and scattered.

Classical Scattering

Before we proceed to use quantum mechanics, let's extend the classical theory of momentum and collisions, presented in Chapters 7 and 8. In Chapter 7, we considered elastic two-body scattering in two and three spatial dimensions and found that conservation of total energy and momentum did not provide enough constraints to predict the final momenta from the initial ones.

Here we want to examine a very simple case of scattering a very small, low-mass particle off a larger and much higher-mass spherical target. In the limit that the target is much more massive than the projectile, we can consider the target to be stationary. Further, we consider only motion along straight-line trajectories, which implies the absence of any force other than the contact force at the instant when the particles collide.

We define the impact parameter b as the perpendicular distance from the incoming trajectory to the trajectory that would result in a direct head-on collision. What is the deflection angle θ of the trajectory after the collision relative to the trajectory before the collision? A side view is shown in Figure 39.7a. In this figure, the acute angle ϕ, in black, is the angle of the perpendicular to the target at the point at which the small particle makes contact with the target relative to the position vector of the low-mass particle before scattering. It is given from trigonometry (see the blue right triangle in Figure 39.7a) that $\sin\phi = b/R$. We also see from Figure 39.7a that the deflection angle θ is given by

$$\theta = \pi - 2\phi = \pi - 2\sin^{-1}(b/R).$$

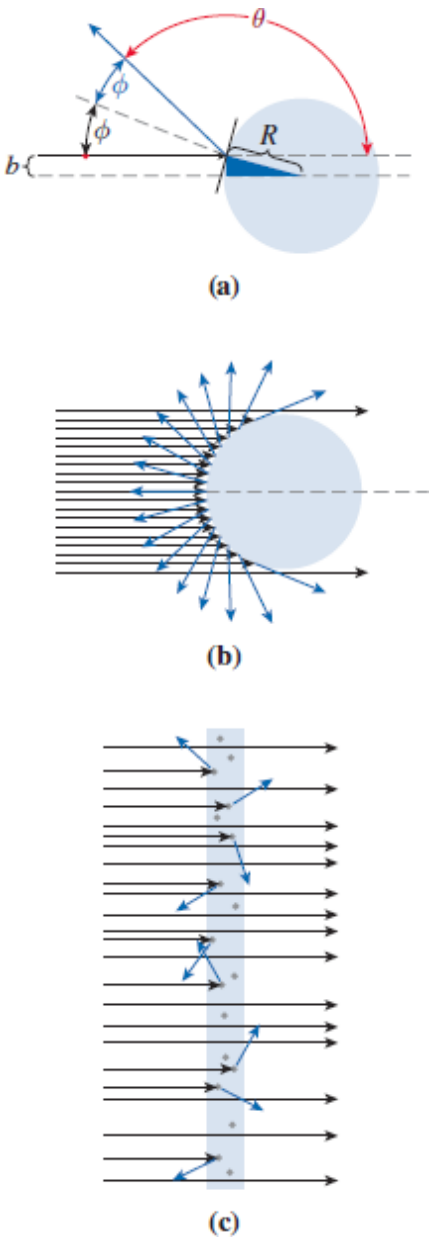

FIGURE 39.7
Classical scattering of a very small, low-mass particle (red dot) off a larger, high-mass one (blue circle). (a) Scattering at one particular fixed impact parameter; (b) superposition of

many scattering events at different impact parameters; (c) superposition of many scattering events of projectile particles off small targets within a thin foil.

Therefore, given the impact parameter and the radius of the target, the deflection angle can be calculated. Alternatively, given the impact parameter and the deflection angle, the radius of the target can be calculated.

In practice, physicists construct macroscopic scattering targets from very thin foils of materials. Because nuclei are so small, each particle hits at most one nucleus in a thin foil. The impact parameter cannot be predicted or measured. However, one can observe the angles at which particles scatter from the foil and make conclusions based on how many particles scatter at a particular angle. This situation is sketched in Figure 39.7b. Because a tiny nucleus will not get hit multiple times, the more realistic situation is shown in Figure 39.7c, which shows a thin foil composed of many very small scattering targets, many of which are not hit, and some of which are hit (but very likely only once). The angular distribution of these scattering events is the same as the one shown in Figure 39.7b.

Instead of a side view of the scattering centers inside the foil, we can sketch a head-on frontal view of the foil as presented to the incoming projectile particles. This situation would look something like Figure 39.8, which shows some unit area A of the foil (gray square) with the scattering centers indicated by the small blue circles. Assume that the projectile particles impinge perpendicular to the page. Each scattering center has an effective area perpendicular to the trajectory of the projectile particles. This effective area is called the **cross section**, denoted by σ. It has the dimension of area, that is, $[\sigma] = \mathrm{m}^2$. However, in nuclear and particle physics, the unit m^2 is not very practical because the

relevant cross sections are such small fractions of a square meter. Instead, the (rather ironically named!) units **barn** (b) and millibarn (mb) have been introduced:

$$1\text{b} = 10^{-28}\,\text{m}^2$$
$$1\text{mb} = 10^{-31}\,\text{m}^2.$$

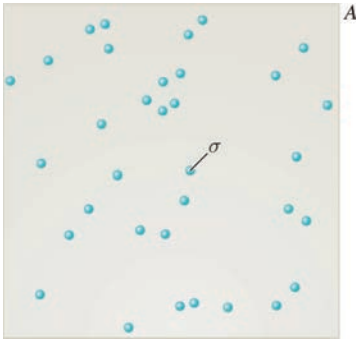

FIGURE 39.8
Frontal view of a target foil composed of many individual, small, randomly distributed scattering centers, as presented to impinging projectile particles.

Assume that the cross section for each scattering center in the target is the same, and that it is small enough that we do not have to worry about the cross sections of different scattering centers overlapping. Then the probability, Π, that any given projectile particle has a scattering event can be stated as the sum of the areas of all scattering centers divided by the area A over which they are spread. Since each scattering center has the same area, σ, the sum

of the areas is then $n_t\sigma$, where n_t is the number of scattering centers contained in the target area A. Thus,

$$\Pi = \frac{n_t\sigma}{A}.$$

If a large number n_p of projectile particles fall on this area A, then the total number of reactions N_{pt} is the product of the probability that a projectile particle has a scattering event times the number n_p:

$$N_{pt} = n_p\Pi = \frac{n_p n_t\sigma}{A}.$$

This equation can be solved for the cross section, σ:

$$\sigma = \frac{N_{pt}A}{n_p n_t}.$$

The same basic relationship is also useful for quantum mechanical problems. In general, a cross section is defined as the number of reactions of a particular kind per second divided by the number of projectile particles falling on the target per second and per unit area:

$$\sigma = \frac{\text{Number of reactions per scattering center/s}}{\text{Number of impinging particles/s/m}^2}.$$

A differential cross section, $d\sigma/d\Omega$, can be defined as the number of reactions that lead to a scattering of a particle into some solid angle $d\Omega$ per second, divided by the same denominator as in the definition of σ above:

$$\frac{d\sigma}{d\Omega} = \frac{\text{Number of scatterings into solid angle } d\Omega \text{ per sca}}{\text{Number of impinging particles/s/n}}$$

The units of the differential cross section are $[d\sigma/d\Omega] = \mathrm{mb/sr}$. The abbreviation *sr* stands for *steradian,* the unit of solid angle. Remember that a sphere subtends a solid angle of $4\pi\,\mathrm{sr}$. Integrating $d\sigma/d\Omega$ over the unit sphere gives the total cross section:

$$\sigma = \int_{4\pi} \left(\frac{d\sigma}{d\Omega} \right) d\Omega.$$

Before we finish with classical considerations, let's examine the impulse (momentum transfer) that the target receives from the projectile. Since the collision is elastic and the target is assumed to be much heavier than the projectile, the lengths of the initial and final momentum vectors of the projectile are the same, $\overrightarrow{p_\mathrm{i}} = \overrightarrow{p_\mathrm{f}}$, and thus the vectors are the equal sides of an isosceles triangle.

Figure 39.9 shows the initial and final momentum vectors for the scattering event depicted in Figure 39.7a, together with the momentum transfer (green vector). If the deflection angle is bisected, the line crosses the momentum transfer vector at a right angle. This forms a right triangle with angles $\frac{1}{2}\theta, \frac{1}{2}\pi$, and α. Because the sum of the angles in a triangle is always π, it follows that $\frac{1}{2}\theta + \frac{1}{2}\pi + \alpha = \pi$, and thus $\alpha = \frac{1}{2}\pi - \frac{1}{2}\theta$. The absolute value of the momentum transfer, $\Delta p = \Delta\overrightarrow{p} \equiv \overrightarrow{p_\mathrm{f}} - \overrightarrow{p_\mathrm{i}}$, can then be expressed as a function of the deflection angle θ:

$$\Delta p = 2p_\mathrm{i}\cos(\alpha) = 2p_\mathrm{i}\cos\left(\tfrac{1}{2}\pi - \tfrac{1}{2}\theta\right) = 2p_\mathrm{i}\sin\left(\tfrac{1}{2}\theta\right). \quad \textbf{(39.2}$$

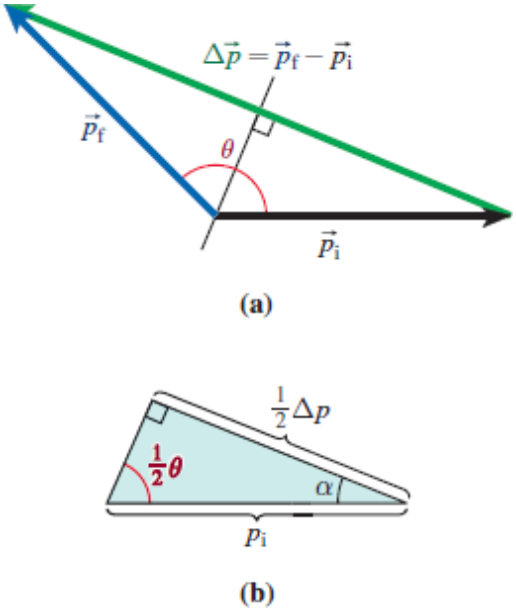

FIGURE 39.9 (a) Momentum transfer for the same deflection angle as in Figure 39.7a. (b) Right triangle formed by the initial momentum and one-half of the momentum transfer.

For backward scattering $(\theta = \pi)$, the momentum transfer is at its maximum, with value $2p_i$, and for forward scattering $(\theta = 0,)$ no collisions), the momentum transfer is zero. Keep in mind that we have assumed that the target is much heavier than the projectile. If this is not the case, then the previous considerations are still true if, instead of using the laboratory frame as was done here, we use the center-of-mass frame to calculate the deflection angle and momentum transfer. In particular, if the projectile is as heavy or heavier than the target, then no backward scattering can be observed in the laboratory frame. (This observation was made in Chapter 7 for one-dimensional collisions of two carts with different masses on a frictionless track.)

Rutherford Scattering

As mentioned in Chapter 38, the experiments of Hans Geiger and Ernest Marsden, and their interpretation by Ernest Rutherford, gave definite proof that the atom consists of an outer layer of electrons surrounding a nucleus. What did Geiger and (then undergraduate student) Marsden actually do?

Figure 39.10 shows the basic setup of the Geiger-Marsden experiment. They used a radioactive polonium source that emitted alpha particles. (Alpha emission as one possible radioactive decay mechanism will be discussed in Chapter 40.) For now, all you need to know is that the alpha particle is the nucleus of a helium atom and has a charge of $+2e$. The kinetic energy of the alpha particle is typically on the order of 5 MeV. Geiger and Marsden scattered alpha particles off thin gold foil and observed the resulting angular distribution. What can we expect from the scattering in this setup?

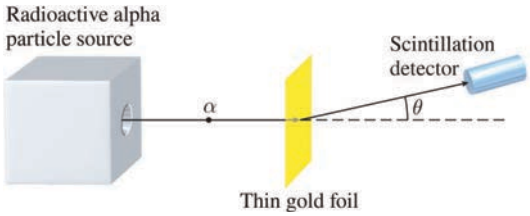

FIGURE 39.10 Basic setup of the Geiger-Marsden experiment in which alpha particles were scattered off gold foil.

Let's first calculate the de Broglie wavelength of a 5-MeV alpha particle. The alpha particle has a mass of $3.73\ \mathrm{GeV}/c^2$, so a kinetic energy of 5 MeV corresponds to a momentum of 193 MeV/c. (Because the mass is very large compared to the kinetic energy in this case, we can use the nonrelativistic approximation, $p = \sqrt{2Em}$.) Thus, the de Broglie wavelength of a 5-MeV alpha particle is

$$\lambda = \frac{h}{p} = \frac{4.136 \cdot 10^{-15}\ \mathrm{eV\,s}}{193\ \mathrm{MeV}/c} = 6.4 \cdot 10^{-15}\mathrm{m}.$$

The discussion of diffractive scattering of waves in Chapter 34 showed that the angle of the diffraction maximum is approximately $\theta_{\mathrm{d}} \approx \lambda/R$, where R is the radius of the object the waves diffract off —in this case, the atom. At the time, the most prominent model of the atom was the "plum pudding" model, in which negatively charged electrons were thought to be randomly distributed over the volume of the atom, similar to raisins within a plum pudding. The dough of the plum pudding was supposed to be the distribution of positive charge. Geiger and Marsden expected to see diffractive scattering with angles

$$\theta_{\mathrm{d}} \approx 6 \cdot 10^{-15}\mathrm{m}/10^{-10}\mathrm{m} = 6 \cdot 10^{-5}\mathrm{rad} = 0.003^{\circ}.$$

In other words, they expected extremely forward-peaked angular distributions. (The limitations imposed by quantum mechanics are discussed in more detail in the next subsection.)

However, to their surprise, Geiger and Marsden observed a significant amount of scattering at large angles, and even some scattering at backward angles. When Ernest Rutherford saw the data, he compared the alpha particles to artillery shells reflected backward by tissue paper. This observation led him to formulate the Rutherford model of the atom, with a very small positively charged nucleus in the center.

Rutherford considered the scattering of a charged particle with (positive) charge $Z_{\mathrm{p}}e$ off a target nucleus with (also positive) charge $Z_{\mathrm{t}}e$. The interaction between these two particles takes place via the Coulomb potential (see Chapter 23), and the potential energy is

$$U = k\frac{Z_{\mathrm{p}}Z_{\mathrm{t}}e^2}{r},$$

where k is Coulomb's constant. Rutherford found that the differential cross section can be written as

$$\frac{d\sigma}{d\Omega} = \left(\frac{kZ_{\mathrm{p}}Z_{\mathrm{t}}e^2}{4K}\right)^2 \frac{1}{\sin^4\left(\frac{1}{2}\theta\right)}, \qquad \textbf{(39.3)}$$

where K is the kinetic energy of the projectile particle.

Note that the Rutherford formula (equation 39.3) assumes that projectile and target are both point charges. As Figure 39.11 shows, this formula has a very good fit with the number of scintillation counts per minute (which are proportional to the differential cross section) as a function of the deflection angle.

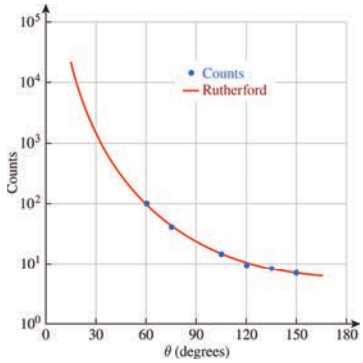

FIGURE 39.11 Comparison of the Rutherford scattering formula (red line) and the angular dependence of the scintillation counts per minute (blue dots), as reported by Geiger and Marsden (*Phil. Mag.* 25 (1913) 604).

Source: Geiger and Marsden (Phil. Mag. 25 (1913) 604).

The relationship between the scattering angle and the momentum transfer that was derived above (equation 39.2) then gives

$$\frac{d\sigma}{d\Omega} = \left(2kZ_{\mathrm{p}}Z_{\mathrm{t}}e^2 m_{\mathrm{p}}\right)^2 \frac{1}{(\Delta p)^4}, \qquad \textbf{(39.4)}$$

where we have used the nonrelativistic approximation $K = p^2/2m_{\mathrm{p}}$, and where m_{p} is the mass of the projectile. (If we drop the assumption of an infinitely heavy target, then we have to use the reduced mass, $\mu = m_{\mathrm{p}}m_{\mathrm{t}}/(m_{\mathrm{p}} + m_{\mathrm{t}})$, instead of m_{p}.)

EXAMPLE 39.1 Backward Scattering of Alpha Particles

We can get a useful upper limit for the size of the atomic nucleus from the observation that 5.00-MeV alpha particles can be scattered in the backward direction.

PROBLEM

How close can a 5.00-MeV alpha particle get to a gold nucleus if the only interaction between them is the Coulomb force?

SOLUTION

We can use a straightforward application of conservation of total mechanical energy. Far from the nucleus, the alpha particle has a kinetic energy of 5.00 MeV and a potential energy of zero. As it approaches the gold nucleus, more and more kinetic energy is converted into potential energy. At the point of closest approach, the alpha particle has zero kinetic energy, and all its initial kinetic energy has been converted to potential energy. The alpha particle has a charge of $+2e$ and the gold nucleus has a charge of $+79e$, so the electrostatic potential energy between them is

$$U(r) = k\frac{(2e)(79e)}{r} = ke^2\frac{2(79)}{r}.$$

This gives us the equation

$$ke^2\frac{2(79)}{r_{\text{min}}} = 5.00\,\text{MeV},$$

which we need to solve for the minimum distance, r_{min}. The product ke^2 has the dimensions of energy times length. We can evaluate it as follows:

$$\begin{aligned} ke^2 &= \left(8.9876 \cdot 10^9 \text{Jm/C}^2\right)\left(1.602 \cdot 10^{-19}\text{C}\right)^2 \\ &= 2.307 \cdot 10^{-28}\text{J m} \\ &= 1.440 \cdot 10^{-9}\text{eV m} = 1.44\,\text{MeV fm}. \end{aligned}$$

Therefore, we find for the minimum distance:

$$r_{\text{min}} = \frac{(1.44\,\text{MeV fm}) \cdot 2 \cdot 79}{5.00\,\text{MeV}} = 45.5\,\text{fm}.$$

The upper bound for the radius of the gold nucleus that we obtain from the backscattering of a 5-MeV alpha particle is $4.55 \cdot 10^{-14}$m, which is approximately a factor of 3000 smaller than the radius of a gold atom, which is $1.4 \cdot 10^{-10}$m.

DISCUSSION

The radius of a gold nucleus is approximately 7 fm. Our upper bound is bigger than the real radius of the gold nucleus by a factor of 7, but it is astonishing that such a simple experiment and calculation can yield a result for the radius of the atomic nucleus that has the right order of magnitude.

Why did we use a 5-MeV alpha particle, and not one with 10 MeV kinetic energy, in this example? One reason is that Geiger and Marsden used alpha particles with approximately 5 MeV of kinetic energy. But more importantly, if alpha particles with kinetic energy that is too high are used, the Rutherford scattering approximation breaks down, as we discuss next.

The Rutherford scattering formula (equation 39.3) predicts a $1/K^2$ dependence of the differential cross section on the kinetic energy. However, as the kinetic energy becomes higher, the alpha particle comes closer to the nucleus. At some point, the two nuclei "touch" and the Rutherford formula breaks down. This result is shown very impressively in Figure 39.12, where the differential cross section for alpha particles deflected off lead at a scattering angle of $\theta = 60^\circ$ is shown as a function of the kinetic energy of the

alpha particles. Clearly, small kinetic energies show agreement with the Rutherford formula, but above 28 MeV, a clear deviation occurs.

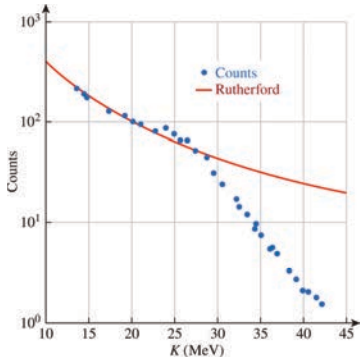

FIGURE 39.12
Dependence of the differential cross section at 60° on the kinetic energy of the alpha particle scattering off lead nuclei (blue circles), as reported by Eisberg and Porter (Rev. Mod. Phys. 33 (1961) 190). The red curve shows the expectation values from Rutherford formula.

Source: Eisberg and Porter (Rev. Mod. Phys. 33 (1961) 190).

Quantum Limitations

Let's now use what we've learned so far about quantum mechanics to estimate the order of magnitude of the various quantities involved in particle scattering. To resolve structure of size Δx, projectile particles are needed that have a momentum that is larger than the momentum uncertainty Δp_x that is associated with a coordinate space uncertainty Δx. The Heisenberg Uncertainty Relation requires that $\Delta x \cdot \Delta p_x \geq \frac{1}{2}\hbar$ (see Chapter 36), so the minimum momentum needed for a particle to probe a spatial size of Δx is of the order

$$p_{\text{min}} \approx \frac{\hbar}{\Delta x}.$$

The minimum particle energy is then

$$E_{\text{min}} = \sqrt{p_{\text{min}}^2 c^2 + m^2 c^4} = \sqrt{\frac{\hbar^2 c^2}{\Delta x^2} + m^2 c^4}.$$

The product of the constants $\hbar$ and c appears frequently enough that it is worthwhile to know its value:

$$\hbar c = \left(6.58212 \cdot 10^{-16}\ \text{eV s}\right)\left(2.99792 \cdot 10^{8}\ \text{m/s}\right) = 197.327\ \text{M}$$

In Example 39.1 we calculated the combination of the Coulomb constant k times the square of the elementary charge quantum e and found that this product also has the units MeV fm. We can take the ratio of these two products that have the same units to find a dimensionless number called the **fine-structure constant**, α, so named because it first appeared in a theory by Arnold Sommerfield to explain the fine structure in spectral lines. His theory was incorrect but the constant is useful, as we will see later, as the coupling constant for electromagnetic interactions:

$$\alpha = \frac{ke^2}{\hbar c} = \frac{e^2}{4\pi \in_0 \hbar c} = \frac{1}{137.036}.$$

The value of α is known to much greater precision than stated here, to about one part in a billion. However, for most purposes it is sufficient to remember that $\alpha = 1/137$.

Page 1238

Probing smaller dimensions requires using projectile particles with higher momenta and energies. Figure 39.13 shows the minimum kinetic energies, $K = E - mc^2$, that electrons (mass $= 511\,\mathrm{keV}/c^2$, red curve), photons (mass = 0, blue line), and alpha particles (mass $= 3.73\,\mathrm{GeV}/c^2$, green line) have to probe structure of size Δx. Note that the curve for the electron kinetic energy merges with that of the photon for energies high enough that the mass of the electron becomes negligible compared to its kinetic energy. (The same would happen for the alpha particle when its kinetic energy exceeds its rest mass of $3.73\,\mathrm{GeV}/c^2$, but as we will see later, the alpha particle is a composite particle, so it does not make sense to use it for scattering experiments at these high energies to probe the substructure of some other object.) Chapter 38 established that the atomic size is on the order of $10^{-10}\mathrm{m}$. Thus, Figure 39.13 shows that probing structure on the atomic scale requires photons with kinetic energies of at least a few thousand electron-volts or electrons with kinetic energies of at least a few tens of electron-volts.

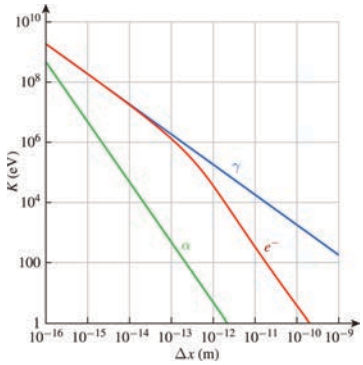

FIGURE 39.13
Minimum kinetic energy required to probe a structure of a given size for electrons (red), photons (blue), and alpha particles (green).

Alternatively, the same order-of-magnitude result can be obtained by using the postulate that the de Broglie wavelength, $\lambda = h/p$, of the probe needs to be smaller than the spatial resolution to be explored. Within a factor of π, the two answers are the same. (We are only interested in the order of magnitude, so a factor of 2 or π is not relevant.)

Quantum Wave Scattering

The Rutherford scattering formula (equation 39.3) was derived with the classical considerations employed above, but it turns out to be correct in the quantum mechanical case as well. For the scattering of quantum waves, consider a plane wave e^{ikz} incident on a target. The target then emits a spherical wave that depends on the polar angle θ, as depicted in Figure 39.14. (Just as for the classical scattering process, we assume no dependence on the azimuthal angle, implying symmetry with respect to rotation about the z-axis.) Then the wave function for the stationary (time-independent) solution of the scattering problem can be written as the sum of the incident plane wave plus the outgoing spherical wave, which is assumed to be emitted from a pointlike distribution without measurable spatial size:

$$\psi_{\text{total}}\left(\vec{r}\right) = \psi_{\text{i}}\left(\vec{r}\right) + \psi_{\text{f}}\left(\vec{r}\right) = N\left(e^{ikz} + f(\theta)\frac{e^{ikr}}{r}\right). \quad \textbf{(39.5}$$

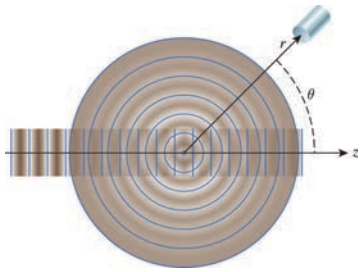

FIGURE 39.14
Scattering of a plane wave, moving from left to right along the z-direction, with a target emitting a spherical wave.

Here N is a normalization constant and $f(\theta)$ is the scattering amplitude. The physical meaning of the scattering amplitude can

be extracted as follows. The number of impinging projectile particles per unit area per unit time used for the definition of the differential cross section (equation 39.1) is the particle density of the incident wave, $\psi_{\mathrm{i}}\left(\overrightarrow{r}\right)^2 = Ne^{ikz}{}^2 = |N|^2$. The number of particles per unit time scattered into the area $dA = r^2 d\Omega$ is

$$\begin{aligned}
\psi_{\mathrm{f}}\left(\overrightarrow{r}\right)^2 dA &= N\left(f(\theta)\frac{e^{ikr}}{r}\right)^2 dA \\
&= |N|^2 |f(\theta)|^2 \frac{1}{r^2} dA \\
&= |N|^2 |f(\theta)|^2 \frac{1}{r^2} d\Omega \\
&= |N|^2 |f(\theta)|^2 d\Omega.
\end{aligned}$$

Therefore, we find from the definition of the differential cross section (equation 39.1) that

$$\frac{d\sigma}{d\Omega} = \frac{\psi_{\mathrm{f}}\left(\overrightarrow{r}\right)^2 dA}{\psi_{\mathrm{i}}\left(\overrightarrow{r}\right)^2 d\Omega} = \frac{|N|^2 |f(\theta)|^2 d\Omega}{|N|^2 d\Omega} = |f(\theta)|^2. \quad \textbf{(39.6)}$$

That is, the differential cross section is the absolute square of the scattering amplitude.

If we relax the condition that the outgoing spherical wave is emitted from a single point, then we can ask how the Rutherford scattering cross section has to be modified. The **form factor,** $F^2(\Delta p)$, is the square of the Fourier transform of the charge distribution, $\rho\left(\overrightarrow{r}\right)$, of the target:

$$F^2(\Delta p) = \left| \frac{1}{e} \int \rho\left(\overrightarrow{r}\right) e^{i\Delta\overrightarrow{p}\cdot\overrightarrow{r}/\hbar} dV \right|^2, \qquad \textbf{(39.7)}$$

where the volume integral extends over three-dimensional coordinate space. A Fourier transform is a technique that allows us to express a function of one variable, such as $\overrightarrow{r}$, as a function of another, related variable, such as Δp.

The form factor determines how the actual charge (or mass) distribution influences the cross section. In other words, the form factor measures the deviation from the Rutherford pointlike scattering formula (equation 39.4) with the Δp^{-4} dependence on the momentum transfer:

$$\frac{d\sigma}{d\Omega} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{point}} \cdot F^2(\Delta p). \qquad \textbf{(39.8)}$$

In general terms, the scattering of a point particle shows the least-steep fall-off as a function of increasing angle or momentum transfer. Any extended source results in a steeper fall-off of the differential cross section, due to the form factor. If the form factor could be measured at all values of the momentum transfer, then the Fourier transform (equation 39.7) could be inverted directly. However, it is usually not feasible to obtain such measurements with the necessary accuracy. Instead, the usual procedure is to use a charge density distribution with adjustable parameters—for example, the mean radius—and fit these parameters to provide the best match with the experimental scattering data. One example of the use of this procedure is shown in Figure 39.15.

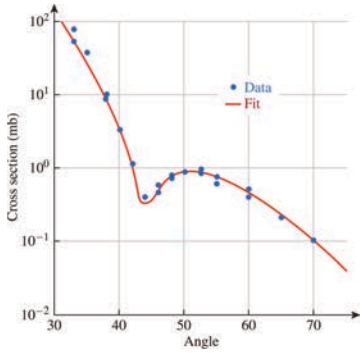

FIGURE 39.15 Scattering of 420-MeV electrons off oxygen. The blue circles represent experimental data; the red curve is the best fit using the form factor, as reported by R. Hofstadter (*Annual Reviews of Nuclear Science* 7 (1957) 231).

39.3 Elementary Particles

A short time after Rutherford's discovery that the nucleus of an atom is smaller than the radius of an atom by a factor of 10,000, it became clear that the atomic nucleus consists of positively charged protons and uncharged neutrons. (Neutrons were discovered in 1932 by the British physicist James Chadwick (1891–1974).)

For a brief period in the 1930s, reductionists were very content with the emerging picture of elementary particles. Only three fundamental indivisible fermionic particles were known—the positively charged proton, the uncharged neutron, and the negatively charged electron. In addition, there was only one known boson, the photon. In 1930, the German physicist Wolfgang Pauli (1900–1958) postulated another fermion, the neutrino, to explain the missing energy in beta decay. (Beta decay is explained later in this chapter.) In addition, in 1935, the Japanese physicist Hideki Yukawa (1907–1981) postulated yet one more boson, the pion, as the particle responsible for the strong interaction (also addressed later in this chapter). Dirac had predicted antiparticles in 1928, and Anderson had identified the positron as the antiparticle to the electron in 1932 (see Section 37.10), so it was generally accepted that each of the elementary particles also has its antiparticle. It seemed that physicists were very close to achieving a satisfactory simple, elegant picture of the layer of truly indivisible elementary particles, similar to the Greek ideal of only four or five elements.

However, small problems began to arise with this picture. In 1936, Anderson discovered another elementary particle, the muon, by examining cosmic rays. At first the muon was thought to be the pion postulated by Yukawa, because it had a mass of approximately $100\,\mathrm{MeV}/c^2$, as demanded by the Yukawa theory. The real pion was discovered 11 years later by Cecil Powell and his collaborators. In 1947, George Rochester and Clifford Butler discovered the kaon in cosmic rays as well. Elementary particles were now grouped into baryons (neutron, proton, and others), mesons (pion, kaon, and

others), and leptons (electron, neutrino, muon, and others). Baryons and mesons together are classified as hadrons, which are particles that experience the strong force.

In 1934, Ernest Lawrence (1901–1958) invented the cyclotron, a powerful tool for accelerating particles to higher energies, and the era of accelerator-based physics began. Ever bigger accelerators reaching ever higher energies led to discoveries of more and more "elementary" particles. Eventually, scientists came to believe that this large number of particles meant that another level of substructure existed underneath the layer of what was previously considered elementary. From 1953 to 1957, Robert Hofstadter (1915–1990) and his collaborators used the newly invented linear accelerators to perform a basic variation of Rutherford scattering with high-energy electrons impinging on protons. Their work revealed the charge distributions of nuclei (see, for example, Figure 39.15), but also showed that the proton has a substructure. This means that the proton is composed of even smaller, more fundamental particles. In 1964, Murray Gell-Mann gave this group of particles that make up the proton and other hadrons the name **quarks** (after the phrase "three quarks for Muster Mark" from the novel *Finnegan's Wake* by James Joyce).

This section summarizes the ingredients of the **standard model** of elementary particle physics. It has been in place in its basic form for more than three decades and has withstood a large number of experimental tests. First, we consider the basic constituents, the set of particles currently thought to be fundamental, elementary, or indivisible. These elementary particles have sizes less than 10^{-16}m, which is the approximate experimental limit we can reach, and are probably pointlike—that is, of a size much smaller than the 10^{-16}m that we can resolve. Next, we discuss how these particles interact. Finally, we investigate how the fundamental particles combine to form the next-higher level in the hierarchy of matter.

Elementary Fermions

The elementary fermions are particles with spin $\frac{1}{2}\hbar$, or simply spin $\frac{1}{2}$. (When we say that a particle has a spin that is a number, such as $\frac{1}{2}$, we imply that this number is to be multiplied by $\hbar$.) Chapter 36 showed that a particle's spin is the maximum measurable value for the component of the particle's spin angular momentum in any direction. Fermions include six quarks having names (or *flavors*) of up, down, strange, charm, bottom, and top. These quarks all have a noninteger charge of $-\frac{1}{3}e$ or $+\frac{2}{3}e$. The other fermions are the electron, muon, and tau leptons and the electron-, muon-, and tau-neutrinos. Each of these 12 fermions has an antiparticle.

The original quark flavors of up, down, and strange were introduced by Gell-Mann, and the other three flavors were discovered subsequently. The charm flavor was predicted theoretically in 1970 by Sheldon Glashow, John Iliopoulos, and Luciano Maiani and was discovered experimentally in the form of the J/ψ particle (a meson composed of the charm quark and its antiquark) in 1974 by groups at Stanford Linear Accelerator Center led by Burton Richter and at Brookhaven National Laboratory led by Samuel Ting. The bottom flavor was discovered in 1977 at Fermilab by a collaboration led by Leon Lederman. The top flavor, finally, was discovered simultaneously by two large collaborations, DØ and CDF, at Fermilab in 1995.

Quarks are grouped into three generations, together with the corresponding leptons and neutrinos, as shown in Figure 39.16, where the quarks are indicated by the first letter of their names. Each particle has an antiparticle with the same mass and opposite charge. Table 39.1 lists the charges, masses, and antiparticles for all elementary fermions. The notation for the antiparticle is the same as for the particle, with a horizontal bar added above the symbol. The only exceptions are the antiparticles of the electron, muon, and tau lepton. These antiparticles have a positive sign as superscript instead of the negative sign of their corresponding particles.

Generation:	1	2	3
Charge −1/3 quark:	d	s	b
Charge +2/3 quark:	u	c	t
Lepton:	e^-	μ^-	τ^-
Neutrino:	ν_e	ν_μ	ν_τ

FIGURE 39.16

Two fundamental conservation laws can be stated at this point: the conservation laws for total lepton number and for total quark number. These laws hold for any reaction or decay process. The **total lepton number,** ℓ_{net}, is simply the number of leptons minus the number of anti-leptons and is constant in time:

$$\ell_{\text{net}} = n_{\ell} - n_{\bar{\ell}} = \text{constant}. \qquad \textbf{(39.9)}$$

An example of the conservation of total lepton number occurs in the decay of the neutron. A neutron decays into a proton, an electron, and an anti-electron-neutrino:

$$n \rightarrow p + e^{-} + \upsilon_e. \qquad \textbf{(39.10)}$$

The total lepton number before the neutron decays is zero. The total lepton number after the decay is $\ell_{\text{net}} = 1 \text{ lepton}(e^{-}) - 1 \text{ anti-lepton}(\upsilon_e) = 0$, so the total lepton number before the neutron decays is equal to the total lepton number after the decay. The process in equation 39.10 is the prototypical beta-decay process, which we will study in Chapter 40.

Until recently, physicists thought not only that total lepton number is conserved, but also that it is conserved separately for each generation. This would mean that the net number of electron leptons (number of electrons plus number of electron-neutrinos minus number of positrons minus number of anti-electron-neutrinos) is conserved, and separately the net number of muon leptons is conserved, and separately the net number of tau leptons

is conserved. Indeed, these separate conservation laws are valid if the standard model of elementary particle physics holds. However, the process of neutrino oscillations, discussed later in this section, invalidates the standard model and the strict conservation laws for each individual lepton species, and only the conservation law for total lepton number in the form of equation 39.9 survives.

In the same way, the **net quark number**, Q_{net}, can be defined as the difference between the total number of quarks and the total number of antiquarks and is also constant in time:

$$Q_{\text{net}} = n_q - n_q = \text{constant}. \qquad \textbf{(39.11)}$$

All physical processes have to obey the fundamental conservation laws of lepton number (equation 39.9) and quark number (equation 39.11), in addition to all of the previously introduced conservation laws of charge (Chapter 21), energy (Chapter 6), momentum (Chapter 7), and angular momentum (Chapter 10). The conservation law of quark number is more often expressed as the conservation law of **baryon number**. This law states that the difference between the number of baryons and the number of anti-baryons is constant in time. It was found before quarks were discovered. Because baryons are composed of quarks, the baryon number conservation law is equivalent to the quark number conservation law stated in equation 39.11.

Elementary particles have a huge range of masses, as shown in Figure 39.17. From the observation of neutrino oscillations, we know that at least one species of neutrino must have a nonzero mass, but presently we can state only upper bounds for the neutrino masses, with the mass of the electron-neutrino being smaller than $0.46\ \text{eV}/c^2$. The light quark masses (u and d) and the lepton mass (e^-) of the first generation are all of the order $1\ \text{MeV}/c^2$. The masses of the second-generation quarks (s and c) and leptons (μ^-) are two to three orders of magnitude larger, in the range $100\ \text{MeV}/c^2$ to GeV/c^2. The masses of the third-generation quarks (b and t) and leptons (τ^-) are in the multi-GeV/c^2 to 100-GeV/c^2 range. Why these particles have the masses they do is currently not known and is an open research

topic. It is thought that a particle called the Higgs boson (discussed in the following subsection) is responsible for the generation of the mass of the elementary particles. A linear collider planned for the future, with the working name International Linear Collider, would enable physicists to study the Higgs boson in detail. They hope to then gain an understanding of what sets the scale for the different particle masses.

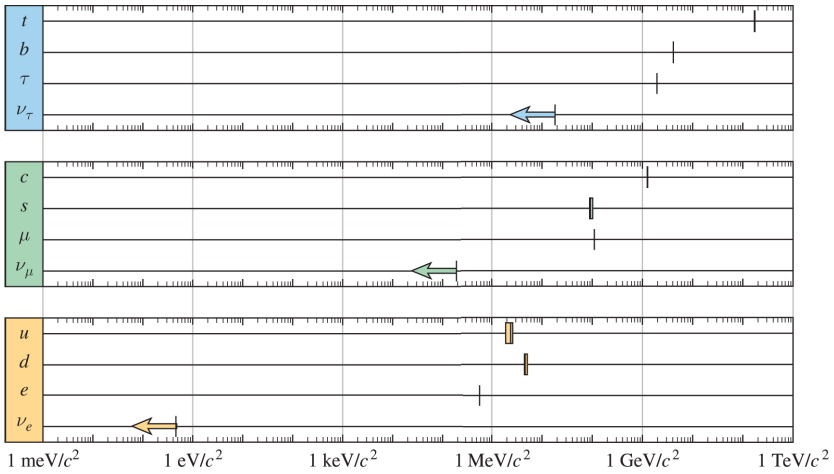

FIGURE 39.17 Current best values for the masses of the elementary fermions. The widths of the boxes indicate the measurement uncertainty. The arrows indicate that the neutrino masses are upper limits.

Is it possible that more than these three generations of fundamental fermions exist? Yes, but we have strong experimental evidence from the decay of W and Z bosons that there are indeed only exactly three generations.

Before we leave the topic of elementary fermions, it is important to note several observations that point to problems in the standard model, possibly hinting at the need for a more fundamental framework.

First, isolated quarks have never been observed, despite a long history of high-precision searches. We will come back to the reason for this when we discuss the interaction of quarks with one

another. While we can understand the reasons why it is impossible to isolate a single free quark, it is still legitimate to ask if it is philosophically consistent to speak of a fundamental indivisible particle, if we cannot isolate it.

Second, it is a puzzle why the combined electrical charge of two up quarks and one down quark (we will see below that they combine to make a proton) is exactly the same as the charge of the positron (the opposite of the charge of an electron). Physicists have tested this equality to an incredible precision, better than one part in a trillion, but have never found any violation of it.

Finally, experimental observations have established that the three neutrino species, v_e, v_μ, and v_τ, can change from one species to the other and back again. This phenomenon of neutrino species changes, or **neutrino oscillations,** cannot be explained by the standard model of particle physics.

Fundamental Bosons and Interactions

What about interactions between elementary fermions? How do they exert forces on each other? The answer is that on the fundamental level, all forces are mediated through the exchange of bosons. A full understanding of this concept requires a grasp of quantum field theory, which goes beyond the scope of this book. Some people find it helpful to think of this particle exchange as being similar to two people standing on skateboards and throwing a heavy ball back and forth, thus exerting forces on each other through the exchange of momentum that accompanies the transfer of the ball. However, this analogy is rather crude, because it neglects the wave character of the bosons exchanged. It also can only account for repulsive, and not attractive, interactions.

In classical mechanics or in relativistic mechanics (see Chapter 35), a free particle cannot emit another particle and conserve energy and momentum in the process. However, the Heisenberg uncertainty relation (see Chapter 36) allows a violation of energy conservation of order ΔE over a time $\Delta t < \hbar/\Delta E$. Because this "borrowed" energy has to include the mass energy, $m_\mathrm{b}c^2$, of the exchange boson, we find $\Delta t < \hbar/\Delta E < \hbar/m_b c^2$. Also, because the exchanged boson can travel with at most the speed of light, we find $\Delta x \leq c\Delta t$ for the range and thus

$$\Delta x < \frac{\hbar c}{m_\mathrm{b}c^2}.$$

Thus, an exchange boson of mass m_b can mediate an interaction only over a range that is inversely proportional to this mass. Infinite-range forces like the Coulomb force thus require an exchange boson that is massless. Table 39.2 lists the elementary bosons of the standard model of particle physics, with their spins (all integers, since they are bosons), their masses, and their charges. You can see that the W^- boson has a mass of more than $80\ \mathrm{GeV}/c^2$. This implies an extremely short-range force of

$$\Delta x\left(W^{-}\right) < \frac{\hbar c}{m_{W^{-}} c^2} = \frac{197.33\ \text{MeV fm}}{80,399\ \text{MeV}} = 2.5 \cdot 10^{-3}\ \text{fm}.$$

Table 39.2 Elementary Bosons

Name	Symbol	Spin ($\hbar$)	Mass$\left(\text{GeV}/c^2\right)$	Charge (e)	Int

Photon

The photon is the massless spin-1 exchange boson of the electromagnetic interaction. It has zero charge. Chapters 21 to 38 examined aspects of the interactions mediated by photons. Since the photon spin is 1, it is called a *vector boson,* as opposed to a *scalar boson* with spin 0.

W Boson

Quarks and leptons can also interact via the so-called **weak interaction.** This interaction can change one quark flavor into another via the emission of a lepton and a neutrino. The weak interaction is the *only* interaction that can change quark flavor. One example of such a reaction is

$$d \rightarrow u + e^- + \nu_e. \qquad \textbf{(39.12)}$$

The decay of a down quark is similar to the decay of a neutron (equation 39.10), but occurs on the fundamental level. The down quark has a charge of $-\frac{1}{3}e$ and thus needs to emit a particle with charge $-e$ to convert itself to an up quark with charge $+\frac{2}{3}e$. This is accomplished by emitting a W^- boson, which in turn decays into an electron and an anti-electron-neutrino. You can easily convince yourself that both sides of equation 39.12 have the same net charge, quark number (equation 39.11), and total lepton number (equation 39.9).

It is also important to note that the masses of the particles on the right side of equation 39.12 must sum up to a number no greater than the mass on the left side. This is required by the conservation of total energy. Table 39.1 shows that the mass of the down quark is $5\text{MeV}/c^2$ This is greater than the mass of the up quark of $2.2\text{MeV}/c^2$ plus the mass of the electron of $0.511\text{MeV}/c^2$ and the negligible mass of the anti-electron-neutrino. In the intermediate stage, the beta-decay process of equation 39.12 may require the emission of a W^- boson with mass of more than 80 GeV/c^2, but in going from the initial state of this reaction to the final state, energy still must be conserved. The intermediate creation and subsequent decay of the W^- boson are said to be *off-shell* (in the sense of "off the energy shell," that is, not at constant

energy), and thus the intermediate W^- boson is called a **virtual particle.**

Figure 39.18 shows a slightly different view of the quark masses than that presented in Figure 39.17. Here the quarks are sorted not by generation but by charge, allowing the diagram to show all possible beta decays. Since all beta decays have to conserve energy, and since the quark mass increases from left to right, the only reactions that are possible have an arrow that points toward the left side, that is, from a higher-mass quark to a lower-mass one. In addition, beta decay involves the emission of a charged lepton, and thus only arrows between quarks of different charge are allowed, that is, no horizontal arrows are possible. The green arrows show all possible β^- decays. One of these was described in equation 39.12. The red arrows show all possible β^+ decays; these are decays that involve creation of a virtual W^+ boson. Beta decays within the same generation of quarks are most common (solid lines in Figure 39.18). Beta decays that involve a jump into a neighboring generation of quarks are much more rare (dashed lines), and beta decays that involve a conversion from the third generation to the first generation (dotted lines) are extremely rare.

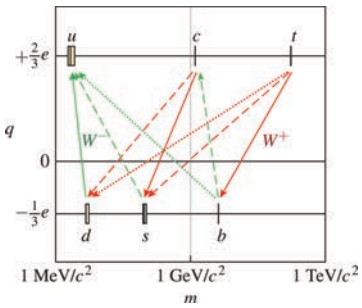

FIGURE 39.18 All possible beta decays of quarks. The red arrows represent β^+ decays, and the green arrows β^- decays. Energy conservation requires that all arrows point only toward the left, never to the right.

Z Boson

So far we have only talked about charged leptons and quarks and their electromagnetic and weak interactions. What about uncharged elementary particles? The chapters on electromagnetism showed that uncharged particles do not participate in the electromagnetic interaction. (The neutron has a magnetic moment, but this is due to the fact that it is a composite particle.) Uncharged elementary particles can, however, participate in the weak interaction. The mediator of this interaction needs to be a charge-0 boson, the Z boson. An exchange of an intermediate Z boson is the underlying mechanism of the scattering of a neutrino off an electron.

Self-Test Opportunity 39.1

Use Figure 39.18 to write reaction equation similar to eqution 39.12 for the other two of the most common beta-decay processes—those represented by the solid arrows in the figure.

The W and Z bosons were both postulated in 1968 in a theory developed by the Americans Sheldon Glashow and Steven Weinberg and the Pakistani Abdus Salam. Their formulation provided a unified description of the electromagnetic interaction and the weak interaction, which is now called the *electroweak interaction*. The scattering of neutrinos off electrons, discovered by the Gargamelle collaboration in 1973 at CERN, provided indirect evidence for the existence of the Z boson and convinced the physics community of the validity of the electroweak theory. The W and Z bosons were discovered in early 1983, right after the completion of the CERN SPS accelerator (which is now used as the smaller injector ring for the LHC; see Figure 39.4), by the UA1 and UA2 collaborations. Glashow, Weinberg, and Salam received the 1979 Nobel Prize in Physics for their theoretical work, and the 1984 Nobel Prize in Physics was awarded to the Italian Carlo Rubbia, the leader of the UA1 collaboration, and the Dutch accelerator physicist Simon van der Meer, whose work on stochastic beam cooling made

possible the operation of the SPS and the discovery of the W and Z bosons.

Table 39.2 shows that the mass of the Z boson is $91.2\ \mathrm{GeV}/c^2$, which is similar to the mass of a niobium atom. The Z boson can decay into an electron and a positron, which provides a clear experimental signature for this boson, allowing it to be detected and studied directly.

Gluon

The gluon is the mediator of the strong interaction between quarks. To discuss gluons, we need one more detail about quarks. So far, we have told you that quarks come in six flavors. However, they also have another property, which is whimsically called *color*. Quark colors come in three varieties: red (r), blue (b), and green (g). Antiquarks have anti-colors: anti-red $(\bar{r})$, anti-blue $\left(\bar{b}\right)$, and anti-green $(\bar{g})$.

A gluon carries a combination of one anti-color and one color. From this information alone, you might conclude that a total of nine different gluons occur. However, a totally color-neutral gluon consisting of equal admixtures of $r\bar{r}$, $b\bar{b}$, and $g\bar{g}$ is not possible, so there are eight gluons. For example, a blue quark can interact with a red quark by exchanging a $b\bar{r}$ gluon, turning the blue quark into a red one and the red into a blue one. Since gluons carry the color charge, they can couple to one another. Thus, gluons can radiate other gluons, which no other exchange boson can do.

Higgs Boson

In 1964, the British theorist Peter Higgs and others postulated a boson that couples to all other elementary particles, including itself, in such a way as to give them mass. This boson is now called the *Higgs boson*. (In Chapter 4, we already briefly mentioned the Higgs boson because of the relationship between force and mass.) The DØ and CDF experiments at Fermilab's Tevatron accelerator complex have been able to extract first possible glimpses of the Higgs boson in their data. With the completion and operation of the LHC at CERN, however, the search for the Higgs boson has now entered a new phase. The first phase of this search came to a successful conclusion on July 4, 2012, when the ATLAS and CMS detector collaborations jointly announced the discovery of the Higgs boson, with a mass of approximately 125 Gev. Figure 39.19 shows two examples of collisions, in which a Higgs boson was produced, and for which characteristic decay signatures were obtained.

Physicists are currently working hard to understand the properties of this new particle and decode its fundamental importance for the generation of the mass of other particles.

Graviton

We have not yet talked about gravity in the context of quantum mechanics and elementary particles. Like the electromagnetic force, the gravitational force has infinite range. Thus, the exchange boson must have zero mass. In addition, because of the structure of the gravitational interaction as described by general relativity, the spin of this exchange particle must be 2. However, the standard model of particle physics does not address gravity at all, for two reasons, one experimental and one theoretical. Experimentally, gravity is so weak that it has not been possible to observe a graviton directly. The LIGO facility has detected gravitational waves from colliding black holes and neutron stars. LIGO cannot detect gravitons directly. However, much more important is that in its present formulation, the standard model (especially quantum mechanics) and gravity (as described by general relativity) are not compatible theories. This conflict has given rise to a whole new set of theories, including string theories, which we discuss further in Section 39.4

Feynman Diagrams

If virtual particles can be created and destroyed in intermediate steps of reactions, possibly multiple times, then calculating anything that can be connected to experimentally observable consequences can become very complicated. Calculations might have to take into account infinitely many possible processes. Even the question of how to distinguish between processes that contribute a lot and those that contribute very little to the final result can be an insurmountable challenge.

The American physicist Richard Feynman (1918–1988) found an ingenious way to solve this problem by dividing complex interactions into a few elementary pieces, each of which can be represented by a simple drawing called a **Feynman diagram,** which is created according to rules formulated by Feynman. In this way, he developed quantum electrodynamics, for which he shared the 1965 Nobel Prize in Physics with Sin-Itiro Tomonaga from Japan and the American Julian Schwinger, who made independent contributions to the field. Even though quantum electrodynamics describes only the interactions of photons and charged particles, Feynman diagrams have proven to be incredibly useful for all interactions of all particles.

This text cannot give you a working knowledge of using Feynman diagrams, but simply introduces them to provide an excellent pictorial representation of the underlying physics of particle interactions. We start with freely moving particles propagating through vacuum. Each is simply represented by a line with an arrow at the end, indicating the direction of travel. This line is called a *propagator*. Conventionally, time moves from left to right and the vertical dimension of the diagram is a spatial coordinate (Figure 39.20). (Usually it is assumed that time and space are the standard coordinates, so Feynman diagrams do not show the coordinate axes explicitly. Thus, subsequent figures do not include the axes.) A lepton or a quark is represented by an arrow from left to right, a photon or a W or Z boson by a wavy line, and a gluon by a coiled line. (There is no deeper meaning to the different line styles, which simply follow historical convention.)

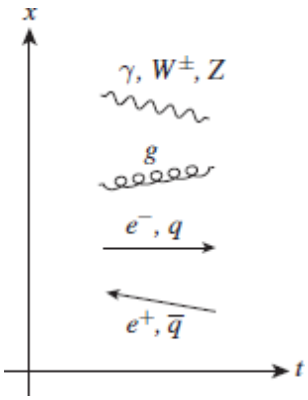

FIGURE 39.20 Feynman diagram showing a freely propagating photon, gluon, electron, positron, quark, antiquark, *W* boson, and *Z* boson.

Antiparticles move from right to left—that is, backward in time. This statement is not just a computational shortcut; it represents a deep underlying symmetry in the physics that governs the particle-antiparticle relationship: The fundamental theoretical construct of physics is invariant under simultaneous reversal of CPT (charge, parity, time). The parity of a particle is an intrinsic property characterized by the behavior of its wave function under reflection through the origin of coordinates, by which the x, y, and z coordinates are replaced by $-x$, $-y$, and $-z$. If the reflected wave function is identical to the original wave function, the parity is positive. If the reflected wave function is the negative of the original wave function, the parity is negative.

Inverting the charge and parity of an electron gives a positron. In order for this conversion to be a physically valid process, time must be reversed as well. The propagator lines are usually not horizontal, because the spatial coordinate is represented in the vertical direction in a Feynman diagram. However, the angle

relative to the horizontal is not a measure for the momentum or velocity, because a Feynman graph is not intended as a plot from which some velocity can be extracted via $\Delta x/\Delta t$-type arguments. The lengths of the lines that represent the different particles also have no physical meaning and are arbitrary.

A Feynman diagram can depict the interaction of different particles. *Any given physical interaction has to have at least two vertices.* A *vertex* is defined as the intersection of three propagator lines. Figure 39.21 shows elementary vertices for six different processes. It is important to realize that none of these vertices shows a physical process that can happen in isolation. For each of these processes, it is impossible to conserve energy and momentum, provided all lines represent real particles. For example, let's look at photon emission from an electron, process (a) in Figure 39.21. In the rest frame of the electron before the emission, all the energy in the system is the rest mass of the electron times c^2, because the electron has no kinetic energy in this frame. After the emission, the photon receives some energy, and the electron experiences recoil, thus also acquiring kinetic energy. Now the total energy in the system in the rest frame is the electron's mass energy plus its kinetic energy plus the photon's energy. Therefore, this process violates energy conservation. From this observation comes an important insight: Each vertex must have at least one virtual particle, which is off-shell, so that $E^2 \neq p^2c^2 + m^2c^4$. Thus, at least two vertices must be combined to create a Feynman diagram that can represent a physically possible process.

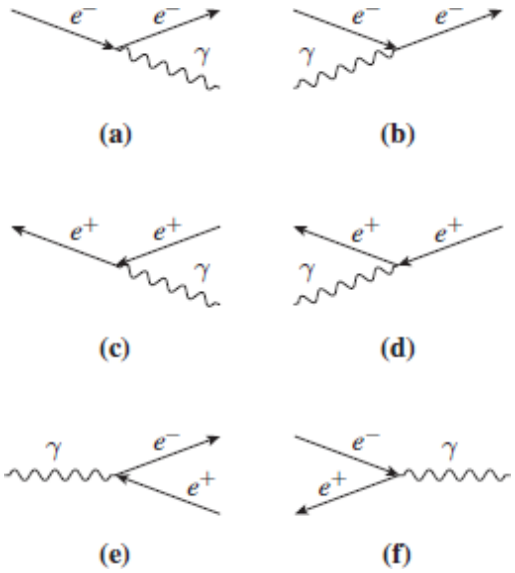

FIGURE 39.21
Elementary Feynman vertices for six different processes: (a) emission of a photon by an electron, (b) absorption of a photon on an electron, (c) emission of a photon by a positron, (d) absorption of a photon by a positron, (e) creation of an electron-positron pair from a photon, (f) electron-positron annihilation into a photon.

The rules that govern the construction of Feynman diagrams representing real processes are as follows:

- All lines that enter or exit a Feynman diagram must represent real particles, for which the energy-momentum relationship $E^2 = p^2c^2 + m^2c^4$ holds.

- Any line that represents a virtual particle, for which $E^2 = p^2c^2 + m^2c^4$ does not hold, must start and end inside the diagram—that is, must have both ends connected to a vertex. This ensures that these virtual particles cannot be observed in experiments.
- At each vertex, energy, momentum, charge, quark number, and all three lepton numbers must be strictly conserved.

From these preliminary considerations, we can produce simple Feynman diagrams. The first physical process we'll consider is the scattering of an electron off a positron (or vice versa).

Figure 39.22 shows four Feynman diagrams, in which an electron and a positron come in and an electron and a positron go out. In all four cases, a virtual photon is exchanged. Thus, all four diagrams represent versions of the same physical process (called *amplitudes*) and need to be added. The cross section for electron-positron scattering can then be calculated by taking the absolute square of this amplitude sum. Note that diagram (a) and diagram (b) in Figure 39.22 differ only in the time ordering of the emission of the photon. In (a) the photon is first emitted by the electron and then absorbed by the positron, and in (b) it is the other way around. Thus, we see that all diagrams that differ only in the internal time ordering represent the same physical process, because there is no way of knowing the internal time ordering of the process. Therefore, both processes (a) and (b) can be written as (c), where the instantaneous exchange of the photon is implied. Process (d) can be interpreted as an electron-positron annihilation into a virtual photon, followed by a pair-creation event.

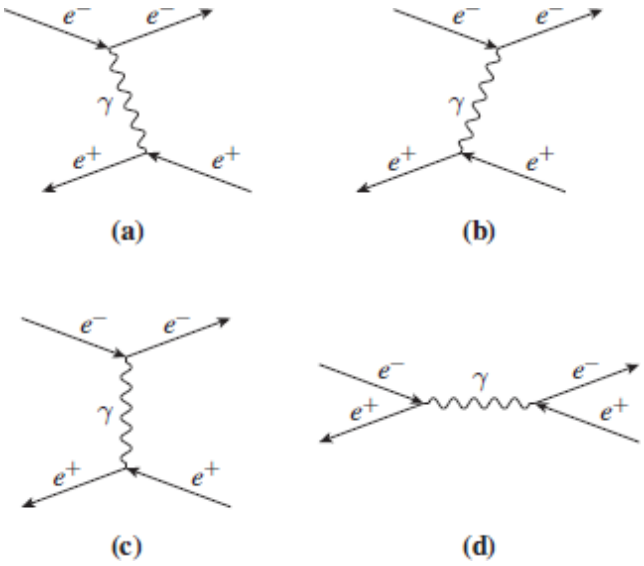

FIGURE 39.22 Four simple Feynman diagrams for electron-positron scattering.

Unfortunately, this is not where the process ends. The electron and positron can also exchange two photons, as shown in Figure 39.23 in one of many possible diagrams, or they can exchange even more photons. For any diagram that involves closed loops of the kind shown in this figure, momentum and energy can travel around a loop without constraint. As a result, we have to integrate over all possible values. Clearly, the summation of diagrams with loops can become arbitrarily complicated very fast.

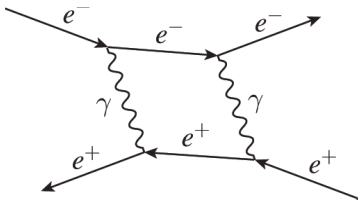

FIGURE 39.23 One possible two-photon exchange diagram for electron-positron scattering.

Here is what saves us: For each virtual photon exchanged, the amplitude for the diagram acquires a multiplicative factor of $\alpha = ke^2/\hbar c = 1/137e$. Thus, the contributions of multiphoton diagrams to the overall amplitude sum quickly become smaller, and the series converges.

This description does not amount to an actual calculation, but at least it indicates what is involved in performing this task. In addition, it allows us to draw a quick picture of the lowest-order contributions to a physical process. For example, we can draw a Feynman diagram for the beta decay (equation 39.12) of the down quark (Figure 39.24). With the aid of this diagram, it is straightforward to check that the conservation laws of charge as well as quark and lepton numbers are obeyed in this process, that is, that the Feynman diagram represents a process that can actually happen physically.

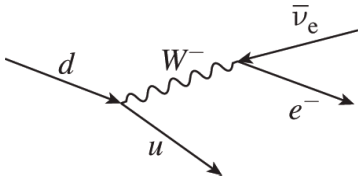

FIGURE 39.24
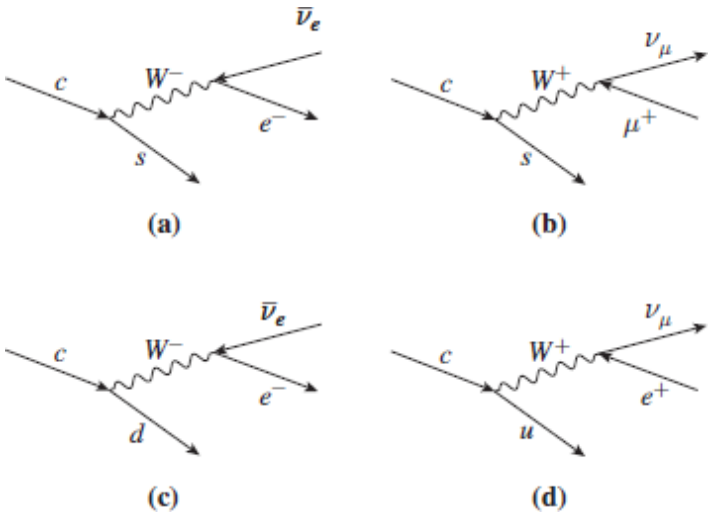
Feynman diagram for the beta decay of a down quark.

Concept Check 39.1

Which of the following is a valid Feynman diagram for the beta decay of a charm quark?



The weak and the electromagnetic interactions can be treated beautifully with Feynman diagrams, because the series of amplitudes represented by different graphs converge quickly. We can also construct Feynman diagrams for the strong interaction. One example is shown in Figure 39.25, where a red up quark exchanges a blue/anti-red gluon with a blue down quark. (More on color will follow in Section 39.5.)

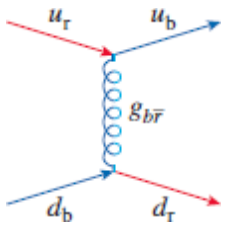


FIGURE 39.25
Simple Feynman graph for a one-gluon exchange in the strong interaction.

However, the situation is much more complicated for the strong interaction, because the coupling constant is not α (which is small compared to 1 in the electromagnetic case), but is approximately 1. Thus, in general, series expansions in terms of Feynman diagrams do not converge. Only for scattering at high momentum are these techniques applicable, as the expansion of the physical process in terms of Feynman diagrams converges quickly enough to be of practical utility. Other methods are needed to perform calculations for the strong interaction.

39.4 Extensions of the Standard Model

Our current understanding is that the interactions in the world around us include three different forces: the strong force, the electroweak force, and gravity. A general guiding principle in the reductionist quest is that it should be possible to show that the different forces are just different aspects of the same force on the next more fundamental level of the reductionist hierarchy. This approach has worked repeatedly to great satisfaction. Figure 39.26 shows a timeline of the unification of forces (previously shown in Chapter 21).

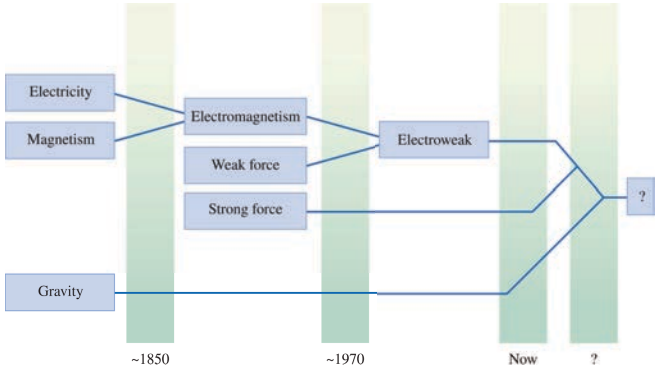

FIGURE 39.26 Timeline of the unification of basic forces.

The chapters on electricity and magnetism described these two forces as two aspects of the electromagnetic force, as described by the set of four Maxwell equations. In Section 39.3, we learned that the weak force can also be unified with electromagnetism to form the electroweak force. Consequently, there have been, and continue to be, new attempts to create theories that provide further unification of all known interactions into one.

In addition, although the standard model of particle interactions has been very successful, many scientists are bothered by its seemingly arbitrary values for parameters such as the quark and lepton masses and the coupling constants. Several candidates for a unified theory free of arbitrary parameters have been

proposed. These theories are mostly based on arguments from a branch of mathematics called *group theory*. However, two essential features are worth discussing: One is the unification energy scale, and another is the decay of the proton.

Unification Energy Scale

The coupling constant of the electromagnetic interaction is the fine-structure constant, α, which has the value 1/137. The coupling constant of the weak interaction has a value of $\sim 1/30$, and the strong interaction has a coupling constant close to 1. The Glashow-Weinberg-Salam theory shows that at high energies, the coupling constants for the electromagnetic and weak force merge. Based on this idea, **grand unified theories** have been proposed that merge all three fundamental interactions at very high energies. Thus, if we were able to scatter particles at extremely high momentum transfer, Δp, we would be able to see all coupling constants merge (Figure 39.27). Unfortunately, the kind of momentum transfer required to test these theories is way beyond what can be achieved with present-day accelerators. However, possible hints about grand unified theories may be hidden in the cosmic ray spectrum, which reaches energies above 10^{20} eV.

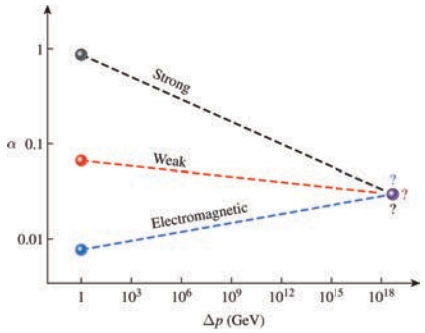

FIGURE 39.27
Proposed change of the coupling constants of fundamental interactions as a function of momentum transfer in a grand unified theory.

Proton Decay

Section 39.3 introduced separate absolute conservation laws for the total number of quarks and for the total number of leptons. However, most grand unified theories predict that at the highest energies, quarks and leptons merge and are thus just different aspects of the same fundamental particle, and that the separation between quarks and leptons that we observe is only a manifestation of the low-energy limit of these unified particles. If this is true, then a quark will be able to decay into a lepton, and a proton (composed of two up quarks and one down quark; see Section 39.5) will not be an absolutely stable particle; instead, it will decay exponentially with a very long (but *not* infinite) lifetime on the order of 10^{30} years.

Because the age of the universe is only on the order of 10^{10} years, a very large number of protons must be observed to have a chance to observe even one proton decay event. This is one of the basic purposes for which the Super-Kamiokande (Super-K) detector was built in Japan (Figure 39.28). Super-K is located 1000 m underground and consists of 50,000 tons of purified water contained in a cylindrical steel tank whose diameter and height are both 40 m. Super-K has 11,200 photon detectors inside the tank walls. It can detect the Cherenkov radiation (see Chapter 16) emitted from the motion of high-energy particles through the water. In 1998, the Super-K collaboration was the first to observe the neutrino oscillations, mentioned previously, which imply that at least one of the neutrino species has nonzero mass. However, after several years of running the detector and looking for possible signals, no proton decay events have been reported, thus setting severe limits for entire classes of possible grand unified theories. The present lower limit on the proton's lifetime has been established experimentally as greater than $1.6 \cdot 10^{34}$ years, approximately one trillion times the current age of the universe.

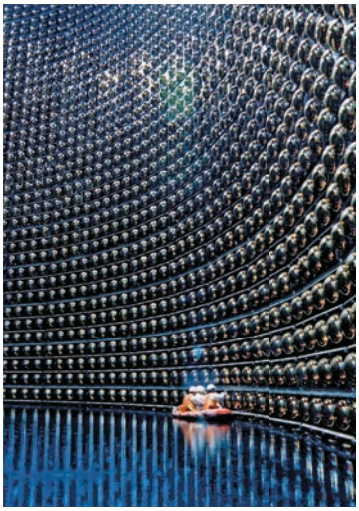

FIGURE 39.28

EXAMPLE 39.2 Planck Units

Max Planck proposed a set of natural units that do not depend on the anthropocentric choices made in determining the SI units that we currently use (see Chapter 1). He looked for combinations of the basic universal physics constants of nature that have the dimensions of length, time, mass, and so on.

PROBLEM

Using the universal constants of the speed of light in vacuum, c, Planck's constant divided by 2π, $\hbar$, Coulomb's constant, $k = 1/4\pi \in_0$, the universal gravitational constant, G,and Boltzmann's constant, k_B, what are the values of the Planck length, time, temperature, mass, and charge in SI units?

SOLUTION

The SI units of the speed of light are $[c] = \mathrm{m/s}$, of Planck's constant are $[\hbar] = \mathrm{kg\,m^2/s}$, of Coulomb's constant are $[k] = \mathrm{kg\,m^3/C^2/s^2}$, of Boltzmann's constant are $[k_\mathrm{B}] = \mathrm{kg\,m^2/s^2/K}$, and of the gravitational constant are $[G] = \mathrm{kg^{-1}m^3/s^2}$.

Our first observation is that the ampere $(\mathrm{A} = \mathrm{C/s})$ appears only in Coulomb's constant and the kelvin (K) appears only in Boltzmann's constant. Therefore, the kinematics-related quantities of length, time, mass, and energy cannot contain either of these two constants, because they are defined in terms of the MKS base units. If we multiply $\hbar$ by G, the unit kg cancels out and we obtain powers of the units m and s. Multiplication with the appropriate power of the speed of light enables us to cancel either one of these. Thus, we obtain for the Planck length and the Planck time:

$$x_\mathrm{p} = \sqrt{\frac{\hbar \mathrm{G}}{c^3}}$$
$$t_\mathrm{p} = \frac{x_\mathrm{p}}{c} = \sqrt{\frac{\hbar \mathrm{G}}{c^5}}.$$

For the Planck mass, we must find a combination of $\hbar$ and G that has some power of kg in it, times m/s to some power, which we can cancel out with the appropriate power of the speed of light. This can be done by taking the ratio $\hbar/G$, which has the units $[\hbar/G] = \mathrm{kg}^2 \cdot \mathrm{s/m}$. Then we obtain the Planck mass from

$$m_\mathrm{p} = \sqrt{\frac{\hbar c}{G}}.$$

The Planck temperature has to have the Boltzmann constant in the denominator, because this is the only way we can obtain K as the unit. The appropriate powers of the Planck length, time, and mass can then be used to cancel out the non-K units of the Boltzmann constant. This results in

$$T_\mathrm{p} = \frac{1}{k_\mathrm{B}} \sqrt{\frac{\hbar c^5}{G}}.$$

A similar procedure leads to the Planck charge:

$$q_\mathrm{P} = \sqrt{\frac{\hbar c}{k}}.$$

Numerically, these Planck units work out to the following:

$$\begin{aligned}
x_\mathrm{P} &= 1.61 \cdot 10^{-35}\,\mathrm{m} \\
t_\mathrm{P} &= 5.39 \cdot 10^{-44}\,\mathrm{s} \\
m_\mathrm{P} &= 2.18 \cdot 10^{-8}\,\mathrm{kg} \\
T_\mathrm{P} &= 1.42 \cdot 10^{32}\,\mathrm{kg} \\
q_\mathrm{P} &= 1.88 \cdot 10^{-18}\,\mathrm{C}.
\end{aligned}$$

The Planck scales for temperature, length, and time are very far from our usual experience and either astronomically high (temperature) or unimaginably small (length and time). The Planck charge, however, is relatively close to the elementary charge quantum e and differs only by a factor of $1/\sqrt{\alpha} = \sqrt{137} = 11.7$.

Concept Check 39.2

The Planck mass is approximately the same as the mass of a

a) Z boson.

b) gold atom.

c) leg of a fruit fly.

d) baseball.

e) aircraft carrier.

Self-Test Opportunity 39.2

What is the value of the Planck energy in SI units?

Supersymmetry and String Theory

The incredible success of the Dirac theory motivated further extension of the standard model of particle physics. Based on symmetries, Dirac predicted that visible matter has undiscovered partners with negative energy states. This led to the discovery of antimatter and to the realization that every particle has a partner in the antiparticle world, with the same mass but opposite charge.

Supersymmetric (abbreviated SUSY) theories propose to do the same for fermions and bosons. **Supersymmetry** postulates for each fermion a supersymmetric bosonic partner, and for each boson a supersymmetric fermionic partner. This idea was originally proposed in 1973 by the Italian-American Bruno Zumino and the Austrian-German Julius Wess.

A severe constraint on SUSY theories is that experimental evidence for these super-symmetric partners has not yet been discovered. This fact excludes all versions of SUSY theories that predict masses below $100\ \mathrm{GeV}/c^2$, the energy-mass region that has been thoroughly explored with existing particle accelerators, for any of the postulated new particles. However, some SUSY extensions of the standard model predict particle masses just above this limit. Thus, there is some hope that the rest-energy regime between 100 Gev and 1 TeV, which is accessible by the Large Hadron Collider at CERN, will reveal discoveries of magnitude comparable to the discovery of the positron.

In addition, many SUSY theories predict the existence of very heavy neutralinos. The neutralinos are thought to be mixtures of zinos (SUSY partner of the *Z* boson), photinos (SUSY partner of the photon), and higgsinos (SUSY partner of the Higgs boson). The lightest variant of the neutralino is absolutely stable according to these theories and is a leading candidate for the component of cold dark matter. It is called a *WIMP* (weakly interacting massive particle). Chapter 12 introduced the concept of dark matter as the explanation for effects like gravitational lensing and the fact that

stars' orbital velocities around their galaxies are in general too large relative to the amount of visible matter.

The branch of particle physics theory that has unquestionably attracted more attention than any other during recent decades is **string theory**. At its most basic level, string theory replaces the elementary (zero-dimensional) point particle as the most basic constituent of matter with one-dimensional strings of very small lengths, possibly on the Planck scale. The elementary particles that are observed experimentally are thought to be strings vibrating at particular resonance frequencies. Strings can merge and split, giving rise to the particle interactions of the standard model discussed in Section 39.3 (see Figure 39.29).

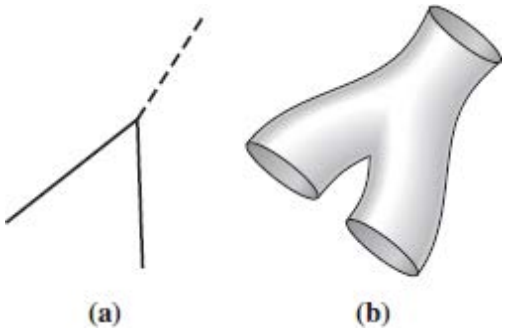

FIGURE 39.29 (a) Conventional Feynman diagram of the interaction of point particles; (b) representation of the same process as string fusion in string theory.

While string theory has been around since the late 1960s, it became dominant after the British theorist Michael Green and the American John Schwartz worked out a version of it in 1984 that was the start of superstring theory for unification of all known forces, including gravity. In the popular press, string theory was called "The Theory of Everything." In the mid-1990s, through the work of Edward Witten and many others, it was discovered that

string theory can be thought of as a certain limit of a perhaps more profound theory, which is called *M-theory*.

String theories predict additional spatial dimensions. The most popular versions postulate a 10- or 11-dimensional space-time. Why, then, can we observe only 4 dimensions? The answer given by string theories is that the extra dimensions are compacted to a size so small that we cannot observe them. This can happen at the Planck scale, but it is not excluded that the compactification length scale can be as large as a few micrometers. If this is correct, then we might expect to find distortion of gravity and deviation from the r^{-2} force law on this scale. Almost three decades of high-precision searches, however, have not come up with positive experimental evidence. String theories are very attractive mathematical frameworks in the eyes of particle theorists, but it has not yet been possible to establish any irrefutable connection to experimental observables. In 1997, however, Juan Maldacena from Argentina and the United States proved that string theory defined in a certain space is equivalent to a quantum field theory without gravity on the lower-dimensional boundary of that space. In the end, this may turn out to be the best connection to the standard model of particle physics and thus connect string theory to observable consequences.

39.5 Composite Particles

With a reasonable understanding of the basic fermionic building blocks of matter and their interactions via the exchange of fundamental bosons, we can begin to try to understand how they form composite particles. All composite particles formed by quarks are called **hadrons.** Hadrons are either quark-antiquark pairs, called **mesons,** or groups of three quarks, called **baryons.** Each quark has another trait that can be one of three values. As mentioned in Section 39.3, this trait is arbitrarily called **color,** even though it has nothing to do with the common use of the word as a visual property. All composite particles are color singlets.

What is a color singlet? Quarks carry something called a color charge, coming in three varieties: red (r), green (g), and blue (b). Antiquarks carry anti-colors, which are marked with horizontal bars above the letters. Of course, quarks cannot really be imagined as having a physical color, because what we see as color is only light from a very limited range of photon energies, energies that are millions of times smaller than the characteristic scales of the realm of elementary particles. However, the algebra of additive color mixing works as a perfect analogy for the algebra of combining quarks into hadrons.

Figure 39.30 shows RGB color selectors from a typical computer graphics program, where any color is created as a mixture of red, green, and blue by picking numbers between 0 and 255 for each of the three color-components. For example, selecting 255 for red, 0 for green, and 0 for blue produces a pure red (upper left corner). Reversing all three sliders—0 for red, 255 for green, and 255 for blue—produces cyan. In a certain sense, it is the anti-color to red, r, because if the RGB values of cyan and red are added, we obtain 255 for all three RGB values, which is the "color" white. Pure red, pure green, and pure blue can also be added to obtain white. Thus, white represents the color singlet resulting

from a combination of equal amounts of all colors or equal amounts of a color and its anti-color. In particle physics, only color singlets can be physically observable particles. Thus, particles we can observe consist of either three quarks of different colors or a quark of a certain color and an antiquark with the quark's anti-color. The first combination is called a baryon and is a fermion (with either spin $\frac{1}{2}\hbar$ or spin $\frac{3}{2}\hbar$), and the second is a meson, which is always a boson (with either spin 0 or spin 1ħ). Three antiquarks with three different anti-colors can also combine to yield a color singlet, and they form the antibaryons.

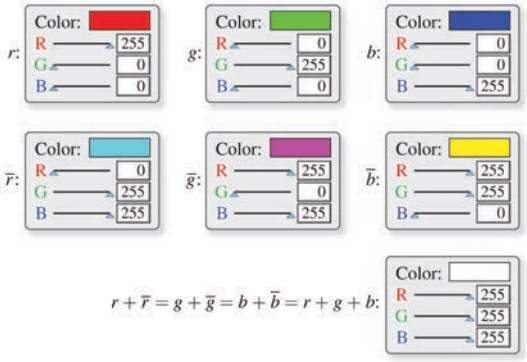

FIGURE 39.30 Additive color sliders in a computer graphics program as a model for quark colors (top row), antiquark anti-colors (middle row), and the color singlet (bottom panel).

Mesons

Table 39.3 gives a partial listing of the known mesons, including all mesons with mass less than $1\,\mathrm{GeV}/c^2$ and a few mesons with special properties and higher masses. Hundreds of other mesons are known.

Table 39.3 The Most Important Mesons, Including Thei Numbers, and Quark Composition

Name	Symbol	$m\left(\mathrm{MeV}/c^2\right)$	Lifetime (s)	s	$\$$

No meson is absolutely stable; they all decay. The lightest mesons are the pions, π^+, π^-, and π^0, all with masses of around $140\ \mathrm{MeV}/c^2$. The neutral pion decays predominantly via the reaction

$$\pi^0 \rightarrow 2\gamma. \tag{39.13}$$

This decay proceeds relatively fast, on a time scale of the order of 10^{-16} s, via the electromagnetic interaction. The charged pions, however, cannot decay in this way because of the conservation law of charge. Instead, they have to decay via the weak interaction, predominantly via

$$\begin{aligned} \pi^+ &\rightarrow \mu^+ + \upsilon_\mu \\ \pi^- &\rightarrow \mu^- + \upsilon_\mu. \end{aligned} \tag{39.14}$$

In comparison with neutral pion decay, the decay of the charged pions takes practically forever, on the order of 10^{-8} s, or approximately 100 million times longer than the neutral pion decay time.

Let's examine the lifetimes of the other mesons. Figure 39.31 shows three vastly different regions of lifetimes. The area highlighted in yellow shows the decays that proceed via the weak interaction; in white, via the electromagnetic interaction; and in pink, via the strong interaction. Because energy must be conserved in every decay, heavier mesons can decay into lighter mesons but not vice versa. This decay into other mesons happens very fast if it proceeds via the strong interaction. There must be a good reason why the kaons and *D* and *B* mesons live such a comparatively long time. From our discussion of quarks, you can understand that it is because they contain strange, charm, and bottom quarks, respectively, which can only decay via the weak interaction into lower-mass quarks of other flavors.

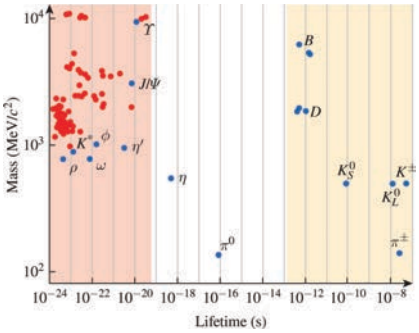

FIGURE 39.31 Plot of the lifetimes and masses for all known mesons. The blue dots represent entries in Table 39.3, and the red dots are other mesons.

The strangeness quantum number, *S*, equals the number of anti-strange quarks in a hadron minus the number of strange

quarks. (It is a purely historical artifact that anti-strange quarks are counted with positive numbers. For the quantum numbers of charm, *C*, and bottom, *B*, which give the net numbers of charm and bottom quarks, the sign is reversed.) Another useful quantum number is the isospin, *t*, and its projection, t_z. Even though no real angular momentum is involved in this case, the same algebra can be used for isospin as was used for conventional spin. In particular, a given isospin *t* has $2t + 1$ states of different projection t_z, just as a given spin *s* has $2s + 1$ states of different projection s_z. The charge number *Z*, the isospin, and the strangeness quantum number for the low-mass mesons (below the mass threshold where they start to contain quarks other than up, down, and strange) are related via

$$Z = t_z + \frac{1}{2}S. \qquad \textbf{(39.15)}$$

Figure 39.32 shows the arrangement of the low-mass mesons with spin 0 (part a) and with spin $1\hbar$ (part b) as a function of isospin and strangeness. They form characteristic nonets, which the quark model is able to explain beautifully. Figure 39.33 shows the same plot, but in terms of the constituent quarks of the different mesons. In each case, the quark composition of the three neutral mesons with $S = t_z = 0$ is a linear combination of the three quark-antiquark pairs. The quark charges in Table 39.1 confirm that their charges always add up to the corresponding charge of the meson.

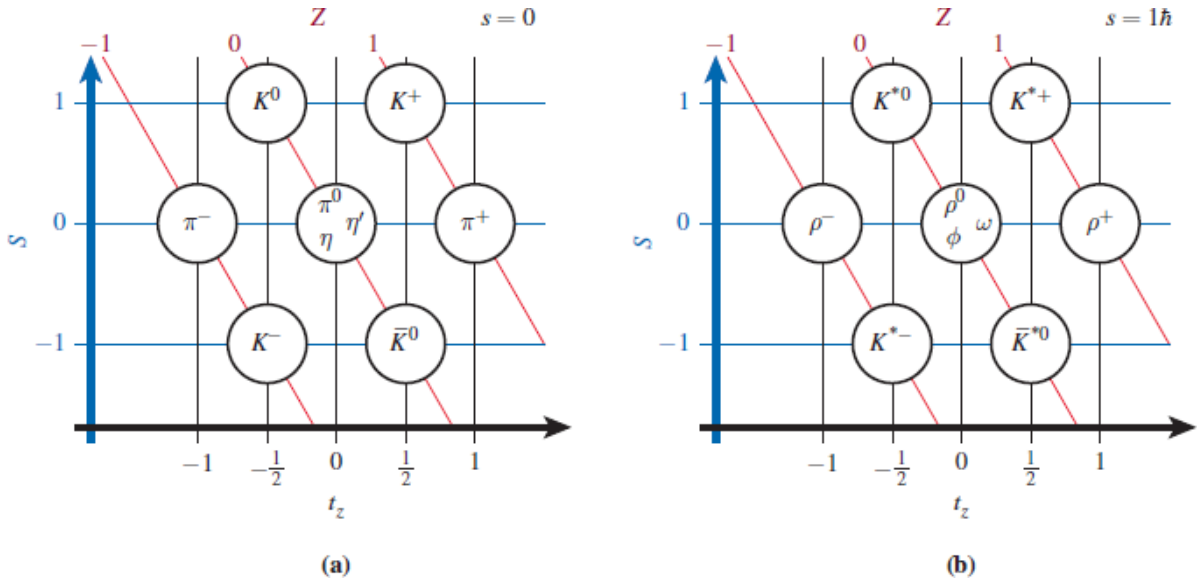

FIGURE 39.32 Meson nonets with (a) spin 0 and (b) spin 1$\hbar$.

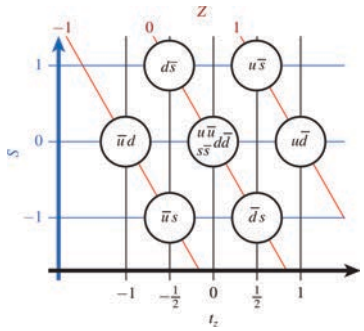

FIGURE 39.33 Quark composition of the two meson nonets.

The up and down quarks have isospin $\frac{1}{2}$, with projections $t_z = \frac{1}{2}$ for the up quark and $t_z = -\frac{1}{2}$ for the down quark. The isospin for all other quarks and antiquarks (strange, charm, bottom, and top) is 0. Similar to the case of angular momentum and regular spin, if a particle with isospin $\frac{1}{2}$ is combined with a particle with isospin 0, the resulting isospin is $\frac{1}{2}$. If two particles with isospin $\frac{1}{2}$ are combined, the resulting isospin can be 0 (if the two isospin vectors are antiparallel) or 1 (if the two isospin vectors are parallel). If three particles with isospin $\frac{1}{2}$ are combined, the resulting isospin can be $\frac{3}{2}$ (all three isospin vectors parallel) or $\frac{1}{2}$

(one antiparallel to the other two). This “algebra of isospin” allows us to determine the observed isospins of all mesons from the quark isospins, as shown in Figure 39.33.

Concept Check 39.3

From Figure 39.33, the isospin projections, t_z, of the anti-up quark (u) and the anti-down quark $\left(d\right)$ are

a) $t_z(u) = -\frac{1}{2},\ t_z\left(d\right) = -\frac{1}{2}.$

b) $t_z(u) = -\frac{1}{2},\ t_z\left(d\right) = \frac{1}{2}.$

c) $t_z(u) = \frac{1}{2},\ t_z\left(d\right) = -\frac{1}{2}.$

d) $t_z(u) = \frac{1}{2},\ t_z\left(d\right) = \frac{1}{2}.$

e) $t_z(u) = 0,\ t_z\left(d\right) = 0.$

Baryons

The most important baryons are listed in Table 39.4. As we have already stated, baryons are composed of three quarks each, with one quark of each color. The only stable baryon is the proton, the lightest baryon. As discussed previously, a neutron can decay into a proton via a beta decay:

$$n \rightarrow p + e^{-} + v_e. \tag{39.16}$$

This is the same process as the beta decay of the down quark expressed in equation 39.12, because in this process one of the two down quarks of the neutron decays into an up quark, and the other up and down quarks remain unchanged (Figure 39.34).

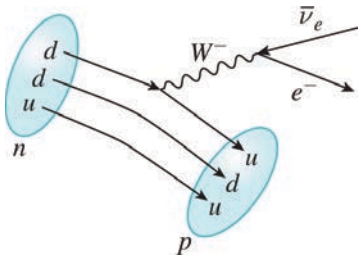

FIGURE 39.34
Feynman diagram for the beta decay of the neutron.

The dominant decay processes for all heavier baryons occur via emission of one or more pions. Any of these processes can involve only the strong interaction, in which case lifetimes of the order of 10^{-20} s or shorter are found. If, in addition, a quark needs to change flavor in the process, then much longer lifetimes are seen, typical of the weak interaction.

In Figure 39.35, the lowest-mass baryons with spin $\frac{1}{2}\hbar$ and spin $\frac{3}{2}\hbar$ are arranged as an octet and a decuplet as functions of isospin and strangeness, similar to the diagrams for the meson nonets in Figure 39.32. This arrangement into nonets (for the mesons) and octet and decuplet (for the baryons) derives naturally from the underlying quark structure. In particular, note the omega baryon. Because it has strangeness -3, it is composed of three strange quarks. Its existence was predicted by the quark model, and it was subsequently discovered in 1964. This was the first great success of the quark model.

Self-Test Opportunity 39.3

Construct the quark composition for the baryons of Figure 39.35 in the same way as in Figure 39.33.

Lattice-QCD, Confinement, and Asymptotic Freedom

The sum of the masses of the constituent quarks inside a proton is less than 15 MeV/c^2, which is only 1.5% of the proton's mass. Where does the rest of its mass come from? Answering this question is very difficult and requires mathematical tools that go beyond the scope of this book. However, we can describe a bit of the search for the answer.

The fundamental theory, including relativity and quantum physics, that describes the interaction of quarks and gluons with one another, with themselves, and with the vacuum, is called **quantum chromodynamics (QCD).** As an illustrative example of the kinds of processes QCD needs to take into account, Figure 39.36 shows a Feynman diagram of a strange quark propagating through the vacuum, emitting and absorbing gluons and virtual quark-antiquark pairs.

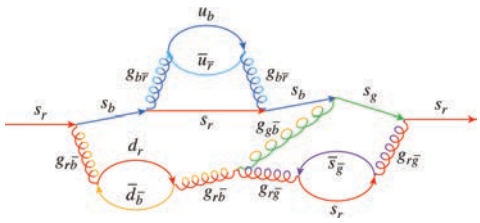

FIGURE 39.36 A Feynman diagram of a red strange quark propagating through the QCD vacuum.

Physicists understand the underlying framework of QCD in principle, but it is very hard to obtain numerical results. To obtain some predictions that can be compared to experimental results, physicists have built customized supercomputers to simulate QCD. Despite the exponential growth of computer power during the last few decades, it is fair to say that progress in computing observables such as hadron masses has been slow.

Solving the equations of QCD is difficult. One method that allows solutions to these equations is **lattice-QCD.** In lattice-QCD, quarks are assumed to reside only on the vertices of a crystal-like lattice and the gluons must travel in straight lines between the

quarks. This technique builds in cutoffs that allow calculations to be done. Of course, the real world is not a crystal lattice. However, the aim is to carry out the calculations for smaller and smaller lattice spacings and larger and larger lattices and thus do a better job of approximating physical reality.

Quarks, antiquarks, and gluons all carry color charge. QCD predicts that only color-neutral objects can exist in isolation. This means that a single quark or gluon cannot be observed by itself. Very sensitive searches for free quarks have been conducted, all of them with negative results.

What happens if we try to remove a quark from a baryon—for example, by shooting an electron with very high energy into a proton, trying to knock out a quark? The quark can acquire a very high momentum after the collision with the electron and move rapidly away from the other two quarks inside the proton. However, it remains tethered to them by a string of gluons called a *flux-tube*. QCD predicts that the energy contained in this flux-tube increases in proportion to its length. Once it is long enough and energetic enough, it can rupture and split into two or more color-neutral objects—mainly pions. This fragmentation is illustrated schematically in Figure 39.37, which shows a meson consisting of a red quark and an anti-red antiquark. The antiquark receives an impulse and moves to the right, stretching the gluon flux-tube joining it and the quark, until the flux-tube ruptures, yielding another quark-antiquark pair. These two newly produced particles pair up with the original quark and antiquark to form two new mesons, which can move freely away from each other. If the impulse that the original quark receives is high enough, the color flux-tube can also rupture in multiple places, producing a quark-antiquark pair at each breakpoint. The result is a group of mesons, which are produced in the process of string fragmentation, and which are all traveling in roughly the same direction. Provided that the initial impulse is large enough, the jet formed by this group of newly produced particles can be observed in particle physics detectors.

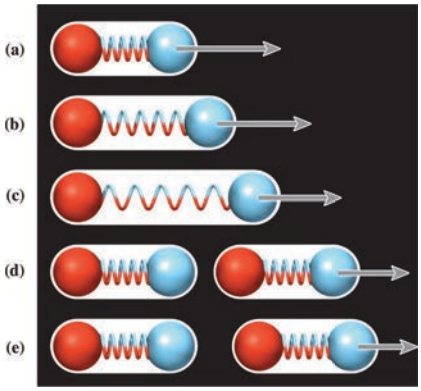

FIGURE 39.37
Schematic diagram of the fragmentation of a color flux-tube.

This means that all elementary particles carrying color charge—all gluons, quarks, and antiquarks—are absolutely confined. Confinement also implies that any attempt to remove a quark from its color singlet will only produce additional color singlets, that is, hadrons.

The color force acts in such a way that the farther away objects with color charge move from each other, the more strongly they are attached to each other. Does this also mean the opposite, that is, that when color-charged particles inside a singlet are close to each other, they can move freely? Indeed, this is the case. At close distances or high relative momenta, color-charged objects experience *asymptotic freedom*. This was predicted by David Gross, Frank Wilczek, and David Politzer in 1973 and subsequently confirmed experimentally. They shared the 2004 Nobel Prize in Physics for this achievement.

EXAMPLE 39.3 Feynman Diagrams of the Decay of Positive Pions and Positive Muons

When high-energy cosmic rays consisting mainly of protons are incident on the Earth's atmosphere, reactions take place that produce positive pions. A positive pion decays with a mean lifetime of 26 ns into a positive muon and a muon-neutrino:

$$\pi^+ \rightarrow \mu^+ + \upsilon_\mu.$$

In turn, the positive muon decays with a mean lifetime of 2.2 μs into a positron, an electron-neutrino, and an anti-muon-neutrino

$$\mu^+ \rightarrow e^+ + \upsilon_e + \upsilon_\mu.$$

PROBLEM

Draw the Feynman diagrams representing these two decays.

SOLUTION

The positive pion is a meson composed of an up quark and an anti-down quark, as shown in Figure 39.38. This quark-antiquark pair u/d annihilates to produce a W^+ meson. The W^+ meson then materializes as the lepton/anti-lepton pair υ_μ/μ^+.

The positive muon that is produced in the decay emits a W^+ meson and transforms into an anti-muon-neutrino, as shown in Figure 39.39. This W^+ meson then materializes as the lepton/anti-lepton pair υ_e/e^+.

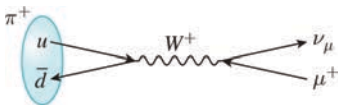

FIGURE 39.38
Feynman diagram of the decay of a positive pion.

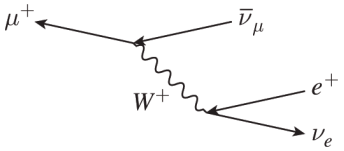

FIGURE 39.39
Feynman diagram of the decay of a positive muon.

DISCUSSION

The decay of positive pions is particularly interesting because these particles are produced at the top of the Earth's atmosphere with relatively high energies via reactions of cosmic ray protons with the nuclei of nitrogen and oxygen atoms. These pions decay into muons, and the resulting muons travel at a large fraction of the speed of light. They should travel at most only 0.66 km before they decay into positrons. However, muons produced by cosmic rays are observed at the surface of the Earth. About 10 muons per second pass through your hand. One reason the muons reach the surface of the Earth is relativistic time dilation, as discussed in Chapter 35 (see Example 35.2). For a speed $\beta = v/c = 0.998$, the time dilation factor is

$$\gamma = \frac{1}{\sqrt{1-\beta^2}} = \frac{1}{\sqrt{1-(0.998)^2}} = 15.8.$$

Thus, the muons will travel a distance of 10 km before they decay, allowing them to reach the surface of the Earth. A second reason the muons reach the Earth's surface is that they

can traverse the Earth's atmosphere without interacting with the nuclei in the atoms of atmospheric gases, because a muon interacts only via the weak force and the electromagnetic force, not via the strong force.

39.6 Big Bang Cosmology

The night sky presents an amazing display of light that has traveled for many years from distant stars (Figure 39.40). Since the dawn of civilization, humans have asked where all of this came from (and how, and why). Since the middle of the 20th century, scientists have been reasonably sure that they know the answer, and the picture is becoming clearer and more detailed. Through the interplay of observational astronomy, cosmology, and nuclear and particle physics, the models have been refined.

FIGURE 39.40 View of the universe from Earth in the visible spectrum. The telescope used for this image is pointed towards the center of our own galaxy, the Milky Way.

Taylor Wilson Smith/Shutterstock

The entire universe came into being through a singular event that we call the *Big Bang*. This event happened

$(13.787 \pm 0.020) \cdot 10^9$ years ago. Although the age of the universe cannot be fixed with an uncertainty smaller than 20 million years, physicists are able to state how the universe developed in the first fractions of a second after the Big Bang.

The Planck time is the earliest time after the Big Bang for which it makes any sense to try to deduce a history of the universe (Figure 39.41). (See Example 39.2.) At a time of 10^{-43} s, the temperature was on the order of 10^{32}K. All forces were unified at that time, with gravity separating from the other forces a short time thereafter. The era of grand unification of the strong and electroweak forces is estimated to have lasted to about 10^{-34} s, when the strong force became separated from the electroweak force. At the end of this era, the universe underwent a rapid inflationary expansion. To understand why this process had to have been part of the universe's history, we need to discuss the cosmological concept of inflation.

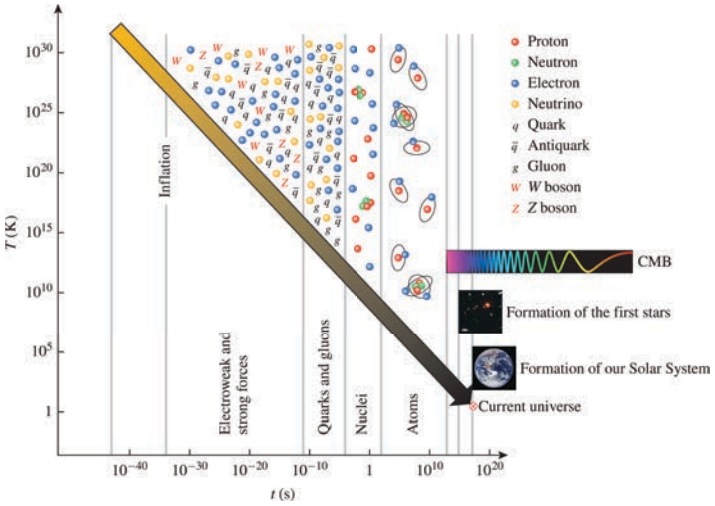

FIGURE 39.41 Temperature of the universe as a function of time. The red circle with the cross marks the current universe, and the vertical gray lines mark the approximate boundaries between the different eras. For each era, the basic constituents are shown. Radiation was present at all times and in equilibrium with matter until 1013 s, when the universe became transparent to radiation.

Inflation

Three important questions have puzzled astronomers for a long time:

1. Why is the cosmic microwave background radiation so incredibly isotropic, which is to say, smooth and very much the same in every direction?
2. Why is the universe made entirely of matter and not of antimatter?
3. Why is the universe so incredibly flat (a term to be explained shortly)?

All three questions deserve some elaboration to show how truly startling these facts are.

First, let's think about the smoothness of the cosmic microwave background. As we saw in Chapter 36, the cosmic microwave background (CMB) radiation shows a perfect blackbody spectrum at a temperature of 2.725 k. CMB radiation was discovered in 1965 by Arno Penzias and Robert Woodrow Wilson, who received the Nobel Prize in Physics for this discovery in 1978. This radiation had been predicted in 1948 by George Gamov, Ralph Alpher, and Robert Herman as a consequence of the Big Bang model, which at that time was still very speculative and only one of several possible models of the time evolution of the universe. Only through the COBE and subsequently the WMAP and Planck satellite missions was it possible to measure just how isotropic this radiation is, an accomplishment that earned the 2006 Nobel Prize in Physics for George Smoot and John C. Mather. Figure 39.42 shows a picture of the universe at microwave wavelengths. This image was produced by the team that operates the Planck satellite. It shows that the fluctuations of the temperature of space as a function of direction are only of the order of $|\delta T/T| \approx 10^{-4}$. For comparison, Figure 39.42 also shows a temperature map of the surface of Earth produced by the WMAP team for June 1992, for which the fluctuations are on the order of $|\delta T/T| \approx 0.2$.

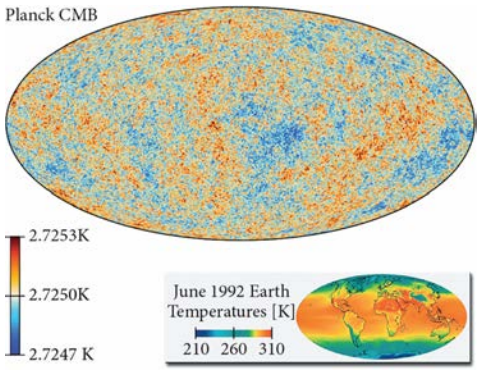

FIGURE 39.42
Temperature map of the cosmic microwave background (CMB) radiation of the universe from the Planck team. The inset shows temperatures on the surface of Earth in June 1992 from the WMAP team.

©ESA/Planck Collaboration

The smoothness of the CMB is so stunning because the radiation comes to us from all directions and has the same value for all points in the sky, even if they could not have been in causal contact during the history of the universe (that is, without inflation).

Second, the universe is currently filled with matter and almost no antimatter. We know that initially matter and antimatter were produced in almost equal amounts and then almost completely annihilated into radiation, which now constitutes the cosmic microwave background. Estimates are that approximately 10^{10} photons presently exist for each hadron. This means that initially there were 10,000,000,001 matter particles for each 10,000,000,000 antimatter particles. Where did this very small asymmetry come from?

Third, after more than 13 billion years, the universe is still expanding, and we still cannot decide whether it will eventually stop expanding or go on expanding forever. The total kinetic energy of the universe is almost exactly equal to the total potential

energy, but opposite in sign, so the total energy of the universe must be unbelievably close to zero. We thus say that the universe is *flat*. Imagine shooting off a gun from the surface of Earth. If the bullet has an initial speed that is large compared to the escape speed, then it will easily leave Earth; whereas if the initial speed is smaller than the escape speed, the bullet will fall back down to Earth's surface. Now imagine that after billions of years we still cannot decide if the bullet will eventually fall back down to Earth or will keep going! (As an aside, we note that recent findings, mentioned in Chapter 12, seem to imply that the universe is dominated by dark energy, which is slowly causing the re-acceleration of the universe, presenting yet another mystery. Thus it seems likely that, according to what we know now, that the universe will continue to expand forever.)

A model proposed by Alan Guth in 1980 and later expanded on by others answers all three questions in the same model, one that sounds like science fiction: A very short fraction of time after the Big Bang, the universe went through a very rapid period of inflation. Figure 39.43 depicts this inflation. The idea is that approximately 10^{-34} s after the Big Bang, the universe was at a temperature of around 10^{27} K and in a process of rapid cooling. It then became supercooled. This is analogous to freezing rain still being liquid at a temperature at which water should be frozen. When the freezing rain hits the ground, the relatively small impact shock creates fluctuations that increase exponentially and cause the formation of very smooth ice. The supercooled state of the freezing raindrop is a false ground state, and small fluctuations cause it to make a transition to the true ground state, ice. At the onset of the period of inflation, the universe also entered a false ground state and became supercooled (albeit still at an astronomically high temperature). The transition to the true ground state caused an exponential expansion in size, resulting in the smoothness of the distribution of matter and radiation still seen today in the cosmic microwave background radiation.

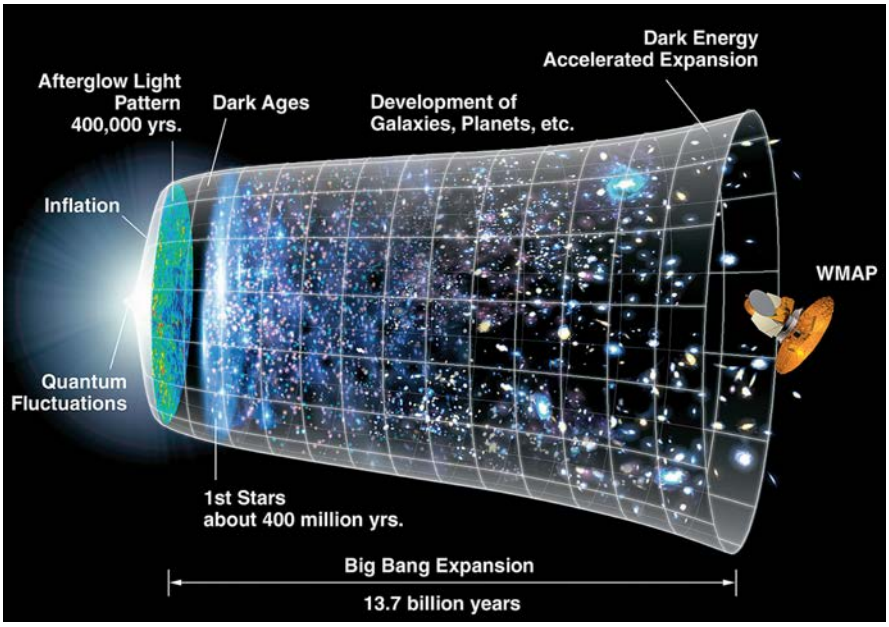

FIGURE 39.43 Illustration of the concept of inflation of the early universe.

NASA/WMAP Science Team

After the reheating of the inflationary period, which may have lasted until 10^{-32} s, the universe entered a radiation-dominated era that lasted until approximately 10^{11} s. During this time, the temperature, T, continued to fall gradually and in inverse proportion to the square root of the time, t:

$$T(t) = \frac{1.5 \cdot 10^{10}\ \text{K}\,\text{s}^{1/2}}{\sqrt{t}}. \qquad \textbf{(39.17)}$$

The electromagnetic and weak forces parted ways at approximately 10^{-11} s. At that point, the W and Z bosons became massive, through a process called *spontaneous symmetry breaking*, and subsequently decayed away rapidly. (Perhaps it is instructive to look at another example of spontaneous symmetry breaking, to illustrate the concept: In liquid water, the water molecules can have any arrangement and orientation. However, in the process of

freezing, this symmetry has to be broken to force the molecules into the crystalline structure of ice.)

Quark-Gluon Plasma

After 10^{-11} s, and lasting until about 10^{-4} s, the universe was a mixture of quarks, gluons, and leptons, forming a plasma. Despite carrying color charges, the quarks and gluons were asymptotically free due to the high temperature. At about 10^{-4} s, the universe had cooled to a temperature of approximately $2.1 \cdot 10^{12}\,\mathrm{K} (k_B T = 180\,\mathrm{MeV})$. Lattice-QCD calculations indicate that at this temperature the quarks and gluons coalesced into color singlets.

Amazingly, the quark-gluon state of matter that dominated the early universe from 10^{-11} s to 10^{-4} s after the Big Bang can be recreated in accelerator-based experiments today. Experiments at the Relativistic Heavy Ion Collider (RHIC) in Brookhaven, Long Island, use colliding beams of gold nuclei with total kinetic energy of up to 20 TeV each to probe the conditions during the early time evolution of the universe and to produce small volumes of the quark-gluon matter. However, this state of matter lasts less than 10^{-23} s in the laboratory before it explodes into more than 5000 particles, mainly pions. A collision event recorded at RHIC is displayed in Figure 39.44. Since 2010, nuclear physicists also have the Large Hadron Collider (LHC) at CERN at their disposal. It can collide lead ions at an energy of 2.76 TeV per nucleon pair, which is 13 times higher than the energy achieved by the RHIC.

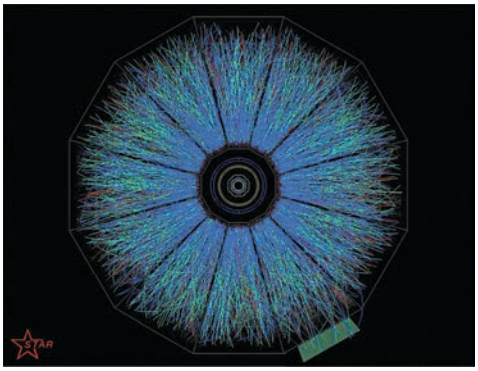

FIGURE 39.44 Event display from a collision of gold nuclei the Relativistic Heavy Ion Collider. Each line represents the track that one of the over 5000 particles resulting from the collision produced in the STAR detector. From these tracks, scientists are trying to determine the properties of the quark-gluon state of matter that was created transiently during the nuclear collision and learn about the history of the universe.

STAR collaboration/RHIC/Brookhaven National Laboratory

Nucleosynthesis

As the universe emerged from its quark-gluon phase at a time of 10^{-4} s after the Big Bang, it consisted overwhelmingly of photons, electrons, positrons, neutrinos, and anti-neutrinos. A small number of protons and neutrons—the lightest color singlets into which the quarks could condense—were also present. The protons and neutrons were constantly interconverting via the reactions

$$\begin{aligned} n + \nu_e &\rightleftarrows p + e^- \\ n + e^+ &\rightleftarrows p + \nu_e. \end{aligned} \qquad \textbf{(39.18)}$$

This interconversion was easily possible because the temperature was still on the order of 10^{11} or 10^{12} K, which corresponds to 10 to 100 MeV, much larger than the mass difference of the neutron and the proton, which is only $1.293\,\mathrm{MeV}/c^2$. This means that protons and neutrons were in equilibrium, with their relative numbers determined by the ratio of their Boltzmann factors:

$$\frac{n_\mathrm{n}}{n_\mathrm{p}} = e^{\left(m_\mathrm{n}c^2 - m_\mathrm{p}c^2\right)/k_\mathrm{B}T}. \qquad \textbf{(39.19)}$$

As the universe reached a temperature of approximately $10^{10}\,\mathrm{K} (\sim 0.86\,\mathrm{MeV})$, the reactions of equation 39.39 proceeded too slowly to maintain equilibrium. At this point, the ratio of neutrons to protons froze at the value $e^{-1.293/0.86} = 0.222$. This means that there were then about 22 neutrons for every 100 protons. At this time, the universe was at an age of 1 s. However, the temperature was still too high at this time for nuclei to form. Instead, all neutrons remained free, and thus could beta decay according to equation 39.16, with a 15-min lifetime.

After 100 s, the universe had cooled down to 10^9 K, and due to beta decay, only about 16 neutrons were left for every 100 protons.

This was the point where alpha particles (consisting of two neutrons and two protons each) could form, and essentially all available neutrons became bound in them. Small traces of deuterium, tritium, helium-3, and lithium (more on these in Chapter 40) were also formed. Sixteen neutrons and 16 protons can form 8 alpha particles. Therefore, the total mass fraction of nucleons trapped inside alpha particles at that time was $16 + 16$ out of $100 + 16 : (16 + 16)/(100 + 16) \approx 27\%$. This rough estimate is consistent with the observed primordial mass fraction of 23% helium atoms (each consisting of an alpha particle plus electrons). This matchup is considered one of the greatest successes of the Big Bang theory.

The radiation dominance ended at approximately $10^{11}\,\mathrm{s} (\sim 3000\,\mathrm{yr})$, when the temperature had reached $10^5\,\mathrm{K}$. As the temperature fell further, to below approximately $3000\,\mathrm{K} (\sim 0.25\,\mathrm{eV})$, electrons were captured by protons and alpha particles to form neutral hydrogen and helium atoms. A photon needs to have at least 10.2 eV of energy to excite a hydrogen atom's electron from the 1*s* to the 2*s* state (see Chapter 38), so the photons then had many fewer electrons to scatter from, and thus the opacity of the universe dropped. At that time, photons were able to roam freely through the universe, and radiation decoupled from matter. The photons thus showed a perfect blackbody spectrum with the temperature of the universe at the time of the decoupling. The universe was then about $10^{13}\,\mathrm{s} (\sim 300{,}000\,\mathrm{yr})$ old. These freely roaming photons are still visible today; they form the cosmic microwave background (CMB).

Why are the CMB photons now showing a temperature of 2.725 k, approximately 1000 times lower than the original temperature? The answer is that the photons have been stretched due to the expansion of the universe. The scale factor of the universe is approximately $R = 1100$ times bigger than it was at the time the CMB decoupled. This means that the wavelengths of these photons are now $\lambda = R\lambda_0$. According to the Wien displacement law (see Chapter 36), the wavelength λ_m at which the blackbody spectrum has its maximum is related to the temperature by $\lambda_\mathrm{m} T = \text{constant}$. Consequently, with the expansion of the wavelengths by a factor of 1100, the temperature has to fall by the

same factor. (Figure 39.41 indicates this effect schematically by stretching the wavelength of the CMB photons and shifting the color toward the longer wavelengths.)

What followed was a period of darkness in the universe, lasting a few million years perhaps, before the first stars were formed through the gravitational interaction in the gas of hydrogen and helium atoms. Our Solar System formed approximately 4.5 billion years ago, about 9 billion years after the Big Bang. In Figure 39.41, this point in time corresponds to the rightmost gray vertical line, which in this logarithmic scale is only ever so slightly to the left of the present, which is marked by the red circle with a cross at a time of $4.3 \cdot 10^{17}$ s after the Big Bang. Chapter 40 will return to the nuclear physics that went into the formation of the heavy elements of which Earth is mainly composed. Their presence cannot be explained based on Big Bang cosmology alone and requires other events, which we will explore.

From this short narration of Big Bang cosmology, it is clear how particle physics at the smallest imaginable scales is intimately connected to astronomy at the largest possible scales. This amazing connection between the smallest and largest has fascinated physicists for the last 60 years and continues to do so, with new results being discovered each year.

WHAT WE HAVE LEARNED EXAM STUDY GUIDE

- The reductionist quest to reduce systems to their component parts is a main theme in science and has its present culmination in particle physics. While an equally valid methodology seeks to understand complexity and emergent structure, this chapter focused on reductionism in particle physics.
- Substructure is probed using scattering experiments. The scattering cross section is defined as

$$\sigma = \frac{\text{Number of reactions per scattering center/s}}{\text{Number of impinging particles/s/m}^2}.$$

- The scattering cross section has the physical dimension of area and is measured in the unit barn (b) or millibarn (mb): $1\,\text{b} = 10^{-28}\text{m}^2$, $1\,\text{mb} = 10^{-31}\,\text{m}^2$.
- The classical Rutherford cross section for scattering from a pointlike target by the Coulomb interaction is

$$\frac{d\sigma}{d\Omega} = \left(\frac{kZ_\text{p}Z_\text{t}e^2}{4K}\right)^2 \frac{1}{\sin^4\left(\frac{1}{2}\theta\right)}.$$

- For scattering of a plane wave off a point source, the scattering wave function is

$$\psi_\text{total}\left(\vec{r}\right) = \psi_i\left(\vec{r}\right) + \psi_f\left(\vec{r}\right) = N\left(e^{ikz} + f(\theta)\frac{e^{ikz}}{r}\right),$$

and the cross section is related to the scattering amplitude by

$$\frac{d\sigma}{d\Omega} = |f(\theta)|^2.$$

- The form factor is the Fourier transform of the density distribution,

$$F^2(\Delta p) = \left| \frac{1}{e} \int \rho\left(\vec{r}\right) e^{i\Delta\vec{p}\cdot\vec{r}/\hbar} dV \right|^2,$$

  and measures the deviation of the scattering cross section from the Rutherford cross section of a pointlike target,

$$\frac{d\sigma}{d\Omega} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{point}} \cdot F^2(\Delta p).$$

- Elementary fermions have spin $\frac{1}{2}\hbar$ and include the six quarks (up, down, strange, charm, bottom, and top), the electron, muon, and tau leptons, and the electron-, muon-, and tau-neutrinos. Each of these 12 fermions has an antiparticle. Quarks all have a noninteger charge of $-\frac{1}{3}e$ or $+\frac{2}{3}e$ and cannot be observed in isolation.
- Elementary bosons are the mediators of the interactions between the fermions. They are the photon (electromagnetic), the W and Z bosons (electroweak), the gluon (strong), and the graviton (gravitational). The graviton is yet to be found experimentally. Gluons can also interact with other gluons.
- The interactions of fundamental particles can be represented pictorially by Feynman diagrams, and calculations can be based on the Feynman diagrams.
- The standard model of particle physics has several extensions, none of which has yet received experimental confirmation. At the Planck scale, a grand unified theory of all forces is postulated, which allows for decay of protons on very long time scales. Supersymmetry is another extension of the standard model, which postulates the existence of a supersymmetric partner for every known fermion and boson. Other particle physics theories are string theories,

which hold that the dimensionality of space-time is 10 or 11, with the other dimensions compacted to very small scales.

- Elementary quarks and antiquarks can combine to form color singlets, which are particles that can be observed in isolation. A quark and an antiquark can form a meson (pion, kaon, etc.). Three quarks can form a baryon (proton, neutron, delta baryon, lambda baryon, etc.). The only stable baryon is the proton, and none of the mesons is stable. Lifetimes of the unstable particles vary from 10^{-23} s to 15 min.
- Because gluons carry color charge, they can interact with other gluons. This leads to the confinement of quarks. The theory of the interaction of quarks and gluons, quantum chromodynamics, can only be analyzed in the realm of large momentum transfer and short distances. There the elementary particles show asymptotic freedom. For low-momentum transfers and large distances, the only solution method is lattice-QCD simulated on a computer.
- The history of the early universe at fractions of a second after the Big Bang is described by particle physics. The early inflationary phase left traces in the isotropy of the cosmic microwave background radiation, which originated 300,000 years after the Big Bang at a temperature of 3000 K and cooled down to the presently observed 2.725 K due to the expansion of the universe. The quark-gluon-plasma phase transition of the early universe can be probed in the laboratory with relativistic heavy ion collisions. The primordial fraction of 23% helium in the universe can be explained from the neutron-proton mass difference, which fixes the ratio of proton and neutron numbers to

$$n_\mathrm{n}/n_\mathrm{p} = e^{(m_\mathrm{n}c^2 - m_\mathrm{p}c^2)/k_\mathrm{B}T}.$$

ANSWERS TO SELF-TEST OPPORTUNITIES

39.1 $c \rightarrow s + \mu^+ + \nu_\mu$ and $t \rightarrow b + \tau^+ + \nu_\tau$

39.2 The Planck energy is most straightforwardly obtained by multiplying the Planck mass with two powers of the speed of light:

$$E_{\mathrm{p}} = m_{\mathrm{p}}c^2 = \sqrt{\frac{\hbar c^5}{G}} = 1.96 \cdot 10^9 \mathrm{J} = 1.22 \cdot 10^{19}\ \mathrm{GeV}.$$

39.3 Most of these are listed in Table 39.4, with the exception of $\sum^*$ and Ξ* which have the same constituent quark composition as $\sum$ and Ξ, respectively.

PROBLEM-SOLVING GUIDELINES

1. The starting point for most calculations involving elementary particles is relativistic kinematics. In particular, $E = mc^2$ is a very useful relationship to remember.

2. Conservation laws for energy and momentum apply to all physical processes. In addition, remember the conservation laws of baryon number, charge, and angular momentum (spin) when solving particle physics problems.

3. Understanding the quark composition of mesons and baryons is important in solving many problems involving decays of these particles.

Multiple-Choice Questions

39.1 According to the text, the de Broglie wavelength, λ of a 5-MeV alpha particle is 6.4 fm, and the closest distance, $r_{\min}$, to the gold nucleus this alpha particle can get is 45.5 fm (calculated in Example 39.1). Based on the fact that $\lambda \ll r_{\min}$, one can conclude that, for this Rutherford scattering experiment, it is adequate to treat the alpha particle as a

a) particle.

b) wave.

39.2 Which of the following is a composite particle? (select all that apply)

a) electron

b) neutrino

c) proton

d) muon

39.3 Which of the following formed latest in the universe?

a) quarks

b) protons and neutrons

c) hydrogen atoms

d) helium nuclei

e) gluons

39.4 An exchange particle for the weak force is the

a) photon.

b) meson.

c) W boson.

d) graviton.

e) gluon.

39.5 Which of the following particles does not have an integer spin?

a) photon

b) ω meson

c) π meson

d) v_e lepton

39.6 At about what kinetic energy is the length scale probed by an α particle no longer calculated by the classical formula but rather by the relativistic formula?

a) 0.3 Gev

b) 0.3 GevV

c) 3 Gev

d) 30 Gev

39.7 Which of the following experiments proved the existence of the nucleus?

a) the photoelectric effect

b) the Millikan oil-drop experiment

c) the Rutherford scattering experiment

d) the Stern-Gerlach experiment

CONCEPTUAL Questions

39.8 Which of the following reactions cannot occur, and why?

a) $p \rightarrow \pi^+ + \pi^0$

b) $p\pi^0 \rightarrow n + e^+$

c) $\Lambda^0(1116) \rightarrow p + K^-\pi^+$

d) $\Lambda^0(1450) \rightarrow p + K^- + \pi^+$

39.9 Would neutron scattering or electromagnetic wave scattering (using X-rays or light) be more appropriate for investigating the scattering cross section of an atom as a whole? Which would be more appropriate for investigating the cross section of a nucleus of an atom? Which result will depend on *Z,* the atomic number?

39.10 Consider a hypothetical force mediated by the exchange of bosons that have the same mass as protons. Approximately what would be the maximum range of such a force? You may assume that the total energy of these particles is simply the rest-mass energy and that they travel close to the speed of light. If you do not make these assumptions and instead use the relativistic expression for total energy, what happens to your estimate of the maximum range of the force?

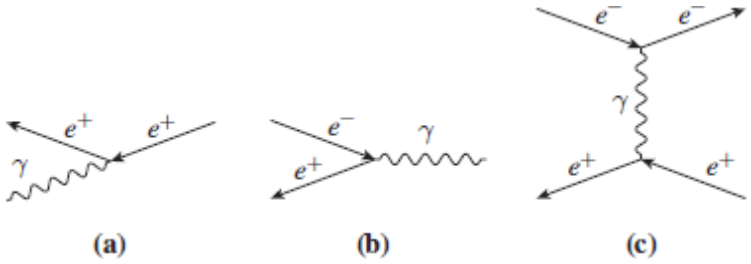
39.11 Looking at Table 39.3, do the constituent quarks uniquely define the type of meson?

39.12 A free neutron decays into a proton and an electron (and an anti-neutrino). A free proton has never been observed to decay. Why then do we consider the neutron to be as “fundamental” (at the nuclear level) a particle as the proton? Why do we not consider a neutron to be a proton-electron composite?

39.13 In a positron annihilation experiment, positrons are directed toward a metal. What are we likely to observe in such an experiment, and how might it provide information about the momentum of electrons in the metal?

39.14 If the energy of the virtual photon mediating an electron-proton scattering, $e^- + p \rightarrow e^- + p$, is E, what is the range of this electromagnetic interaction in terms of E?

39.15 Describe the physical processes that the following Feynman diagrams represent:



39.16 Figure 39.34 shows a Feynman diagram for the fundamental process involved in the decay of a free neutron: One of the neutron's down quarks converts to an up quark, emitting a virtual W^- boson, which decays into an electron and an anti-electron-neutrino (the only decay energetically possible). Sketch the basic Feynman diagram for the fundamental process involved in each of the following decays:

a) $\mu^- \rightarrow e^- + v_\mu + v_e$

b) $\tau^- \rightarrow \pi^- + v_\tau$

c) $\Delta^{++} \rightarrow p + \pi^+$

d) $K^+ \rightarrow \mu^+ + v_\mu$

e) $\Lambda^0 \rightarrow p + \pi^-$

39.17 Does the decay process $n \rightarrow p + \pi^-$ violate any conservation rules?

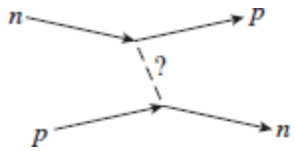
39.18 Consider the decay process $\pi^+ \rightarrow \mu^+ + v_\mu + v_e$. Can this decay occur?

39.19 Can the reaction $\pi^0 + n \rightarrow K^- + \sum^+$ occur?

39.20 How do we know for certain that the scattering process $e^+ + \nu_\mu \rightarrow e^+ + \nu_\mu$ proceeds through an intermediate Z boson and cannot proceed through an intermediate charged W boson, while both options are possible for $e^+ + \nu_e \rightarrow e^+ + \nu_e$?

39.21 What baryons have the quark composition *uds*? What is the mass of these baryons?

39.22 In the following Feynman diagram for proton-neutron scattering, what is the virtual particle?



EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 39.2

39.23 A 4.50-MeV alpha particle is incident on a platinum nucleus ($Z = 78$). What is the minimum distance of approach, r_{min}?

39.24 A 6.50-MeV alpha particle is incident on a lead nucleus. Because of the Coulomb force between them, the alpha particle will approach the nucleus to a minimum distance, r_{min}.

a) Determine r_{min}.

b) If the kinetic energy of the alpha particle is increased, will the particle's distance of approach increase, decrease, or remain the same? Explain.

39.25 A 6.50-MeV alpha particle scatters at a 60.0° angle off a lead nucleus. Determine the differential cross section of the alpha particle.

39.26 Protons with a kinetic energy of 2.00 MeV scatter off gold nuclei in a foil target. Each gold nucleus contains 79 protons. If both the incoming protons and the gold nuclei can be treated as point objects, what is the differential cross section that will cause the protons to scatter off the gold nuclei at an angle of 30.0° from their initial trajectory?

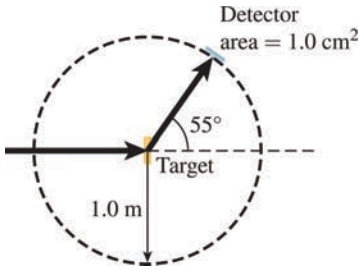
•**39.27** The de Broglie wavelength, λ, of a 5.00-MeV alpha particle is 6.40 fm,and the closest distance, r_{min}, to the gold nucleus this alpha particle can get is 45.5 fm (calculated in Example 39.1). How does the ratio r_{min}/λ vary with the kinetic energy of the alpha particle?

•**39.28** An experiment similar to the Geiger-Marsden experiment is done by bombarding a 1.00-μm-thick gold foil with 8.00-MeV alpha particles. Calculate the fraction of particles scattered at an angle (a) between 5.00° and 6.00° and (b) between 30.0° and 31.0°.

(The atomic mass number of gold is 197, and its density is $19.3\ \text{g/cm}^3$.)

•**39.29** The differential cross section that will cause particles to scatter at an angle 55° off a target is $4.0 \cdot 10^{-18}\text{m}^2/\text{sr}$. A detector with an area of $1.0\ \text{cm}^2$ is placed 1.0 m away from the target in

order to detect particles that have been scattered at 55°. If $3.0 \cdot 10^{17}$ particles hit the 1.0-mm^2-area target every second, how many will strike the detector every second?



•• **39.30** Some particle detectors measure the total number of particles integrated over part of a sphere of radius R, where the target is at the center of the sphere. Assuming symmetry about the axis of the incoming particle beam, use the Rutherford scattering formula to obtain the total number of particles detected in an an interval of width $d\theta$ as a function of the scattering angle, θ.

•• **39.31** Evaluate the form factor and the differential cross section, $d\sigma/d\Omega$, for a beam of electrons scattering off a *uniform-density* charged sphere of total charge Ze and radius R. Describe the scattering pattern.

Section 39.3

39.32 A proton is made of two up quarks and a down quark (*uud*). Calculate its charge.

39.33 Use the fact that the observed magnetic moment of a proton is $1.4 \cdot 10^{-26}$ A m^2 to estimate the speed of its quarks. For this estimate, assume that the quarks move in circular orbits of radius 0.80 fm and that they all move at the same speed and direction. Ignore any relativistic effects.

39.34 Determine the approximate probing distance of a photon with an energy of 2.0 keV.

39.35 Draw a Feynman diagram for an electron-proton scattering, $e^- + p \rightarrow e^- + p$, mediated by photon exchange.

39.36 Based on the information in Table 39.2, what is the approximate upper bound on the range of a reaction mediated by the Higgs boson?

39.37 Draw Feynman diagrams for the following phenomena:

a) protons scattering off each other

b) a neutron beta decays to a proton: $n \rightarrow p + e^- + v_e$

• **39.38** A proton and a neutron interact via the strong nuclear force. Their interaction is mediated by a meson, much like the interaction between charged particles is mediated by photons—the particles of the electromagnetic field.

a) Perform a rough estimate of the mass of the meson from the uncertainty principle and the known dimensions of a nucleus $\left(\sim 10^{-15}\ \text{m}\right)$. Assume that the meson travels at relativistic speed.

b) Use a line of reasoning similar to that in part (a) to prove that the theoretically expected rest mass of the photon is zero.

Section 39.5

39.39 How many fundamental fermions are there in a carbon dioxide molecule (CO_2)?

39.40 Suppose a neutral pion at rest decays into two identical photons.

a) What is the energy of each photon?

b) What is the frequency of each photon?

c) To what part of the electromagnetic spectrum do the photons correspond?

•**39.41** Draw a quark-level Feynman diagram for the decay of a neutral kaon into two charged pions: $K^0 \rightarrow \pi^+ + \pi^-$.

Section 39.6

39.42 During the radiation-dominated era of the universe, the temperature was falling gradually according to equation 39.17. Using Stefan's Law, find the time dependence of background-radiation intensity during that era.

39.43 Use equation 39.17 to estimate the age of the universe when protons and neutrons began to form.

39.44 Three hundred thousand years after the Big Bang, the average temperature of the universe was about 3000 k.

a) At what wavelength would the blackbody spectrum peak for this temperature?

b) In what portion of the electromagnetic spectrum is this wavelength found?

•**39.45** At about 10^{-6} s after the Big Bang, the universe had cooled to a temperature of approximately 10^{13} K.

a) Calculate the thermal energy $k_B T$ of the universe at that temperature.

b) Explain what happened to most of the hadrons—protons and neutrons—at that time.

c) Explain what happened to electrons and positrons in terms of temperature and time.

•**39.46** Three hundred thousand years after the Big Bang, the temperature of the universe was 3000 k. Because of expansion, the temperature of the universe is now 2.75 k. Modeling the universe as an ideal gas and assuming that the expansion is adiabatic, calculate how much the volume of the universe has changed. If the process is irreversible, estimate the change in the entropy of the universe based on the change in volume.

•**39.47** The fundamental observation underlying the Big Bang theory of cosmology is Edwin Hubble's 1929 discovery that the

arrangement of galaxies throughout space is expanding. Like the photons of the cosmic microwave background, the light from distant galaxies is stretched to longer wavelengths by the expansion of the universe. This is *not* a Doppler shift: Except for their local motions around each other, the galaxies are essentially at rest in space; it is space itself that expands. The ratio of the wavelength of light received at Earth from a galaxy, λ_{rec}, to its wavelength at emission, λ_{emit}, is equal to the ratio of the scale factor (radius of curvature) a of the universe at reception to its value at emission. The redshift, z, of the light—which is what Hubble could measure—is defined by $1 + z = \lambda_{\text{rec}}/\lambda_{\text{emit}} = a_{\text{rec}}/a_{\text{emit}}$.

a) Hubble's Law states that the redshift, z, of light from a galaxy is proportional to the galaxy's distance from Earth (for reasonably nearby galaxies): $z \cong c^{-1}H\Delta\text{s}$, where c is the vacuum speed of light, H is the *Hubble constant,* and Δs is the distance of the galaxy from Earth. Derive this law from the relationships described in the problem statement, and determine the Hubble constant in terms of the scale-factor function $a(\text{t})$

b) If the Hubble constant currently has the value $H_0 = 72(\text{km/s})/\text{Mpc}$, how far away is a galaxy whose light has the redshift $z = 0.10$? (The megaparsec (Mpc) is a unit of length equal to $3.26 \cdot 10^6$ light-years. For comparison, the Great Nebula in Andromeda is approximately 0.60 Mpc from Earth.)

Additional Exercises

39.48 What is the minimum energy of a photon capable of producing an electron-positron pair? What is the wavelength of this photon?

39.49

a) Calculate the kinetic energy of a neutron that has a de Broglie wavelength of 0.15 nm. Compare this with the energy of an X-ray photon that has the same wavelength.

b) Comment on how this energy difference is relevant to using neutrons or X-rays for investigating biological samples.

39.50 A photon can interact with matter by producing a proton-antiproton pair. What is the minimum energy the photon must have?

9.51 Suppose you had been doing an experiment to probe structure on a scale for which you needed electrons with 100. eV of kinetic energy. Then a neutron beam became available for the experiment. What energy would the neutrons need to have to give you the same resolution?

39.52 What is the de Broglie wavelength of an alpha particle that has a kinetic energy of 100. MeV? According to Figure 39.13, how does this wavelength compare to the size of structure that can be probed with this alpha particle?

39.53 One of the elementary bosons that can mediate electroweak interactions is the Z^0 boson, having the mass of $91.1876\ \mathrm{GeV}/c^2$. Find the order of magnitude of the range of the electroweak interaction.

39.54 What are the wavelengths of the two photons produced when a proton and an antiproton at rest annihilate?

39.55 Estimate the cross section of a Λ^0 particle decay (into $p + \pi^-, n + \pi^0$) if the time it takes for this electroweak interaction to occur is $\sim 10^{-10}$ s.

39.56 Determine the classical differential cross section for Rutherford scattering of alpha particles of energy 5.00 MeV projected at uranium atoms and scattered at an angle of 35.0° from

the initial trajectory. Assume that both the target and the projectile atoms are pointlike.

39.57 The Geiger-Marsden experiment successfully demonstrated the existence of the nucleus and put limits on its size using the scattering of alpha particles from gold foils. Assume that the alpha particles were fired with a speed about 5.00% of the speed of light.

a) Derive the upper bound of the radius of the nucleus in terms of the speed of the alpha particle that is scattered in the backward direction.

b) Calculate the approximate radius of the gold nucleus using the result from part (a).

•39.58 An electron-positron pair, traveling toward each other with a speed of 0.99*c* with respect to their center of mass, collide and annihilate according to $e^- + e^+ \rightarrow \gamma + \gamma$. Assuming that the observer is at rest with respect to the center of mass of the electron-positron pair, what is the wavelength of the emitted photons?

•39.59 Electron and positron beams are collided, and pairs of tau leptons are produced. If the angular distribution of the tau leptons varies as $\left(1 + \cos^2\theta\right)$, what fraction of the tau lepton pairs will be captured in a detector that covers only the angles from 60° to 120°?

•39.60 On July 4, 2012, the discovery of the Higgs boson at the Large Hadron Collider (LHC) was announced. During the data-taking run, the LHC reached a peak luminosity of $4.00 \cdot 10^{33}\ \text{cm}^{-2}\ \text{s}^{-1}$ (this means that in an area of 1 square centimeter, $4.00 \cdot 10^{33}$ protons collided every second). Assume that the cross section for the production of the Higgs boson in these proton-proton collisions is 1.00 pb (picobarn). If the LHC accelerator ran without interruption for 1.00 yr at this luminosity, how many Higgs bosons would be produced?

•• 39.61 Evaluate the form factor and the differential cross section, $d\sigma/d\Omega$, for a beam of electrons scattering off a *thin spherical shell* of total charge *Ze* and radius *a*. Could this scattering experiment

distinguish between thin-shell and solid-sphere charge distributions? Explain.

MULTI-VERSION EXERCISES

39.62 A neutrino beam with $E = 337$ GeV is passed through a 68.5-cm-thick slab of aluminum-27 (with 27 nucleons in each nucleus). What fraction of the neutrinos will scatter off a nucleon if the cross section is given by $\sigma(E) = \left(0.68 \cdot 10^{-38}\ \text{cm}^2\ \text{GeV}^{-1}\right)E$? (Aluminum has a density of $2.77\ g/\text{cm}^3$.)

39.63 A neutrino beam with $E = 143$ GeV is passed through a slab of aluminum-27 (with 27 nucleons in each nucleus). The probability that a neutrino in the beam will scatter off a nucleon in the aluminum slab is $4.19 \cdot 10^{-12}$. The scattering cross section is given by $\sigma(E) = \left(0.68 \cdot 10^{-38}\ \text{cm}^2\ \text{GeV}^{-1}\right)E$, and aluminum has a density of $2.77\ g/\text{cm}^3$. How thick is the slab?

39.64 A high-energy neutrino beam is passed through a slab of aluminum-27 (with 27 nucleons in each nucleus) of thickness 71.1 cm. The probability that a neutrino in the beam will scatter off a nucleon in the aluminum slab is $6.00 \cdot 10^{-12}$. The scattering cross section is given by $\sigma(E) = \left(0.68 \cdot 10^{-38}\ \text{cm}^2\ \text{GeV}^{-1}\right)E$, and aluminum has a density of $2.77\ g/\text{cm}^3$. What is the energy (in GeV) of the neutrino beam?

39.65 A Geiger-Marsden experiment, in which alpha particles are scattered off a thin gold film, yields an intensity of $I(94.9^\circ) = 853$ counts$/s$ at a scattering angle of $94.9^\circ \pm 0.7^\circ$. What is the intensity (in counts/s) at a scattering angle of $60.5^\circ \pm 0.7^\circ$. if the scattering obeys the Rutherford formula?

39.66 A Geiger-Marsden experiment, in which alpha particles are scattered off a thin gold film, yields an intensity of $I(95.1^\circ) = 1129$ counts/s at a scattering angle of $95.1^\circ \pm 0.4^\circ$. At a second scattering angle, the intensity is measured to be 4840 counts/s. Assuming that the scattering obeys the Rutherford

formula, what is that second angle (in degrees, to the same uncertainty)?

39.67 A Geiger-Marsden experiment, in which alpha particles are scattered off a thin gold film, is set up with two detectors at $\theta_1 = 85.1^\circ \pm 0.9^\circ$ and $\theta_2 = 62.9^\circ \pm 0.9^\circ$. Assuming that the scattering obeys the Rutherford formula, what is the ratio of the measured intensities, I_1/I_2?

Almost all of the energy resources used on Earth trace back to nuclear reactions. The overwhelming majority of these resources are due to our Sun (Figure 40.1), which at its core is a nuclear fusion reactor. This dependence on nuclear reactions makes it important to try to understand them better.

Chapter 39 explained that most of the mass of an atom resides in a small central region called the *nucleus*. This chapter explores the physics of the nucleus, which offers unique insights into the behavior of matter at its most basic level.

We will examine several models that help explain the properties of the nucleus, particularly those that explain the stability of some nuclei and the decay modes of others. Most nuclei are unstable, or radioactive, which has led to many important applications of nuclear physics, including nuclear power, nuclear

weapons, and nuclear medicine. In addition, studies of nuclear properties have contributed to our understanding of astronomy and of the origin of the chemical elements in the life cycles of stars.

WHAT WE WILL LEARN

- The atomic nucleus is composed of nearly equal numbers of protons and neutrons (nucleons), densely packed so that the nuclear volume increases approximately linearly with the mass number (which equals the number of nucleons).
- Nucleons interact primarily via the strong interaction, which has a short range, on the order of $10^{-15}\mathrm{m}$.
- Only 251 stable isotopes are known to exist. More than 2400 unstable isotopes have been discovered, with several thousand more predicted to exist.
- Nuclear masses can be measured very precisely, typically with the precision of 1 part in 100 million. Knowing the masses, we can calculate the binding energies of the isotopes, as well as the Q-values of nuclear reactions. The Q-value determines whether or not a reaction is allowed by energy conservation and is used to find how much energy the reaction releases.
- Several different models of the nucleus can be constructed. One model is based on the assumption that nuclear matter behaves like a liquid drop. This liquid-drop model explains the systematics of the nuclear binding energy. Another model proposes a quantum gas of particles trapped inside the nuclear walls. A third model takes into account the angular momentum quantum numbers and yields a picture of nuclear shells not unlike the electron shells in the atom.
- Unstable isotopes and their excited states can decay in three primary ways. Alpha decay is the emission of a helium-4 nucleus. Beta decay is a weak interaction process and results in either the emission of an anti-neutrino and an electron, the emission of a neutrino and a positron, or the capture of an electron by the nucleus along with the emission of a neutrino. Gamma decay is the emission of a high-energy photon.
- Energy can be released from nuclear reactions in two primary ways—fission and fusion. In fission, a massive nucleus splits into two less massive nuclei and a few neutrons. In fusion, two light nuclei merge into a heavier one.
- Neutron-induced nuclear fission and the ensuing chain reactions can be used for nuclear power plants, but also for nuclear weapons.
- Nuclear fusion powers most stars and is responsible for the light emitted by them as well as the creation of the elements up to iron and nickel.
- Elements heavier than iron are predominantly produced in supernova explosions.

- Nuclear physics has many applications in medicine, both in diagnostics and in the radiation treatment of cancers.

40.1 Nuclear Properties

Isotopes

The atomic nucleus consists of two kinds of **nucleons:** protons and neutrons. These nucleons are held together by the strong interaction. However, not all combinations of protons and neutrons are possible, because of the limitations imposed by the strong interaction, the Coulomb interaction, and quantum mechanics. The number of protons, Z, inside a nucleus determines the element that is formed. Z is the *charge number,* which is sometimes called the *atomic number*. For atoms of a given element, different numbers of neutrons, N, are possible. Nuclei of the same element with different numbers of neutrons are called **isotopes.** The total number of protons and neutrons combined is called the **mass number,** A:

$$A = Z + N. \tag{40.1}$$

Conventionally, a given nucleus is denoted by the symbol that represents its atom in the periodic table, with a superscript for the mass number of the isotope on the left and a subscript for the charge number on the left, and sometimes a subscript for the number of neutrons on the right. For example, the nucleus formed by 8 protons and 9 neutrons is written as ${}^{17}_{8}\mathrm{O}_{9}$, and the nucleus formed by 92 protons and 146 neutrons is written as ${}^{238}_{92}\mathrm{U}_{146}$. This is the most complete notation for isotopes. However, most of the time the subscript on the right is omitted, because the neutron number is simply $N = A - Z$ and thus can be computed easily from the superscript and subscript on the left. Most practicing nuclear physicists also omit the subscript for the charge number; they simply assume we know that uranium has 92 protons and oxygen has 8 protons. Thus, the above two isotopes are written in many nuclear physics textbooks as ${}^{17}\mathrm{O}$ (pronounced “oxygen seventeen”) and ${}^{238}\mathrm{U}$ (pronounced “uranium two-thirty-eight”). This book will show the subscript for the charge number, but not that for the neutron number. The above isotopes of oxygen and uranium are thus written as ${}^{17}_{8}\mathrm{O}$ and ${}^{238}_{92}\mathrm{U}$.

The only two isotopes that have historically received special names are the hydrogen isotopes deuterium (${}^{2}_{1}\mathrm{H} \equiv d$, an atom made up of a nucleus with a proton and a neutron, and a single electron) and tritium (${}^{3}_{1}\mathrm{H} \equiv t$, an atom made up of a nucleus with a proton and two neutrons, and a single electron).

What kinds of isotopes are found in nature? Answering this question will occupy us several times during this chapter. The overwhelming majority of isotopes decay over time. Only 251 stable isotopes are known, and they are shown in Figure 40.2, where each of them is marked by a blue square that indicates its neutron and proton numbers.

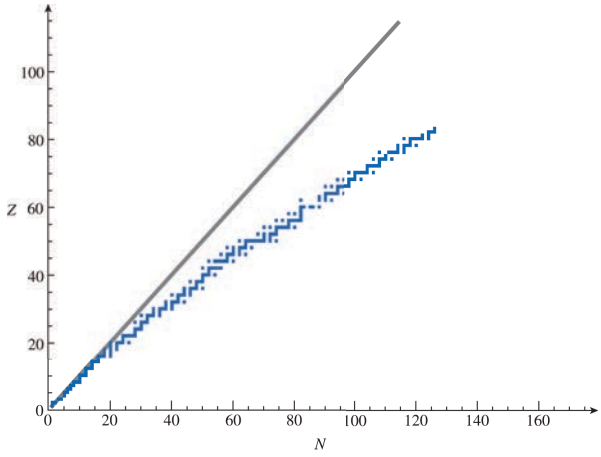

FIGURE 40.2 Stable isotopes, marked with blue squares that indicate their neutron and proton numbers. The gray line marks the $N = Z$ line.

Right away, we can see that there is no stable isotope with $Z > 83$ (bismuth has $Z = 83$). Also, note that there are no stable isotopes for $Z = 43$ (technetium) or for $Z = 61$ (promethium). Further, it is apparent that only a few stable isotopes occur for each Z value, and they are located along a narrow region in this plot, known as the *valley of stability*. For small values of N, this valley follows the $N = Z$ line, which is shown as a diagonal gray line in the plot. However, at $N \approx 20$, the valley of stability begins to veer off this line toward the neutron-rich $(N > Z)$. side. This effect is due to the Coulomb interaction among the protons, which also limits the size of the largest nucleus.

Nuclear Interactions

It is not convenient to describe the strong interaction between nucleons as being based on gluon exchange as proposed in QCD, described in Chapter 39. Instead, it is more efficient to describe effective interactions as being based on the exchange of color-singlets between the nucleons (which are also color-singlets). Since the least massive color-singlets are mesons, and the least massive meson is the pion, characterizing the nucleon-nucleon interaction in terms of pion exchange has been very successful. Historically, pion exchange potentials were formulated before the strong interaction was understood in terms of quarks and gluons, but that understanding explains the success of those potentials.

The Japanese physicist Hideki Yukawa (1907–1981) invented the pion exchange potential theory in 1935 and won the 1949 Nobel Prize in Physics for this achievement. The Yukawa potential is conventionally written in the form

$$U(r) = -g^2 \frac{e^{-r/R_\pi}}{r}, \tag{40.2}$$

where g is a real number and is the effective coupling constant in the same way that ke^2 is the coupling constant for the Coulomb potential of the electrostatic interaction. Here R_π is the range of the potential and is given in terms of the pion's mass as

$$R_\pi = \frac{\hbar}{m_\pi c} = \frac{\hbar c}{m_\pi c^2} = \frac{197.3 \text{ MeV fm}}{139.6 \text{ MeV}} = 1.413 \text{ fm}.$$

The derivative of the one-pion exchange potential with respect to r is greater than zero, so the corresponding force, $F(r) = -dU(r)/dr$, is attractive at all distances r.

The one-pion exchange potential is a very good approximation to the nucleon-nucleon potential at large separations. However, at shorter distances, two- and three-pion exchanges dominate nucleon-nucleon interactions. The effective nucleon-nucleon potential is strongly repulsive at short distances, thus preventing nucleons from penetrating each other. Schematically, the nucleon-nucleon potential is plotted inFigure 40.3. It varies depending on the spin and isospin projections (proton or neutron) of the two nucleons involved in the interaction, but has the general shape shown in the plot, with the minimum located at approximately 1 fm.

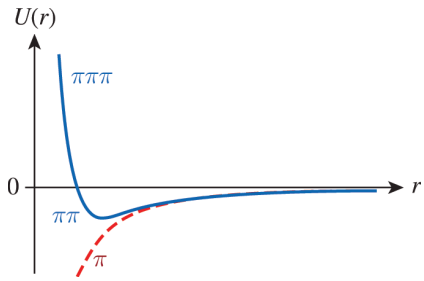

FIGURE 40.3 Schematic plot of the nucleon-nucleon potential (blue). At the point labeled *ππ*, two-pion exchange begins to dominate. At the point labeled *πππ*, three-pion exchange becomes important. The one-pion exchange potential is shown in red.

Nuclear Radius and Nuclear Density

Because the strong nuclear interaction is very short range, what is most important for nuclear physics is the nearest-neighbor interactions between nucleons. The repulsive nature of the potential at close distances prevents the nucleons from penetrating each other, so it has become common to visualize the nucleus as a roughly spherically shaped and densely packed collection of nucleons. This means that the volume of the nucleus should be proportional to the mass number, A. Since the volume of a sphere is proportional to the third power of the radius, the third power of the nuclear radius is proportional to its mass number, or, alternatively:

$$R(A) = R_0 A^{1/3}, \tag{40.3}$$

where the constant $R_0 = 1.12\ \text{fm}$ has been determined experimentally.

EXAMPLE 40.1 Nuclear Density

PROBLEM

What is the nuclear matter density, that is, the mass density inside an atomic nucleus?

SOLUTION

Since the nucleus can be approximated by a sphere with a radius given by equation 40.3, we can calculate its volume. We know the number of nucleons inside the sphere and their mass, so we can find the nuclear density as the ratio of the mass to the volume.

The volume of a nucleus of mass number A is

$$V = \frac{4\pi R(A)^3}{3} = \frac{4\pi R_0^3 A}{3} = \left(5.88\ \text{fm}^3\right)A.$$

This tells us that on average a nucleon occupies approximately $5.9\ \text{fm}^3$ of space inside a nucleus. We can now find the number density of nucleons inside the nucleus:

$$n = \frac{A}{V} = \frac{A}{\left(5.88\ \text{fm}^3\right)A} = 0.170\ \text{fm}^{-3}.$$

Thus, an atomic nucleus has 0.170 nucleons per cubic femtometer. The mass of a nucleon is approximately $1.67 \cdot 10^{-27}\text{kg}$. Multiplying this mass of a single nucleon by the number density of nucleons gives us the mass density of a nucleus:

$$\rho = m_{\text{nucleon}} n = m_{\text{nucleon}} \frac{A}{V} = \left(1.67 \cdot 10^{-27}\text{kg}\right)\left(0.170\left(10^{-15}\text{m}\right)^{-3}\right) =$$

For comparison, the density of liquid water is $10^3\,\text{kg/m}^3$; thus, nuclear matter density is approximately 280 trillion times higher than the density of liquid water.

Electron-scattering experiments of the kind described in Chapter 39 have established that the density is approximately constant in the interior of a heavy nucleus, and it falls off gradually near the surface. The dependence of the nuclear density on the radial coordinate r can be described by the *Fermi function*:

$$n(r) = \frac{n_0}{1 + e^{(r - R(A))/a}}, \tag{40.4}$$

where $R(A)$ is given by equation 40.3, and the constant a has the value of 0.54 fm (Figure 40.4). The distance over which the density falls from 90% of its central value to 10% of the central value is conventionally defined as the nuclear surface thickness, t. By using equation 40.4, we can show that $t \approx 4.4a$ (see Solved Poblem 40.1). Also, with $a = 0.54$ fm, the nuclear surface thickness for large nuclei is found to be approximately $t = 2.4$ fm.

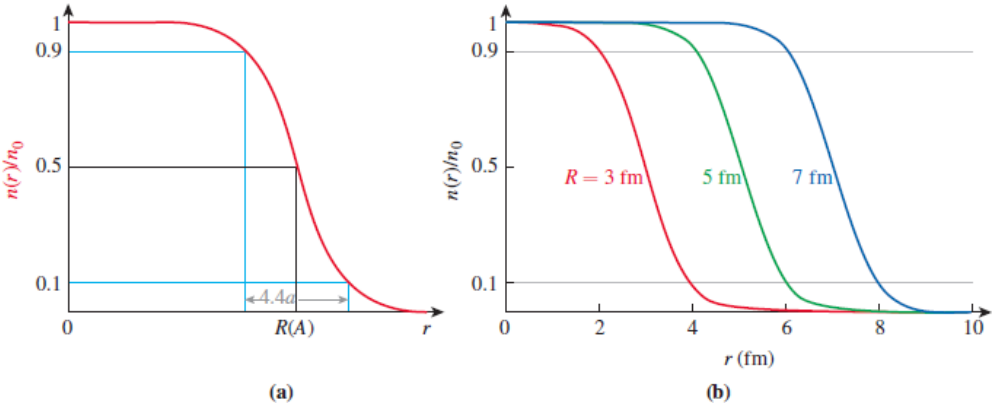

FIGURE 40.4 (a) Nuclear density profile as a function of the radial coordinate. (b) Fermi function for three different nuclear radii.

SOLVED PROBLEM 40.1 Nuclear Surface

PROBLEM

Derive a relationship between the nuclear surface thickness, t, and the parameters of the Fermi function (equation 40.4). What are the distances over which the nuclear density falls from 80% to 20% and from 70% to 30% of its central value?

SOLUTION

THINK

Equation 40.4 gives the Fermi function for the nuclear density, $n(r)$, as a function of the radial coordinate r. It contains the three parameters n_0, $R(A)$, and a:

$$n(r) = \frac{n_0}{1 + e^{(r-R(A))/a}}.$$

We know that $a = 0.54$ fm, $n_0 = 0.17$ fm^{-3}, and $R(A) = R_0 A^{1/3}$, with $R_0 = 1.12$ fm. Since n_0 is a multiplicative constant in the Fermi function, it cannot have any influence on the thickness of the nuclear surface. However, it is not quite as easy to tell whether $R(A)$ or a determines the surface thickness.

SKETCH

Figure 40.4b shows the Fermi function for three different values of the nuclear radius, R. It is clear from this sketch that the nuclear surface thickness, t, is independent of R. Thus, the nuclear surface thickness can only be a function of the parameter a.

RESEARCH

Our starting point is the Fermi function, which gives us the nuclear density as a function of the radial coordinate:

$$\frac{n(r)}{n_0} = \frac{1}{1 + e^{(r-R)/a}}. \qquad \textbf{(i)}$$

Here we have simplified the notation by writing R instead of $R(A)$ recognizing from our sketch that the particular value of the nuclear radius will have no influence on the nuclear surface thickness. We need to invert this function to obtain the radial coordinate as a function of the density, $r(n/n_0)$. Then the thickness is defined as

$$t = r(10\%) - r(90\%). \qquad \textbf{(ii)}$$

SIMPLIFY

We solve equation (i) for r by taking the inverse of both sides and then subtracting 1 from both sides:

$$\frac{n_0}{n} = 1 + e^{(r-R)/a} \Rightarrow \frac{n_0}{n} - 1 - e^{(r-R)/a}.$$

Now we take the natural log and find

$$\ln\left(\frac{n_0}{n} - 1\right) = (r - R)/a.$$

Multiplication of both sides by a and addition of R then results in

$$r = R + a\ln\left(\frac{n_0}{n} - 1\right),$$

which expresses the radial coordinate as a function of the density, $r(n/n_0)$, as desired. Using this expression with $n = 0.1n_0$ and $n = 0.9n_0$ as desired. Using this expression with equation (ii), we can obtain the surface thickness:

$$t = r(0.1) - r(0.9) = \left[R + a\ln\left(\frac{1}{0.1} - 1\right)\right] - \left[R + a\ln\left(\frac{1}{0.9} - 1\right)\right]$$

$$t = a\left[\ln\left(\frac{1}{0.1} - 1\right) - \ln\left(\frac{1}{0.1} - 1\right)\right] = a\left[\ln 9 - \ln 0.1\right] = 2a\ln 9$$

$$t = 4.39445a.$$

CALCULATE

We have obtained the desired relationship between the parameter a of the Fermi function and the nuclear surface thickness: $t \approx 4.4a$. Using $a = 0.54$ fm, we find that the surface thickness is 2.4 fm. What remains to be calculated are the thicknesses of the regions over which the density falls from 80% to 20% and from 70% to 30% of its central value:

$$r(0.2) - r(0.8) = (0.54\text{ fm})\left[\ln\left(\frac{1}{0.2} - 1\right) - \ln\left(\frac{1}{0.8} - 1\right)\right] = 1.497$$

$$r(0.3) - r(0.7) = (0.54\text{ fm})\left[\ln\left(\frac{1}{0.3} - 1\right) - \ln\left(\frac{1}{0.7} - 1\right)\right] = 0.915$$

ROUND

Since the constant $a = 0.54$ fm is given to only two significant figures, we round our results to

$$r(0.2) - r(0.8) = 1.5 \text{ fm}$$
$$r(0.3) - r(0.7) = 0.92 \text{ fm}.$$

DOUBLE-CHECK

As you can see from Figure 40.4b, the Fermi function falls off almost linearly between $n/n_0 = 0.9$ and $n/n_0 = 0.1$. Since the density interval between $n/n_0 = 0.7$ and $n/n_0 = 0.3$ is half of that between 0.9 and 0.1, we expect that the distance over which this fall-off occurs is approximately half of the nuclear surface thickness. (Remember: The surface thickness is defined as the distance over which the density falls off from 0.9 to 0.1 of the central density!) We found that the thickness is $t = 2.4$ fm, so it is not unreasonable to find $r(0.3) - r(0.7) = 0.92$ fm.

Nuclear Lifetimes

The stable isotopes shown in Figure 40.2 are not the only isotopes that can exist. A huge number of unstable isotopes are produced through natural nuclear decays and interactions or in the laboratory. The mean lifetime of an unstable isotope, which is also called its **nuclear lifetime,** is the average time it exists prior to decaying. A quantitative discussion of lifetimes is presented in section 40.2. Lifetimes vary over an incredible range, from greater than the age of the universe to less than a microsecond. So far, more than 3100 unstable isotopes are known to exist in addition to the 251 stable ones. Theoretical predictions of the number of isotopes that can possibly exist range up to approximately 6000, so there are many yet to be discovered. Several new rare isotope facilities in Dubna (Russia), Tokyo (Japan), Darmstadt (Germany), East Lansing, MI (USA), as well as many smaller laboratories around the world, are poised to advance the state of the art in this field in the coming decade.

Figure 40.5 shows the isotopes for which lifetimes have been measured. Each square represents an isotope, and the color of the square indicates the isotope's lifetime, according to the scale to the right of the plot. In general, lifetimes are longest for isotopes that are near the stable isotopes, with some lifetimes (shown in dark red) even exceeding the age of the universe (which is approximately $4.3 \cdot 10^{17}$s). Moving away from the stable isotopes, lifetimes become rapidly shorter. Note in particular the very short lifetimes of all isotopes with neutron numbers around 130 and the longer lifetimes for those with larger neutron numbers and proton numbers around 90. These isotopes with longer lifetimes include the isotopes of the actinides, most notably thorium, uranium, and plutonium. Uranium has no stable isotopes, but the isotopes ${}^{235}_{92}\mathrm{U}$ and ${}^{238}_{92}\mathrm{U}$ have lifetimes of 700 million years and 4.5 billion years, respectively, and thus live long enough to be found in large quantities on Earth. The following discussion will help you understand the systematic trends of the observed lifetimes.

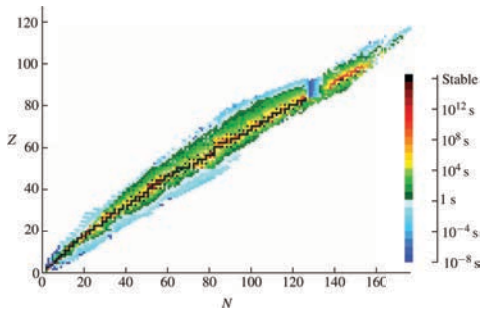

FIGURE 40.5 Measured lifetimes of the known isotopes.

Nuclear and Atomic Mass

The masses of the proton and the neutron are known to great precision. The values of the mass and the mass-energy equivalent for the proton are

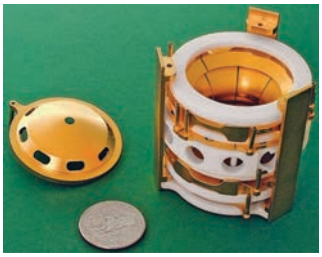
$$\begin{aligned} m_p &= 1.672\ 621637(83) \cdot 10^{-27}\ \text{kg} \\ m_p c^2 &= 1.503\ 277\ 359(75) \cdot 10^{-10}\ \text{J} = 938.272\ 013(23)\text{MeV} \end{aligned}$$

and the values for the neutron are

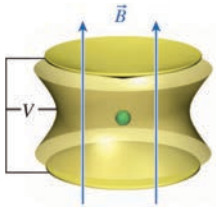
$$\begin{aligned} m_n &= 1.674\ 927\ 211(84) \cdot 10^{-27}\ \text{kg} \\ m_n c^2 &= 1.505\ 349\ 505(75) \cdot 10^{-10}\ \text{J} = 939.565\ 346(23)\text{MeV}. \end{aligned}$$

The parentheses around the last two digits in these numbers indicate that the preceding two digits are uncertain by those amounts; this is a more concise notation for the standard use of $\pm$ to denote uncertainties. For example, the notation $1.672\ 621\ 637(83)$ is equivalent to $1.672\ 621\ 637\ \pm\ 0.000\ 000\ 083$. The stated uncertainties in the proton and neutron masses mean that they are known to approximately 1 part in 10 million. Interestingly, what limits the precision of these masses is the accuracy to which Avogadro's number (N_A; see Chapter 13) is determined or, equivalently, to what precision the SI standard measure of the kilogram is known (Chapter 1).

Mass measurements for nuclei also reach this precision, even if the isotopes in question live only a few seconds or even a fraction of a second. One way to achieve such a mass measurement is to trap a single ion of a given atom in an electromagnetic trap inside a magnetic field (Figure 40.6a) and then measure its cyclotron frequency $\omega = qB/m \Rightarrow m = qB/\omega$ (see Chapter 27). Ion manipulation and storage are made possible by the electrode configurations shown in Figure 40.6b.



(a)



(b)

FIGURE 40.6 (a) Ion trap, which provides mass measurements by measuring an ion's cyclotron frequency. A U.S. silver dollar is shown for a scale comparison. (b) The configuration of the electrodes and magnetic field of the ion trap. The green sphere indicates the region where the ions are trapped.

a: MSU National Superconducting Cyclotron Laboratory

The charge of an ion is known precisely, because it is an integer multiple of the electron charge, and frequencies can be measured to essentially arbitrary accuracy by simply counting cycles, so the limit of this type of mass measurement depends on the accuracy with which the strength of the magnetic field, B, can be measured. The magnetic field cannot be measured to the necessary accuracy, so the cyclotron frequency of a known reference atom is measured in the same trap, thereby determining the unknown mass relative to the known one.

The reference mass usually chosen is the isotope $^{12}_{6}\mathrm{C}$. Because this isotope consists of 12 nucleons, the **atomic mass unit (u)** is defined as exactly $\frac{1}{12}$ of the mass of a $^{12}_{6}\mathrm{C}$ atom (mass of the nucleus of $^{12}_{6}\mathrm{C}$ plus the mass of the six electrons bound to the nucleus via the Coulomb interaction). The conversion of the atomic mass unit to kilograms and MeV/c^2 is given by

$$1\ \mathrm{u} = 1.660538782(83) \cdot 10^{-27}\ \mathrm{kg} = 931.494028(23)\mathrm{MeV}/c^2. \quad \textbf{(40.5)}$$

Note that some older references use “amu” instead of “u,” and in chemistry the dalton (Da) is often used instead of the atomic mass unit.

Chapter 13 introduced Avogadro’s number as the number of atoms making up exactly 1 mole of a substance; a mole of an element has a mass in grams equal to the atomic mass number of the element. Since the atomic mass number of $^{12}_{6}\mathrm{C}$ is 12, Avogadro’s number of $^{12}_{6}\mathrm{C}$ atoms have a mass of 12 g, and we can see that the relationship between the atomic mass unit and Avogadro’s number is given by

$$1\ \mathrm{u} = 1\ \mathrm{g}/N_\mathrm{A}.$$

If masses are stated in terms of the atomic mass unit and the above definition of this unit is used, the masses of other atoms can be measured relative to that of $^{12}_{6}\mathrm{C}$. Such a measurement has a high precision because it is not limited by the precision to which Avogadro’s number is known. For example, the proton and neutron masses can be specified to 10 significant digits (1 in 10 billion accuracy!):

$$\begin{aligned} m_\mathrm{p} &= 1.007\ 276\ 466\ 77(10)\ \mathrm{u} \\ m_\mathrm{n} &= 1.008\ 664\ 915\ 97(43)\mathrm{u}. \end{aligned} \quad \textbf{(40.6)}$$

Why use the mass of the neutral atom of $^{12}_{6}\mathrm{C}$, including its six electrons, as a reference value, instead of the mass of just the nucleus of $^{12}_{6}\mathrm{C}$? This is simply for convenience, because it is very hard to strip all the electrons off an atom. For the same reason, masses of all isotopes are always listed as atomic masses and include the same number of electrons as an isotope’s protons.

An ion trap like the one shown in Figure 40.6 can yield a precision of 1 part in 100 million for measurement of the mass of an atom with a lifetime of only 1 s. This precision is equivalent to measuring the mass of a convoy of 10 large 18-wheel trucks, each of mass 20 tons, to the accuracy of the weight of a single dime in the pocket of one of the truck drivers!

The mass of a nucleus is not simply the sum of the masses of the protons and neutrons contained in it. The nucleus is a bound object, and it takes energy to pull it apart into its constituents. Chapter 35 showed that energy is stored in the form of mass, and that energy and mass are related through the famous Einstein formula, $E = mc^2$. Thus, the **binding energy,** $B(N, Z)$, of a nucleus that

consists of N neutrons and Z protons can be written as the difference between the mass-energy of the collection of N neutrons plus Z hydrogen atoms (consisting of 1 proton and 1 electron each) and the mass-energy of the atom of mass $m(N, Z)$, consisting of N neutrons, Z protons, and Z electrons:

$$B(N, Z) = Zm(0, 1)c^2 + Nm_n c^2 - m(N, Z)c^2. \qquad \textbf{(40.7)}$$

Here $m(0, 1)$ is the mass of the hydrogen atom, with 0 neutrons, 1 proton, and 1 electron:

$$m(0, 1) = 1.007825032 \text{ u}.$$

Note that this value is slightly bigger than the mass of a proton given in equation 40.6; the difference is due to the electron's mass.

While equation 40.7 gives an expression for the total binding energy of a nucleus, it is more instructive to examine the binding energy per nucleon:

$$\frac{B(N, Z)}{(N + Z)} = \frac{B(N, Z)}{A}. \qquad \textbf{(40.8)}$$

Figure 40.7 shows the binding energy per nucleon (blue dots) for all stable isotopes as a function of the mass number, A. There is a strong increase for small Z, with a spike at $Z = 2$, a data point representing the binding energy of the nucleus of the helium atom—that is, the alpha particle. The value of the binding energy per nucleon of the alpha particle is $B\left({}^{4}_{2}\text{He}\right)/A = 7.074$ MeV. The curve reaches a maximum at iron $(Z = 26)$ and nickel $(Z = 28)$. The highest experimentally measured values of the binding energy per nucleon are $B\left({}^{62}_{28}\text{Ni}\right)/A = 8.795$ MeV, $B\left({}^{58}_{26}\text{Fe}\right)/A = 8.792$ MeV, and $B\left({}^{56}_{26}\text{Fe}\right)/A = 8.790$ MeV (indicated by the yellow dots in Figure 40.7). For $Z > 28$ and $A > 60$, the binding energy per nucleon falls gradually to a value slightly below 8 MeV. For $A > 100$, the binding energy per nucleon falls very nearly linearly with A, with a slope of

$$\left.\frac{\Delta(B/A)}{\Delta A}\right|_{A>100} = -7.1 \cdot 10^{-3}\text{MeV}.$$

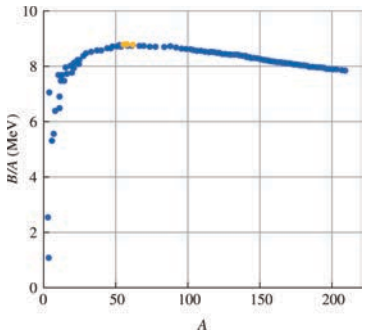


FIGURE 40.7 Binding energy per nucleon as a function of the mass number for all stable isotopes.

section 40.3 will present models for the nucleus that will help you understand why the binding energies of nuclei exhibit the trends shown in Figure 40.7.

Another way to express how well a nucleus is bound is the **mass excess,** defined as the difference between the mass of a nucleus and the mass number times the atomic mass unit: mass excess $= m(N, Z) - (A)(1\text{ u})$

The mass excess can be expressed in terms of energy units by converting from atomic mass units using equation 40.5. The binding energy is defined in terms of the mass of the neutron and the hydrogen atom, while the mass excess is defined in terms of the mass of ${}^{12}_{6}\text{C}$. The mass of ${}^{12}_{6}\text{C}$ is defined to be 12 u, so its mass excess is zero. Thus, the mass excess and the binding energy are similar but are not the same. If the mass excess of a nucleus is very negative, the nucleus will have a large binding energy per nucleon, as defined by equations 40.7 and 40.8. For example, one of the most tightly bound nuclei, ${}^{56}_{26}\text{Fe}$, has a mass excess of $-60.6\text{ MeV}/c^2$ and a binding energy per nucleon of $8.79\text{ MeV}/c^2$. The mass excesses for nuclei with $Z \leq 40$ are shown in Figure 40.8. The valley of stability described in Section 40.1 is clearly visible in this plot.

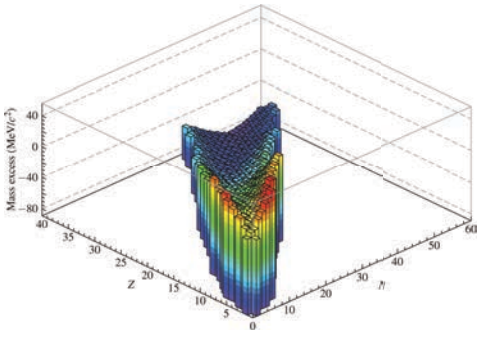

FIGURE 40.8 Mass excesses for nuclei with $Z \leq 40$

Nuclear Reactions and Q-Values

The calculation of the binding energy of a nucleus with equation 40.7 is a special case of a larger class of problems. The binding energy is simply the energy that must be supplied to break up one nucleus consisting of *N* neutrons and *Z* protons into its individual nucleons. In general, we can ask about the net energy change due to any rearrangement of an arbitrary group of neutrons and protons from an initial distribution into a final distribution. This rearrangement is called a **nuclear reaction,** in analogy with chemical reactions in which atoms get redistributed among different molecules. In chemical reactions, the number of atoms of a given species on the right-hand side (final state) of a reaction equation is exactly the same as that on the left-hand side (initial state). In nuclear reactions, a similar conservation law is observed: Because baryon number is a conserved quantity, the numbers of nucleons on the left-hand side and the right-hand side are the same. In addition, the number of protons and the number of neutrons are also separately conserved, with reactions that involve the weak force constituting the only exception. (The weak force was discussed in Chapter 39, in the form of the beta decay of the neutron or, equivalently, of the down quark.)

In practically all nuclear reactions, the initial state consists of either one or two nuclei, but not more, because nuclear sizes and therefore nuclear cross sections (see Chapter 39) are so small that the probability of three or more nuclei running into each other simultaneously is negligible.

The energy difference between the initial and final states is conventionally called the **Q-value** of the reaction. If the masses of all isotopes involved are known, then the Q-value is easily computed as the difference between the sum of the masses of the initial state nuclei and the sum of the masses of the final state nuclei. For example, for an initial state composed of a deuteron (${}^{2}_{1}\mathrm{H}$ nucleus) and ${}^{12}_{6}\mathrm{C}$ and a final state composed of an isolated proton and ${}^{13}_{6}\mathrm{C}$, the reaction can be written as ${}^{2}_{1}\mathrm{H} + {}^{12}_{6}\mathrm{C} \rightarrow p + {}^{13}_{6}\mathrm{C}$, and the Q-value of this reaction is computed as $Q = m(1,1)c^2 + m(6,6)c^2 - \left(m(0,1)c^2 + m(7,6)c^2\right)$, where the mass of a hydrogen atom is $m(0,1)$ and the mass of a deuterium atom is $m(1,1)$. (An often-used alternative notation for the same reaction is ${}^{12}_{6}\mathrm{C}\left({}^{2}_{1}\mathrm{H}, p\right){}^{13}_{6}\mathrm{C}$ or ${}^{12}_{6}\mathrm{C}(d,p){}^{13}_{6}\mathrm{C}$. Such *d,p reactions* are very popular tools for exploring nuclear structure.)

Why is the Q-value an interesting quantity? The answer is the same as in chemistry: The Q-value indicates whether the reaction is exothermic $(Q > 0)$ or endothermic $(Q < 0)$ in other words, whether energy is derived from the reaction or must be put in to make the reaction proceed. Many concepts and applications of nuclear physics depend on the Q-value, and we will repeatedly return to it in this chapter.

If we know the masses of the isotopes, we can also ask how much energy it takes to separate a particular isotope into two parts. In general, for division of a nucleus with N neutrons and Z protons into two smaller nuclei with neutron numbers N_1 and N_2 and proton numbers Z_1 and Z_2, the Q-value can be computed as

$$Q_{12} = m(N, Z)c^2 - m(N_1, Z_1)c^2 - m(N_2, Z_2)c^2, \qquad \textbf{(40.9)}$$

where $N_1 + N_2 = N$ and $Z_1 + Z_2 = Z$. The negative of the Q-value associated with this separation process, $-Q_{12}$, is called the **separation energy,** denoted by S; so $S = -Q_{12}$. If $S > 0$, then energy is required to separate the nucleus into the two parts; while if $Q_{12} > 0$, then energy is released when the separation takes place.

In these separation reactions, the numbers of protons and the numbers of neutrons remain the same in the initial and final states, so equation 40.7 can be used and the separation energy can be expressed as the difference in binding energies:

$$S = B(N_1 + N_2, Z_1 + Z_2) - B(Z_1, Z_1) - B(Z_2, Z_2). \qquad \textbf{(40.10)}$$

In the special case where one of the two nuclei is an alpha particle, this separation energy is usually denoted by the symbol S_α. Other conventionally quoted separation energies are those for proton emission, S_p, and single- and double-neutron emission, S_n and S_{2n}.

Concept Check 40.1

Which isotope X is needed to complete the reaction $n + {}^{235}_{92}\mathrm{U} \rightarrow {}^{134}_{34}\mathrm{Xe} + 2n + X$?

a) $X = {}^{100}_{38}\mathrm{Sr}$

b) $X = {}^{100}_{38}\mathrm{Xe}$

c) $X = {}^{100}_{62}\mathrm{Sr}$

d) $X = {}^{102}_{38}\mathrm{Sr}$

e) $X = {}^{100}_{37}\mathrm{Rb}$

Self-Test Opportunity 40.1

Is the reaction $d + {}^{12}_{6}\mathrm{C} \rightarrow p + {}^{13}_{6}\mathrm{C}$ exothermic or endothermic?

EXAMPLE 40.2 Separation Energy

PROBLEM

The binding energy per nucleon of the tin isotopes $^{136}_{50}\text{Sn}$, $^{134}_{50}\text{Sn}$, $^{132}_{50}\text{Sn}$, $^{130}_{50}\text{Sn}$, $^{128}_{50}\text{Sn}$, and $^{126}_{50}\text{Sn}$, are measured as 8.1991 MeV, 8.2778 MeV, 8.3549 MeV, 8.3868 MeV, 8.4167 MeV, and 8.4435 MeV, respectively. What are the two-neutron separation energies of the first five of these isotopes?

Page 1276

SOLUTION

From the given values of the binding energy per nucleon, we can obtain the total binding energy of each isotope by multiplying by its respective number of nucleons. We thus find

$$
\begin{aligned}
^{136}_{50}\text{Sn}: &\quad B(86,50) = 136 \cdot 8.1991\ \text{MeV} = 1115.08\ \text{MeV} \\
^{134}_{50}\text{Sn}: &\quad B(84,50) = 134 \cdot 8.2778\ \text{MeV} = 1109.23\ \text{MeV} \\
^{132}_{50}\text{Sn}: &\quad B(82,50) = 132 \cdot 8.3549\ \text{MeV} = 1102.85\ \text{MeV} \\
^{130}_{50}\text{Sn}: &\quad B(80,50) = 130 \cdot 8.3868\ \text{MeV} = 1090.28\ \text{MeV} \\
^{128}_{50}\text{Sn}: &\quad B(78,50) = 128 \cdot 8.4167\ \text{MeV} = 1077.34\ \text{MeV} \\
^{126}_{50}\text{Sn}: &\quad B(76,50) = 126 \cdot 8.4435\ \text{MeV} = 1063.88\ \text{MeV}.
\end{aligned}
$$

Since two neutrons do not form a bound state, the binding energy of the two neutrons is zero. Thus, in general, we have this simple formula for the two-neutron separation energy:

$$S_{2n}(N,Z) = B(N,Z) - B(N-2,Z). \qquad \textbf{(40.11)}$$

Inserting the values for the total binding energies that we have just computed into equation 40.11, we then find

$$
\begin{aligned}
S_{2n}\left(^{136}_{50}\text{Sn}\right) &= (1115.08\ - 1109.23)\ \text{MeV} = 5.85\ \text{MeV} \\
S_{2n}\left(^{134}_{50}\text{Sn}\right) &= (1109.23 - 1102.85)\ \text{MeV} = 6.38\ \text{MeV} \\
S_{2n}\left(^{132}_{50}\text{Sn}\right) &= (1102.85 - 1090.28)\ \text{MeV} = 12.57\ \text{MeV} \\
S_{2n}\left(^{130}_{50}\text{Sn}\right) &= (1090.28 - 1077.34)\ \text{MeV} = 12.94\ \text{MeV} \\
S_{2n}\left(^{128}_{50}\text{Sn}\right) &= (1077.34 - 1063.88)\ \text{MeV} = 13.46\ \text{MeV}
\end{aligned}
$$

This is a very interesting result. It shows that it suddenly becomes much harder to remove a pair of neutrons from a tin isotope as the neutron number reaches 82. Why is there a big jump in the value of the two-neutron separation energy at this neutron number? This question will be answered in the discussion of the nuclear shell model in Section 40.3.

40.2 Nuclear Decay

As we've noted, not all nuclear isotopes found in nature are stable. An example is uranium, which can be found on Earth in three naturally occurring isotopes: $^{238}_{92}\mathrm{U}$ (99.3% abundance), $^{235}_{92}\mathrm{U}$(0.7%), and $^{234}_{92}\mathrm{U}$ (trace amounts). They all decay naturally over very long times, and thus are present in appreciable quantities that have survived since the time Earth was formed approximately 4.5 billion years ago. This section looks at the factors that make nuclei unstable and cause them to decay over time. We will discuss alpha, beta, and gamma decays, as well as other decays. These nuclear decays are collectively called **radioactivity.** Radioactivity was discovered in 1896 by Pierre (1859–1906) and Marie Curie (1867–1934) and by Henri Becquerel (1852–1908), for which the three shared the 1903 Nobel Prize in Chemistry.

Exponential Decay Law

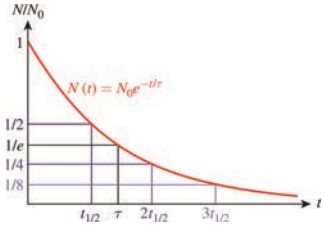
Because the laws of quantum mechanics govern atomic nuclei, all decays can be viewed as transitions from one quantum state to another. Thus, decay processes follow quantum mechanical probability rules like those for tunneling, presented in Chapters 36 and 37. It is possible to quantify most decays using quantum mechanics, but we do not need to do that here. All we need to know to understand radioactive decays is that the probability of observing a decay in a given set of atomic nuclei in a given time interval, dt, is proportional to the number of nuclei present. Letting the rate of change of the number of nuclei be dN/dt, we can express this proportionality as

$$dN = -\lambda N dt \Leftrightarrow \frac{dN}{dt} = -\lambda N,$$

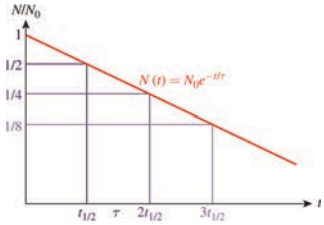
where λ is the decay constant. (The negative sign indicates that nuclei are lost as a function of time.) The solution of this differential equation leads to the exponential decay law:

$$N(t) = N_0 e^{-\lambda t}, \qquad \textbf{(40.12)}$$

where N_0 is the initial number of nuclei and $N(t)$ is the number of nuclei that remain as a function of time. Figure 40.9 shows plots of equation 40.12.



(a)



(b)

FIGURE 40.9
Exponential decay over time: (a) linear plot; (b) logarithmic plot.

The **half-life,** $t_{1/2}$, is defined as the time it takes a quantity of nuclei of a given material to decay to half of the original number, N_0:

$$N\left(t_{1/2}\right) = \tfrac{1}{2}N_0. \tag{40.13}$$

After two half-lives, the population has decreased to one-quarter of its initial value, and after three half-lives, to one-eighth. The decay constant can be related to the half-life by substituting from equation 40.13 into equation 40.12. This results in

$$\begin{aligned} &\tfrac{1}{2}N_0 = N_0 e^{-\lambda t_{1/2}} \Rightarrow \\ &\tfrac{1}{2} = e^{-\lambda t_{1/2}} \Rightarrow \\ &\ln\tfrac{1}{2} = -\lambda t_{1/2} \\ &t_{1/2} = \frac{\ln 2}{\lambda}. \end{aligned} \tag{40.14}$$

It is also common to talk about the **mean lifetime,** τ. This is defined as the average time it takes a nucleus to decay if the population of nuclei obeys the exponential decay law (equation 40.12). The mean lifetime is obtained by integration:

$$\tau = \langle N(t) \rangle_t = \frac{\int_0^\infty t\ N(t) dt}{\int_0^\infty N(t) dt} = \frac{\int_0^\infty t\ N_0 e^{-\lambda t} dt}{\int_0^\infty N_0 e^{-\lambda t} dt} = \frac{N_0\left(-1/\lambda^2\right) e^{-\lambda t}(1+\lambda}{N_0(-1/\lambda) e^{-\lambda t}\ {}_0^\infty}$$

Thus, the mean lifetime, τ, is simply the inverse of the decay constant, λ. Therefore, as an alternative to equation 40.12, the exponential decay law can be written as

$$N(t) = N_0 e^{-t/\tau}.$$

After one mean lifetime, the population has been reduced by a factor of $1/e$:

$$N(\tau) = N_0 e^{-\tau/\tau} = N_0/e.$$

Finally, combining equations 40.15 and 40.14, we find that the half-life $t_{1/2}$ and the mean lifetime τ are related via

$$t_{1/2} = \frac{\ln 2}{\lambda} = \tau \ln 2.$$

Thus, the half-life is not a half of the lifetime, but a factor $\ln 2 \approx 0.693$ of the lifetime. For example, Chapter 39 gave the lifetime of the neutron as 881.5 s. This means that its half-life is (881.5 s) $\ln 2 = 611.0$ s.

The mean lifetimes of isotopes are the values displayed in Figure 40.5. What kinds of nuclear decays leading to the lifetimes shown in Figure 40.5 are possible in nature?

The three main nuclear decays are the emission of an alpha particle, the emission of an electron or a positron (or, equivalently, the capture of an electron), and the emission of a photon. These decays constitute the three components of what is commonly called *radioactivity*. Radioactive decays can be very harmful to human health, completely harmless, or in some cases even very helpful in medical diagnostics and treatment. Their effect on health depends on the type of decay, the energy of the decay product, and the radiation dose, that is, the amount of radioactive material present and the amount of radiation emitted. Figure 40.10 shows how the different radioactive decays change the nucleus that decays. The following subsections discuss each decay mode in more detail.

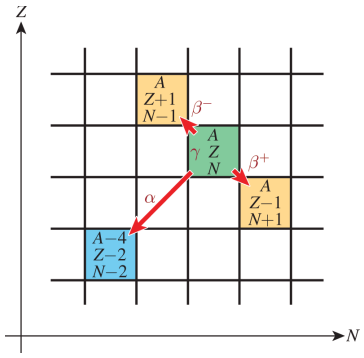


FIGURE 40.10 Nuclear decays in a chart of isotopes.

In all decays, the decaying nucleus is called the *parent* and the nucleus it decays into is the *daughter*. If the parent and daughter nuclei are different elements, the process is known as **transmutation**. Only those decays that obey the conservation laws, in particular those of energy, charge, and baryon number, are possible.

Alpha Decay

In an **alpha decay** (α decay), the nucleus emits an alpha particle, which is the nucleus of a helium atom, ${}^{4}_{2}\mathrm{He}$. This means that the mass number of the parent nucleus decreases by four and the charge number by two:

$$ {}^{A}_{Z}\mathrm{Nuc} \rightarrow {}^{4}_{2}\mathrm{He} + {}^{A-4}_{Z-2}\mathrm{Nuc}'. \qquad \textbf{(40.16)} $$

(The notation Nuc' is used to indicate a nucleus that is different in its composition from the initial nucleus, before the decay.) In general, alpha decays are possible when the energy contained in the mass of the alpha particle plus the mass of the daughter nucleus, $m\left({}^{A-4}_{Z-2}\mathrm{Nuc}'\right)$, is smaller than the mass of the nucleus that undergoes the alpha decay:

$$ m\left({}^{A}_{Z}\mathrm{Nuc}\right) > m_{\alpha} + m\left({}^{A-4}_{Z-2}\mathrm{Nuc}'\right). \qquad \textbf{(40.17)} $$

Since the binding energy per nucleon of the alpha particle (of mass m_{α}) is very large, 7.074 MeV, the mass of the alpha particle is comparatively low. In addition, as shown in Figure 40.7, the binding energy per nucleon falls very gradually as a function of the mass number, A, for nuclei with large mass numbers. This makes alpha decay possible for almost all unstable isotopes with $A > 150$.

Chapter 37 mentioned that alpha decay is an example of tunneling—the transmission of the wave function of the alpha particle through a classically forbidden region. This is illustrated in Figure 40.11, where the total energy of the nuclear system is plotted as a function of the separation r between the center of the alpha particle and the center of the daughter nucleus. If the four nucleons that constitute the alpha particle are approximately in the center of the parent nucleus, then the total energy is approximately just the energy contained in the mass of the parent nucleus, $m\left({}^{A}_{Z}\mathrm{Nuc}\right)c^2$, as shown in Figure 40.11 at r = 0. When the alpha particle and the daughter nucleus are widely separated, $r \rightarrow \infty$, the interaction between the two becomes negligible, and the total energy is the mass-energy of the daughter nucleus plus that of the alpha particle, $\left(m\left({}^{A\ \ -4}_{Z\ -2}\mathrm{Nuc}'\right) + m(\alpha)\right)c^2$. For many heavy nuclei, this value of the total energy is *lower* than the value at the center. Therefore, the emission of the alpha particle from the parent nucleus is energetically favorable.

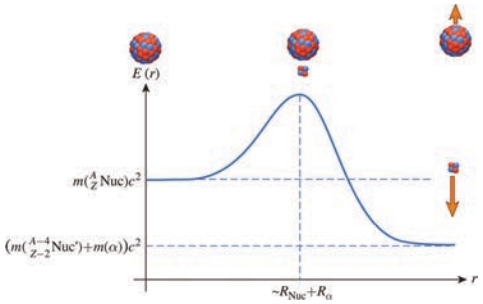

FIGURE 40.11 Plot of the potential energy of the alpha particle and the daughter nucleus, showing the potential barrier (located at the vertical dashed line) for alpha decay.

However, first the alpha particle has to get out of the parent nucleus. Moving the four nucleons of the alpha particle to one side or the other deforms the nucleus. This deformation increases the excitation of the nucleus, and the potential energy increases relative to the value at $r = 0$. At a configuration where the alpha particle and the daughter nucleus barely touch, indicated by the vertical dashed line in Figure 40.11, the potential energy has a maximum, because of the Coulomb repulsion between the alpha particle and the daughter nucleus. This increase in potential energy forms a potential barrier and prevents spontaneous alpha decay. However, the wave function of the alpha particle can tunnel through this potential barrier, leading to emission of the alpha particle. The tunneling probability and thus the lifetime of the nucleus before alpha decay depend very strongly on the shape (mainly width, but also height) of the barrier.

When the alpha particle escapes from the nucleus, the energy difference between the mass-energies of the parent and daughter nuclei, which is the Q-value of the reaction, is converted into kinetic energy of the alpha particle and the heavy remnant:

$$K_{\alpha} + K_{\text{Nuc}'} = Q = \left(m\left({}^{A}_{Z}\text{Nuc}\right) - m\left({}^{A}_{Z}\,{}^{-4}_{-2}\text{Nuc}'\right) - m_{\alpha}\right)c^2. \quad \textbf{(40.18)}$$

Total momentum is conserved, so the momentum of the alpha particle and the momentum of the daughter nucleus must be equal in magnitude and opposite in direction in the rest frame of the parent nucleus, $\vec{p}_{\alpha} = \vec{p}_{\text{Nuc}'}$. For the low kinetic energies occurring here, the nonrelativistic approximation $K = p^2/2m$ is sufficient. Momentum conservation then means that the kinetic energy of the daughter nucleus is related to the kinetic energy of the alpha particle via

$$K_{\mathrm{Nuc}'} m\left({}^{A}_{Z}{}^{-4}_{-2}\mathrm{Nuc}'\right) = K_\alpha m_\alpha \Leftrightarrow K_{\mathrm{Nuc}'} = K_\alpha \frac{m_\alpha}{m\left({}^{A}_{Z}{}^{-4}_{-2}\mathrm{Nuc}'\right)}.$$

Inserting this result into equation 40.18, we find that the kinetic energy of the alpha particle in the rest frame of the parent nucleus is

$$K_\alpha = \frac{m\left({}^{A}_{Z}{}^{-4}_{-2}\mathrm{Nuc}'\right)}{m\left({}^{A}_{Z}{}^{-4}_{-2}\mathrm{Nuc}'\right) + m_\alpha}\left(m\left({}^{A}_{Z}\mathrm{Nuc}'\right) - m\left({}^{A}_{Z}{}^{-4}_{-2}\mathrm{Nuc}'\right) - m_\alpha\right)c^2. \quad \textbf{(4}$$

EXAMPLE 40.3 Roentgenium Decay

By shooting a beam of $^{64}_{28}\text{Ni}$ nuclei at a $^{209}_{83}\text{Bi}$ target in December 1994, a group at the GSI national laboratory in Germany was able to produce a new element with 111 protons and 161 neutrons through the reaction $^{64}_{28}\text{Ni} + ^{209}_{83}\text{Bi} \rightarrow ^{272}_{111}\text{Rg} + n$. Here Rg stands for roentgenium, the official name this new element received in November 2006. The GSI group detected three events in which the new element was produced by observing successive alpha decays of the new element and its known daughter nuclei. One of the three events, with the measured alpha decay times, is shown in Figure 40.12.

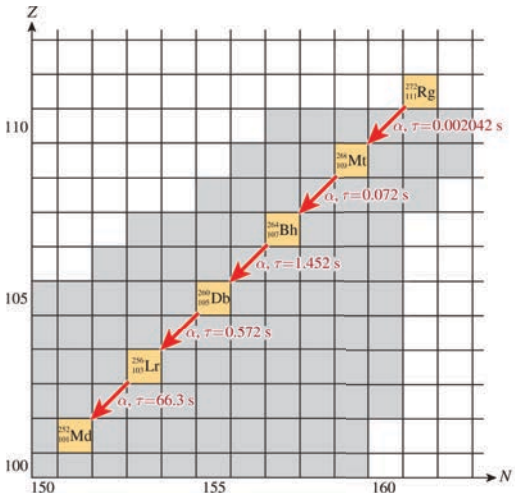

FIGURE 40.12 Roentgenium decay chain as observed on Dec. 17, 1994, at the GSI. The alpha decay chain proceeds through meitnerium (Mt), bohrium (Bh), dubnium (Db), and lawrencium (Lr) to mendelevium (Md). The gray boxes indicate isotopes that have been observed.

PROBLEM

The masses of the nuclei in the decay chain are listed in nuclear data tables (in atomic mass units) as 272.1536, 268.138728, 264.1246, 260.1113, 256.098629, and 252.08656. What energies would you predict for the emitted alpha particles?

SOLUTION

Since the masses of the isotopes are given, we can calculate the Q-value for each decay using equation 40.18. We can then use equation 40.19 to calculate

the expected kinetic energy of the alpha particle. This is done in the table below for each of the decays.

The last column of the table compares our predictions with the experimental results that were reported by the GSI group. As you can see, the two sets of numbers are in reasonably good agreement.

DISCUSSION

In practice, the masses of the so-called superheavy elements (those with triple-digit charge numbers) are mostly determined from measurements of the kinetic energies of the alpha particles from the isotopes' decays. The values listed in the table are from one particular event in one particular experiment. The isotope masses are determined from best fits to all available data. For the heaviest elements, these data consist of only a few events, but for charge numbers below 100, millions of events have been recorded. The fact that the observed kinetic energies of the emitted alpha particles and the decay times agreed so well with previously measured data served to convince the GSI group that they had indeed seen the first events of the production of the new element roentgenium.

Name	A	Z	m (u)	$m_\alpha + m$ (u)	Q (MeV)	K_α predicted (MeV)

Beta Decay

In a **beta decay** β decay), the nucleus emits an electron (e^-) or a positron (e^+) or captures one of its own orbiting electrons. Chapter 39 discussed the beta decay of quarks, particularly the β^- decay of a down quark into an up quark: $d \rightarrow u + e^- + v_e$. Since the neutron is composed of two down quarks and an up quark, one way that the β^- decay of the down quark manifests itself is the β^- decay of the neutron, $n \rightarrow p + e^- + v_e$, discussed earlier. The general form of a nuclear β^- decay can be written as

$$ {}^{A}_{Z}\text{Nuc} \rightarrow {}^{A}_{Z+1}\text{Nuc}' + e^- + v_e. \qquad \textbf{(40.32)} $$

Note that in nuclear β^- decay, the mass number of the nucleus remains the same, but the charge number increases by 1.

Because nuclei are made of neutrons and protons, it might seem that beta decays should always be possible. However, a beta decay can happen only if it is allowed by energy conservation—that is, the combined mass of the electron and the daughter nucleus must be smaller than the mass of the parent nucleus. It might be expected that this will always be the case because of the mass difference of $1.293\ \text{MeV}/c^2$ (or 0.00139 u) between neutron and proton, which is quite a bit larger than the electron mass of $0.511\ \text{MeV}/c^2$. Although this argument is correct for free neutrons, it is not always true for neutrons bound inside a nucleus. The reason is that the nuclear interaction favors configurations with equal numbers of neutrons and protons. As an example of the effect that this part of the nuclear interaction has, Figure 40.13 plots the experimentally measured masses (horizontal red lines) of all known isotopes with $A = 82$ as a function of the charge number, Z. Clearly it is energetically possible for the bromine $(Z = 35)$ isotope with mass number 82 to undergo the β^- decay ${}^{82}_{36}\text{Br} \rightarrow {}^{82}_{36}\text{Kr} + e^- + v_e$, but the β^- decay of ${}^{82}_{36}\text{Kr}$ into ${}^{82}_{37}\text{Rb}$ is energetically forbidden, because ${}^{82}_{37}\text{Rb}$ has a greater mass than ${}^{82}_{36}\text{Kr}$.

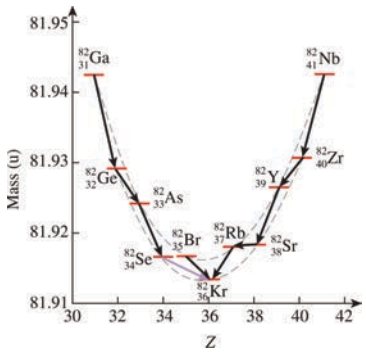

FIGURE 40.13 Nuclei of mass number 82. Their measured masses (in atomic mass units) are shown as a function of the charge number. The black arrows represent beta-decay processes. The purple arrow represents a double beta decay.

Furthermore, it is also possible for beta decays to proceed in the opposite direction inside nuclei. In such a β^+ decay, a proton is converted into a neutron via the emission of a positron and an electron-neutrino: $p \rightarrow n + e^+ + v_e$. For a free proton, this process is energetically not possible because the neutron has a higher mass than the proton. However, inside the nucleus, the reaction

$$ {}^{A}_{Z}\text{Nuc} \rightarrow \ {}^{A}_{Z-1}\text{Nuc}' + e^+ + v_e, \qquad \textbf{(40.21)} $$

can proceed when the masses of initial and final isotopes are such that the Q-value of the reaction is positive. In addition, a proton inside the nucleus can be converted into a neutron via electron capture: $e^- + p \rightarrow n + v_e$. In this β^+ decay, the nucleus captures one of its own orbiting electrons:

$$ e^- + {}^{A}_{Z}\,\text{Nuc} \rightarrow {}^{A}_{Z-1}\,\text{Nuc}' + v_e. \qquad \textbf{(40.22)} $$

We use β^+ decay to refer to both processes, positron emission (equation 40.21) and electron capture (equation 40.22). Theoretically, a third way to convert a proton into a neutron is via anti-neutrino capture: $v_e + p \rightarrow n + e^+$. However,

this process is of negligible importance to us because the cross section is extremely small and because an atom does not have a source of anti-neutrinos present. Consulting Figure 40.13 once again, you see that the nuclei on the right-hand side of the figure can all undergo β^+ decay.

Note that the Q-values for the reactions in equations 40.21 and 40.22 are not the same. The initial state of the reaction in equation 40.21 consists of Z protons, $N = A - Z$ neutrons, and Z electrons, all of which are accounted for in the mass of the initial atom, $m(N, Z)$. The final state consists of an atom with $Z - 1$ protons, $N + 1$ neutrons, and $Z - 1$ electrons, plus one additional electron, plus the newly created positron and neutrino. This atom has a mass of $m(N + 1, Z - 1)$, and the electron and the positron each have a mass of $m_e = 0.511\ \text{MeV}/c^2$. Neglecting the binding energy of the electron and the mass of the neutrino, each of which are on the order of 1 eV or less, we then obtain for the Q-value of the positron-emitting β^+ decay (equation 40.21)

$$Q(e^+) = m(N, Z)c^2 - m(N + 1, Z - 1)c^2 - 2(0.511\ \text{MeV}).$$

The initial state of the reaction in equation 40.22 consists of the same atom with Z protons, $N = A - Z$ neutrons, and Z electrons, and the final state consists of a neutrino and an atom with $Z - 1$ protons, $N + 1$ neutrons, and $Z - 1$ electrons. Thus, in this case, the Q-value is simply

$$Q(ec) = m(N, Z)c^2 - m(N + 1, Z - 1)c^2.$$

(Remember, the nucleus captured one of its atom's own electrons!) Therefore, the Q-value of the electron capture (ec) reaction is always 1.022 MeV larger than that for the same β^+ decay that involves positron emission (e^+). This implies that for some isotopes only electron capture is possible, not positron emission.

Concept Check 40.2

The isotopes ${}^{82}_{36}\text{Kr}$, ${}^{82}_{37}\text{Rb}$, and ${}^{82}_{38}\text{Sr}$ have masses of 81.9134836 u, 81.9182086 u, and 81.91840164 u, respectively. For which of the β^+ decays of ${}^{82}_{37}\text{Rb}$ and ${}^{82}_{38}\text{Sr}$ is positron emission possible?

a) for neither

b) only for the ${}^{82}_{37}\text{Rb}$ decay

c) only for the ${}^{82}_{38}\text{Sr}$ decay

d) for both

For alpha decay, we have seen that the emitted alpha particle has a characteristic energy (equation 40.19), because energy and momentum need to be conserved in the decay. However, in beta decays, the situation is more

complicated. In β^- decays as well as in positron-emitting β^+ decays, the final state consists of three particles that can share the decay energy. The emitted neutrinos cannot be observed directly and can carry different amounts of energy. Thus, the electrons or positrons produced by these decays do not have well-defined kinetic energy values, but instead show a continuous distribution of energies.

Gamma Decay

A **gamma decay** (γ decay) is the emission of a photon from a nucleus and is always the product of de-excitation of an excited nuclear state. Gamma decays are qualitatively different from alpha or beta decays in that they do not result in transmutation. Nuclei can attain excited states similarly to how atoms can, by collisions with other objects. The kinetic energy from these processes can be converted into excitation energy, lifting nucleons into higher shells or causing collective vibrations or rotations of the entire nucleus.

The process of gamma decay in nuclei is similar to the emission of photons in the de-excitation of atoms. However, the characteristic electron energies in the atom are on the order of electron-volts, whereas the characteristic energies of nuclear excited states are on the order of millions of electron-volts. Thus, the photons emitted in gamma decays typically are a million times more energetic than the photons emitted in atomic decays.

The initial and final states of the nucleus have well-defined energies, so the photon energy is also, in principle, well defined. However, an excited nuclear state has a finite lifetime, τ Thus, the uncertainty in the energy of the emitted photon, denoted as the width, Γ, has a lower limit given by the uncertainty relation: $\Gamma > \hbar/\tau$. Thus, the measured energies of gamma rays resulting from the decay between two specific states with finite lifetimes in a nucleus will have a distribution that is not a spike at a single energy, but rather takes the form of a peak in energy with a characteristic width in energy.

Most excited isotopes can de-excite via gamma decay. However, the larger the difference between the angular momentum of the initial state and that of the final state, the lower the probability for gamma decay becomes. In some isotopes, the angular momentum of the lowest excited state has a large difference from that of the ground state, and so a gamma decay is very improbable. These isotopes form very long-lived “isomer” states.

Gamma rays emitted from nuclei are very important diagnostic tools for learning about nuclear structure. Since a very large number of states exist in any sample of a given isotope, a large number of gamma rays can be detected at different energies. It requires ingenious detective work and large photon detector arrays (Figure 40.14) to interpret the information on nuclear structure contained in these spectra.

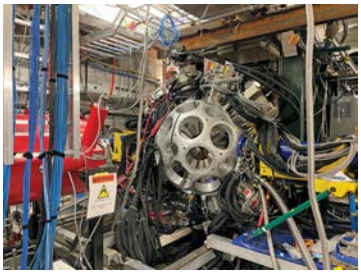

FIGURE 40.14 Photo of the GRETINA (Gamma-Ray Energy Tracking In-beam Nuclear Array) photon detection array. GRETINA will detect photons from reactions induced by beams from FRIB (Facility for Rare Isotope Beams).

W. Bauer

Gamma rays are not only emitted in single-particle transitions in which a single nucleon jumps from an excited state to another state. They can also be emitted from collective vibrations of nuclei, as well as from rotating deformed nuclei. *Superdeformed nuclei,* which are cigar-shaped with an axes ratio of 2:1, were discovered only recently with the aid of gamma-ray spectroscopy. Figure 40.15 shows the gamma-ray spectrum of $^{152}_{66}\mathrm{Dy}$, whose most prominent feature is the sequence of peaks with a very regular spacing of $\Delta E = 47.5\ \mathrm{keV}$. These peaks result when a rotating nucleus makes transitions between angular momentum states having even multiples of $\hbar$.

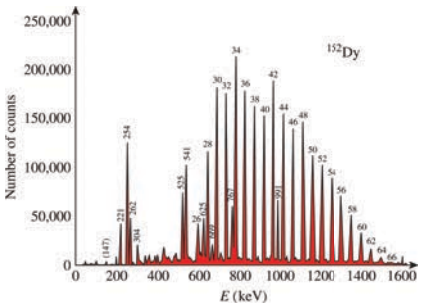

FIGURE 40.15 Gamma-ray spectrum of the superdeformed isotope dysprosium-152. The measured gamma rays are identified either by the energy (in keV, vertical numbers) or by the angular momentum (in units of $\hbar$, horizontal numbers).

Other Decays

While alpha, beta, and gamma decays constitute the overwhelming majority of radioactive decay, we should note a few other decay modes.

Light, very neutron-rich isotopes can decay by emission of a single neutron. Light and very proton-rich isotopes can decay via the emission of a proton. Neutron and proton emitters usually have extremely short lifetimes and are not quite bound nuclei. An example of a neutron emitter is ${}^{10}_{3}\text{Li}$. The isotope with one more neutron than ${}^{10}_{3}\text{Li}$, ${}^{11}_{3}\text{Li}$, has been intensively investigated recently because it consists of three parts $\left({}^{9}_{3}\text{Li} + 2n\right)$ that form a bound state only if all three are together. There is no bound state of two neutrons, and the neutron emitter ${}^{10}_{3}\text{Li}\left({}^{9}_{3}\text{Li} + 1n\right)$ is also not a bound nucleus. Thus, ${}^{11}_{3}\text{Li}$ is a strange nucleus consisting of a core of ${}^{9}_{3}\text{Li}$ and a very large "halo" made of two neutrons. The diameter of this halo has been measured to be almost as large as that of a lead nucleus, which consists of 208 nucleons. ${}^{11}_{3}\text{Li}$ therefore deviates strikingly from the nuclear size law expressed in equation 40.3.

A few isotopes are known to exhibit cluster decays. **Cluster decays** involve the emission of nuclei heavier than helium. Almost all known cluster decays emit carbon nuclei, ${}^{12}_{6}\text{C}$ or ${}^{14}_{6}\text{C}$, and in some very rare cases oxygen, neon, or magnesium nuclei.

One very important decay mode of heavy nuclei, fission, will be discussed in Section 40.4.

Many isotopes have two or more possible decay modes. Figure 40.16 presents an overview of the dominant decay modes for all known isotopes. Proton-rich isotopes decay via β^+ decays or proton emission, and neutron-rich nuclei via β^- decays or neutron emission. For heavier nuclei, alpha decay becomes dominant, and the heaviest isotopes often decay predominantly via spontaneous fission.

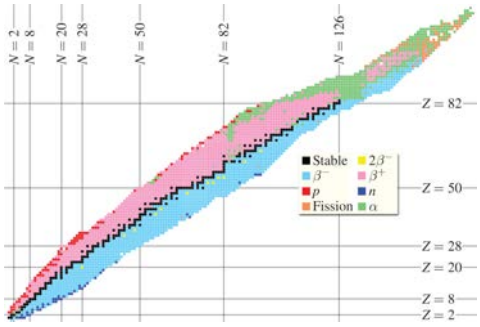

FIGURE 40.16 Dominant decay modes for the known isotopes.

Concept Check 40.3

Which of the following types of nuclear decays are possible for the isotope $^{82}_{33}$As? (*Hint:* The mass of $^{82}_{33}$As is 81.925 u, the mass of $^{82}_{32}$Ge is 81.930 u, the mass of $^{82}_{34}$Se is 81.917 u, the mass of $^{78}_{31}$Ga is 77.932 u, and the mass of $^{4}_{2}$He is 4.0026u.)

a) alpha decay

b) beta decay

c) positron emission

d) electron capture

e) gamma decay

An extremely rare decay mode of some isotopes is *double beta decay,* which was first observed in 1987 in an isotope of selenium, $^{82}_{34}$Se, by Michael Moe and colleagues at the University of California–Irvine. Referring back to Figure 40.13, you can see that $^{82}_{34}$Se cannot undergo a simple β^- decay to $^{82}_{35}$Br. because its mass is lower than that of $^{82}_{35}$Br. Thus, that reaction is forbidden by energy conservation. However, the mass of $^{82}_{36}$Kr is lower than that of $^{82}_{34}$Se So a nucleus of $^{82}_{34}$Se can be converted to a nucleus of $^{82}_{36}$Kr via double beta decay:

$$^{82}_{34}\text{Se} \rightarrow ^{82}_{36}\text{Kr} + 2e^- + 2\nu_e. \qquad \textbf{(40.23)}$$

Double beta decay is the only reaction that prevents $^{82}_{34}$Se from being a stable isotope. This decay is depicted in Figure 40.17. Chapter 39 noted the beta-decay process involves the exchange of a *W* boson and thus leads to comparatively long lifetimes. A double beta decay requires two *W* boson exchanges and thus leads to extremely long lifetimes. The lifetime of $^{82}_{34}$Se has been determined to be 10^{20} years, which is approximately 10 billion times the age of the universe! Only 12 isotopes are known to undergo double beta-decay processes (shown in yellow in Figure 40.16), and their average lifetimes are all of the same order as that of $^{82}_{34}$Se Thus, double beta-decay event rates are extremely small, making the detection of these decays very difficult experimentally.

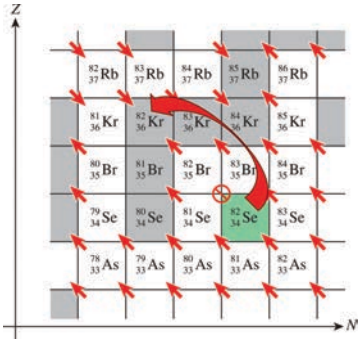

FIGURE 40.17 Chart showing nuclei around mass number 82. The gray shaded squares indicate stable nuclei. The red arrows indicate the directions of beta decays. The green shaded box highlights the isotope selenium-82, which can undergo double beta decay.

Research into double beta decays is flourishing. Double β^+ decays are theoretically possible, but no isotope showing this type of decay has yet been observed. In addition, there are ongoing searches for double beta decays in which no anti-neutrino is emitted. This process could work only if the neutrino is its own antiparticle. If this decay mode were observed, it would violate the standard model of particle physics, introduced in Chapter 39, and would point toward completely new discoveries in physics.

Carbon Dating

Carbon has two stable isotopes: ${}^{12}_{6}\mathrm{C}$ at 98.90% abundance and ${}^{13}_{6}\mathrm{C}$ at 1.10% abundance. All other carbon isotopes, except ${}^{14}_{6}\mathrm{C}$, decay with half-lives ranging from milliseconds to minutes. The exception, ${}^{14}_{6}\mathrm{C}$, has a half-life of $t_{1/2}\left({}^{14}_{6}\mathrm{C}\right) = (5730 \pm 40)$ years. It decays via β^- decay into nitrogen: ${}^{14}_{6}\mathrm{C} \rightarrow {}^{14}_{7}\mathrm{N} + e^- + \nu_e$. The Q-value of this reaction is 156.5 keV.

The ${}^{14}_{6}\mathrm{C}$ isotope is produced in the upper atmosphere at a constant rate via the interaction of cosmic rays with atmospheric nitrogen. Because this isotope is produced at a constant rate and decays at a constant rate, its concentration in the atmosphere, and thus the ratio of the number of ${}^{14}_{6}\mathrm{C}$ atoms relative to the number of ${}^{12}_{6}\mathrm{C}$ atoms, is constant in time, at a value of approximately $1.20 \cdot 10^{-12}$. The plants on Earth's surface consume both carbon isotopes, mainly in $\mathrm{CO_2}$ molecules. Thus, the ratio of ${}^{14}_{6}\mathrm{C}/\ {}^{12}_{6}\mathrm{C}$ is also constant in living plants, and consequently all the way up the food chain as well.

While plants and animals are living and consuming food, their carbon isotope ratio stays at a constant value. However, at the moment of death, the intake of carbon isotopes ceases, and thus the ratio ${}^{14}_{6}\mathrm{C}/\ {}^{12}_{6}\mathrm{C}$ decreases in time as ${}^{14}_{6}\mathrm{C}$ decays. Measuring this ratio in a tissue sample can determine how long a plant or animal has been dead. This method can also be used on products made from plants or animals, such as textiles and wooden objects. The procedure of age determination using radioactive decays, called **radiocarbon dating,** or just *carbon dating,* revolutionized the field of archeology. It allows dating of samples up to an age of approximately 10 half-lives of ${}^{14}_{6}\mathrm{C}$ more than 50,000 years. The American physical chemist Willard Frank Libby (1908–1980) discovered the method of carbon dating in 1949 and was awarded the 1960 Nobel Prize in Chemistry for this achievement. In principle, any other long-lived isotope for which the initial concentration is known can be used as a tool for dating objects, but carbon dating is by far the most important.

SOLVED PROBLEM 40.2 Carbon Dating

The Shroud of Turin, shown in Figure 40.18, is a large piece of linen cloth that some people claim is the burial shroud of Jesus of Nazareth. It is kept in the Cathedral of Saint John the Baptist in Turin, Italy, and displayed for viewing only on very rare occasions. However, some people expressed doubts concerning the authenticity of this object, and other people claimed it to be a hoax of medieval origin. In 1988, the Vatican allowed radiocarbon dating of the shroud by three laboratories, in Zürich, Oxford, and Arizona, and it was shown to be of medieval origin. The testing concluded with a 95% confidence level that the shroud was made between 1260 and 1390.

FIGURE 40.18 Example of the use of carbon dating: the Shroud of Turin.

PROBLEM

If a textile sample contains $(1.08 \pm 0.01) \cdot 10^{-12}$ atoms of ${}^{14}_{6}\mathrm{C}$ for each atom of ${}^{12}_{6}\mathrm{C}$, what is its age?

SOLUTION

THINK

We know that radioactive decays follow an exponential decay law that determines the number of remaining ${}^{14}_{6}\mathrm{C}$ atoms as a function of time (equation 40.12). The number of ${}^{12}_{6}\mathrm{C}$ atoms stays constant in time because this isotope is stable. Therefore, the ratio of the two isotopes, $f_{14/12}(t) = N({}^{14}_{6}\mathrm{C}, t)/N({}^{12}_{6}\mathrm{C})$, follows the same exponential decay law. Because we know the half-life of ${}^{14}_{6}\mathrm{C}$ and the initial and final fractions of ${}^{14}_{6}\mathrm{C}$ we can solve the exponential decay law for the time and obtain our answer.

SKETCH

Figure 40.19 serves to remind us that the exponential decay law also holds for the fraction of ${}^{14}_{6}\mathrm{C}$ relative to ${}^{12}_{6}\mathrm{C}$. Given a certain number for the fraction, we can obtain the age of the sample.

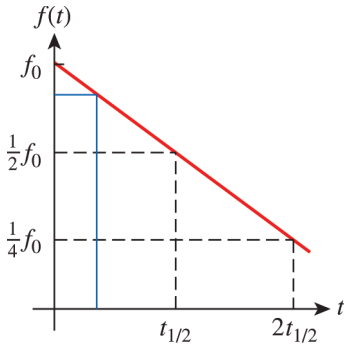

FIGURE 40.19
Carbon-14 fraction as a function of time, plotted on a semilogarithmic scale.

RESEARCH

We can use the exponential decay law (equation 40.12) for the number of ${}^{14}_{6}\mathrm{C}$ atoms as a function of time:

$$N(t) = N_0 e^{-\lambda t}.$$

Since we are given the half-life of the isotope, we need to relate the decay constant λ to the half-life by using the relationship in equation 40.14:

$$t_{1/2} = \ln 2/\lambda.$$

SIMPLIFY

First, we write the decay law in terms of the half-life:

$$N\left({}^{14}_{6}\mathrm{C}, t\right) = N_0\left({}^{14}_{6}\mathrm{C}\right)e^{-\lambda t} = N_0\left({}^{14}_{6}\mathrm{C}\right)e^{-t\,\ln 2/t_{1/2}}.$$

Dividing both sides by the number of ${}^{12}_{6}\mathrm{C}$ isotopes gives us the fraction of ${}^{14}_{6}\mathrm{C}$ relative to ${}^{12}_{6}\mathrm{C}$:

$$f_{14/12}(t) = f_{14/12}(t=0)e^{-t\,\ln 2/t_{1/2}}.$$

Now we can solve this equation for the time:

$$\frac{f_{14/12}(t)}{f_{14/12}(t=0)} = e^{-t\,\ln 2/t_{1/2}} \Rightarrow$$
$$\ln\left(\frac{f_{14/12}(t)}{f_{14/12}(t=0)}\right) = -t\frac{\ln 2}{t_{1/2}} \Rightarrow$$
$$t = -\frac{t_{1/2}}{\ln 2}\ln\left(\frac{f_{14/12}(t)}{f_{14/12}(t=0)}\right).$$

CALCULATE

Now we are in a position to insert numbers. We know that the half-life of ${}^{14}_{6}\mathrm{C}$ is $t_{1/2}\left({}^{14}_{6}\mathrm{C}\right) = (5730 \pm 40)$ years and $f_{14/12}(t=0) = 1.20 \cdot 10^{-12}$. The problem specifies the fraction: $f_{14/12}(t) = (1.08 \pm 0.01) \cdot 10^{-12}$. Thus, we insert the average value of the fraction into the above equation for the time to find the mean value:

$$t = -\frac{5730\ \text{yr}}{\ln\ 2}\ln\left(\frac{1.08}{1.20}\right) = 870.978\ \text{yr}.$$

Inserting the value 1.09 in the equation for the time results in an upper limit of uncertainty of 794.787 yr (76 years less), and the value 1.07 yields a lower limit of uncertainty of 947.877 yr (77 years more).

ROUND

From the given uncertainty in the fraction of ${}^{14}_{6}\mathrm{C}$ we have determined the uncertainty in the time. Thus, we round our final answer to a value of 870 yr and quote the uncertainty as ±80 yr:

$$t = (870 \pm 80)\ \text{yr}.$$

The textile sample in question was probably produced in the 12th century, but perhaps as early as the 11th or as late as the 13th century.

DOUBLE-CHECK

It is quite reasonable that the time we calculated is small compared to the half-life of ${}^{14}_{6}\mathrm{C}$, because after one half-life the remaining concentration of that isotope would be $0.60 \cdot 10^{-12}\left(= \frac{1}{2} \cdot 1.20 \cdot 10^{-12}\right)$, and the problem statement indicated that the textile sample had lost only 10% of its ${}^{14}_{6}\mathrm{C}$ content. In fact, for small values of $t/t_{1/2}$ the exponential decay function can be expanded as $e^{-\ln\ 2.t/t_{1/2}} \approx 1 - \ln\ 2 \cdot t/t_{1/2}$. Since 90% of the initial ${}^{14}_{6}\mathrm{C}$ concentration is left over at that time, this linear approximation results in

$$0.9 = 1 - \ln 2 \cdot t/t_{1/2} \Rightarrow t = t_{1/2} \cdot 0.1/\ln\ 2 = 0.144 t_{1/2} = 830\ \text{yr}.$$

It's worthwhile noting that the assumption that the atmospheric concentration of $^{14}_{6}\mathrm{C}$ has always been constant is not quite true. Historic changes in the cosmic-ray flux and other events have resulted in temporal fluctuations. In addition, since the 1950s, the atmospheric concentrations of $^{14}_{6}\mathrm{C}$ and other isotopes have been changed by atmospheric tests of nuclear weapons. However, correlating the results of carbon dating with other sources of age determination (ice cores, tree rings, etc.) has allowed calibration curves for the numerical results obtained with carbon dating to be developed.

Units of Radioactivity

How can the radioactivity of a sample be measured? There are two main quantities of interest. First is the intensity of the emission from the sample of radioactive material, that is, the number of decays per unit time. Second is the effect that a given type of radiation has on the human body. (Figure 40.20 is a radioactivity warning sign.)

FIGURE 40.20 The trefoil symbol is internationally recognized as indicating radioactive material.

The SI unit of radioactivity is the **becquerel (Bq)** named in honor of the French physicist Henri Becquerel (1852–1908), co-discoverer of radioactivity:

$$1 \text{ Bq} = 1 \text{ nuclear decay/s}. \tag{40.24}$$

This is an extremely small unit of radioactivity. A non-SI, but commonly used, unit of radioactivity is the **curie (Ci)**, named in honor of the husband-and-wife team of Frenchman Pierre Curie (1859–1906) and his Polish-born wife Marie Skłodowska-Curie (known as Madame Curie, 1867–1934), who were the other two co-discoverers of radioactivity. Initially, the curie was defined as the activity of 1 gram of the isotope $^{226}_{88}\text{Ra}$, which decays via emission of an alpha particle. Currently, the curie is defined in terms of the becquerel as follows:

$$\begin{aligned} 1 \text{ Ci} &= 3.7 \cdot 10^{10} \text{ Bq} \\ 1 \text{ Bq} &= 2.7 \cdot 10^{-11} \text{ Ci}. \end{aligned} \tag{40.25}$$

Older textbooks used a unit called the rutherford (Rd): $1 \text{ RD} = 1 \text{ MBq}$.

As mentioned above, the number of decays alone is not enough to measure the effects of radioactivity. Much more important is the absorbed radiation dose. The SI unit for the absorbed dose is the *gray* (Gy), defined in terms of other SI units as an absorbed energy of 1 joule per kilogram of absorbing material:

$$1\ \text{Gv} = 1\ \text{J/kg}. \tag{40.26}$$

A commonly used non-SI unit is the *rad* (rd). Its conversion to the gray is given by

$$\begin{aligned} 1\ \text{rd} &= 0.01\ \text{Gy} \\ 1\ \text{Gy} &= 100\ \text{rd}. \end{aligned} \tag{40.27}$$

For X-rays and gamma rays, it is also important to measure the amount of ionization (separation of electrons from their previously neutral atoms). This quantity is called *exposure* and is measured in coulombs per kilogram. A non-SI unit for exposure is the *röntgen* (R), and it is defined when the material is in air as

$$1\ \text{R} = 2.58 \cdot 10^{-4}\text{C/kg of air}. \tag{40.28}$$

The exposure and absorbed dose are closely related, and for biological tissue 1 röntgen is a close approximation to 1 rad.

The extent of damage to biological tissue depends not only on the deposited energy (absorbed dose), but also on the type of particle the nuclear decay emitted. Different types of radiation interact in very different ways with matter, in particular with biological tissue, and deposit energy with very different depth profiles. When photons penetrate into matter, they lose energy exponentially as a function of depth into the material. Alpha particles and heavy nuclei, on the other hand, lose a very small fraction of their energy at the entry point, but deposit almost all of their energy at their maximum penetration depth, which is a function of the initial energy. Thus, for example, alpha particles of a given initial energy all penetrate to approximately the same depth in biological tissue and then deposit a very significant fraction of their energy at that depth (Figure 40.21).

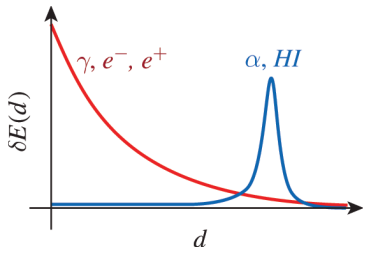

FIGURE 40.21 Profile of energy deposition as a function of penetration depth, *d*. Blue curve: profile for alpha particles and heavy ions. Red curve: profile for photons and leptons.

Because of the differences in energy deposition as a function of penetration depth, an alpha particle is much more damaging to the cell walls of biological tissue than a photon of the same energy. *The radiation weight factor,* $w_r = 5$ is 1 for all photons and leptons, independent of their energy. Also, $w_r = 5$ for protons with energy greater than 2 MeV, and for neutrons with energy either greater than 20 MeV or less than 10 KeV. In the energy intervals between 10 KeV and 100 MeV and between 2 MeV and 20 MeV, the weight factor has the value of 10 for neutrons. Neutrons are at their most damaging in the energy interval between 100 KeV and 2 MeV, where the weight factor is $w_r = 20$. The same weight factor of 20 is also assigned to alpha particles and heavy nuclei. The weight factor is used to determine the dose equivalent, which is the absorbed dose times the weight factor.

The SI unit for the dose equivalent is the *sievert* (Sv), defined as

$$1\ \text{Sv} = w_r(1\ \text{Gy}). \tag{40.29}$$

Again, a non-SI unit is commonly used, the *rem* (short for "röntgen equivalent, man"). It is defined as

$$1\ \text{rem} = w_r(1\ \text{rd}). \tag{40.30}$$

Comparing equations 40.30, 40.29, and 40.27, we see that

$$1\ \text{Sv} = 100\ \text{rem}. \tag{40.31}$$

Radiation Exposure

What is the average dose of radiation that a typical U.S. resident receives each year? To answer this question, we need to consider many sources of radiation. Perhaps the easiest to quantify is the dose we receive from cosmic radiation, or cosmic rays. This dose strongly depends on the elevation above sea level of the city or town in which you live (Figure 40.22). At sea level you receive an annual dose equivalent of 0.26 mSv, whereas in Denver your annual dose equivalent is almost 0.5 mSv. If you build your dream house on a mountaintop, you may get up to 1 mSv per year.

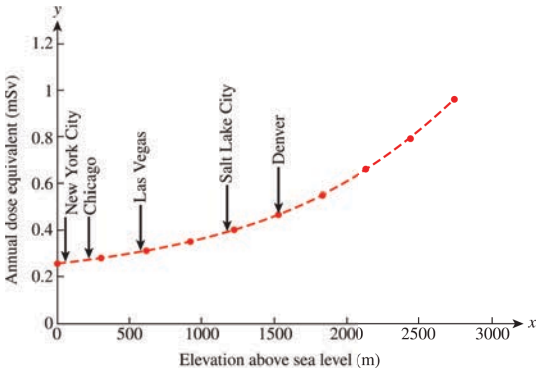

FIGURE 40.22 Annual dose equivalent from cosmic rays for U.S. residents as a function of elevation.

Among other sources of natural radiation, the most important is radon gas. This gas is part of the air you breathe, and it deposits its radiation on the inside of your body, in your lungs. This radiation contributes 2 mSv per year to your dose equivalent. You also ingest radioactive isotopes (mainly $^{14}_{6}\mathrm{C}$ and $^{40}_{19}\mathrm{K}$) with your food, another 0.4 mSv annually. The Earth itself contributes radiation: 0.16 mSv at the Atlantic Coast, 0.3 mSv in the continental United States, except for the area around Denver, where the dose equivalent is 0.63 mSv per year.

Medical X-rays (dental imaging is 0.01 mSv at the lower end and upper-GI-tract imaging is 2.5 mSv at the upper end) and other procedures add an average of 0.5 mSv to your annual dose equivalent. Each hour of air travel contributes approximately 0.005 mSv to your dose equivalent; a passenger enjoying Gold Elite status (flying more than 50,000 mi/yr) receives an additional 0.5 to 1 mSv. Other minute sources of radiation (watching TV, working at a computer, airport screening, using a gas lantern while camping or a smoke detector, etc.) contribute a combined 0.1 mSv per year. The total annual exposure dose equivalent for the average U.S. resident, the sum of all of the above contributions, is approximately 3.6 mSv and is broken down by source in Figure 40.23.

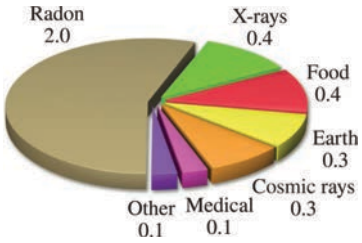

FIGURE 40.23 Average annual radiation exposure dose equivalent for a U.S. resident (in mSv).

People who work with radiation sources such as X-ray machines or nuclear reactors are strictly monitored for radiation exposure. Their maximum annual dose equivalent is not allowed to exceed 50 mSv, which is approximately 15 times the dose they receive from the natural environmental sources listed here.

EXAMPLE 40.4 Chest X-Ray

Suppose your last physical exam included a chest X-ray, during which you received a dose of 60. μSv.

PROBLEM 1

What was your dose in millirems (mrem)?

SOLUTION

The conversion factor from sieverts to rems is given by equation 40.31, so you can convert your dose as follows:

$$\left(60. \cdot 10^{-6}\ \text{Sv}\right)\frac{100\ \text{rem}}{1\ \text{Sv}} = 6.0 \cdot 10^{-3}\ \text{rem} = 6.0\ \text{mrem}.$$

PROBLEM 2

What was the absorbed dose in micrograys (μGy) and millirads (mrad)?

SOLUTION

The radiation weight factor, w_r, for X-rays is 1. Therefore, the absorbed dose according to equation 40.29 was

$$\frac{60.\ \mu\text{Sv}}{1\ \text{Sv/Gy}} = 60.\ \mu\text{Gy} \quad \text{or} \quad \frac{6.0\ \text{mrem}}{1\ \text{rem/rad}} = 6.0\ \text{mrad}.$$

PROBLEM 3

How much energy did you absorb, assuming that the X-rays illuminated 15 kg of your body?

SOLUTION

The gray (equation 40.26) is defined in terms of the energy absorbed divided by the mass over which the energy is absorbed. Thus, the energy you absorbed was

$$(60.\mu\text{Gy})(15\ \text{kg}) = \left(60. \cdot 10^{-6}\ \text{J/kg}\right)(15\ \text{kg}) = 9.0 \cdot 10^{-4}\ \text{J}.$$

PROBLEM 4

What fraction of your average annual dose of radiation did this chest X-ray represent?

SOLUTION

The average annual radiation dose is 3.6 mSv. Thus, the fraction of your annual dose was

$$\frac{60.\ \mu\text{Sv}}{3.6\ \text{mSv}} = \frac{60. \cdot 10^{-6}\text{Sv}}{3.6 \cdot 10^{-3}\text{Sv}} = 1.7\%.$$

40.3 Nuclear Models

Liquid-Drop Model and Empirical Mass Formula

How can we understand the systematic trends of the binding energy per nucleon, given by equation 40.7 and displayed in Figure 40.7? One model of the nucleus that yields astonishingly good results is the **liquid-drop model.** In this model, the nucleus is treated as a spherical drop of quantum liquid composed of individual nucleons. Because the strong interaction between the nucleons inside the nucleus is attractive, each nucleon in the drop receives a positive contribution to the binding energy. Conventionally, this contribution is called the *volume term* and is proportional to the number of nucleons A:

$$B_{\mathrm{v}}(N, Z) = a_{\mathrm{v}} A = a_{\mathrm{v}}(N + Z). \qquad \textbf{(40.32)}$$

Here a_{v} is a positive constant that is adjusted to the data.

Nucleons at the surface of the liquid drop are not surrounded by other nucleons. Thus, they have fewer nearest-neighbor interactions and therefore are less strongly bound. Accordingly, the model must include a negative term that is proportional to the nuclear surface area. The surface area of a spherical drop is proportional to R^2, the square of its radius. According to equation 40.3, the nuclear radius is proportional to $A^{2/3}$. Therefore, the surface area of the nucleus is proportional to $A^{1/3}$, and the contribution of the nuclear surface to the overall binding energy can be parameterized as

$$B_{\mathrm{s}}(N, Z) = -a_{\mathrm{s}} A^{2/3} = -a_{\mathrm{s}}(N + Z)^{2/3}, \qquad \textbf{(40.33)}$$

with a positive fit constant a_{s}.

Next, we need to take into account that the protons are all positively charged and thus have repulsive Coulomb interactions with one another. Since the Coulomb potential is proportional to the square of the charge number and inversely proportional to the radius, we can write for this term:

$$B_{\mathrm{c}}(N, Z) = -a_{\mathrm{c}} \frac{Z^2}{A^{1/3}} = -a_{\mathrm{c}} \frac{Z^2}{(N + Z)^{1/3}}, \qquad \textbf{(40.34)}$$

where we have again made use of $R \propto A^{1/3}$ from equation 40.3. The constant a_{c} can be calculated if the protons are assumed to be evenly distributed throughout the nucleus. It has the value $a_{\mathrm{c}} = 0.71\ \mathrm{MeV}$.

The Coulomb interaction alone might make us conclude that it is most advantageous to fill the nucleus with neutrons. Because neutrons do not experience the Coulomb interaction, the term in equation 40.34 does not contribute to their binding energy, so a number of neutrons alone would have a higher binding energy than the same number of neutrons and protons mixed.

However, we also have to take into consideration that protons and neutrons are fermions and thus need to respect the Pauli Exclusion Principle (see Chapter 36) separately, for spin-up and spin-down protons and for spin-up and spin-down neutrons. Just as in the case of the electrons filling shells in the atom at higher and higher angular momentum and energy, higher and higher energy levels are filled as more protons and neutrons are added. Simply adding neutrons would become energetically unfavorable at some point. Thus, filling the nucleus approximately equally with protons and neutrons is encouraged by the Pauli Exclusion Principle (Figure 40.24).

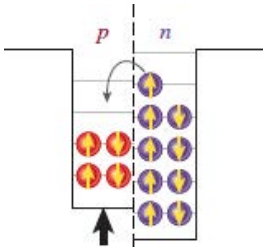

FIGURE 40.24 Illustration for the asymmetry term in the mass formula of the liquid-drop model.

This effect can be parameterized via an *asymmetry term,* which is negative (representing decreased binding) when the number of protons is different from the number of neutrons. This motivates the following expression for the asymmetry term, where $A = Z + N$ in the second equality:

$$B_{\mathrm{a}}(N,Z) = -a_{\mathrm{a}}\frac{\left(Z-\frac{1}{2}A\right)^2}{A} = -\frac{a_{\mathrm{a}}}{4}\frac{(Z-N)^2}{N+Z}. \qquad \textbf{(40.35)}$$

Finally, the two-body interaction of nucleon pairs depends on their relative spin. This leads to higher binding energies for nuclei that have all of their protons paired up and all of their neutrons paired up. Thus, an even number of protons in a nucleus results in an additional positive contribution to the binding energy. In the same way, an even number of neutrons creates a higher binding energy as well. Empirically supported results are found with this parameterization for the *pairing term*:

$$B_{\mathrm{p}}(N,Z) = +a_{\mathrm{p}}\frac{(-1)^Z + (-1)^N}{\sqrt{A}} = +a_{\mathrm{p}}\frac{(-1)^Z + (-1)^N}{\sqrt{N+Z}}. \quad \textbf{(40.36)}$$

By combining equations 40.32 to 40.36, we can write an expression for the binding energy as a function of the mass number and charge number of a given nucleus:

$$\begin{aligned} B(N,Z) &= B_{\mathrm{v}}(N,Z) + B_{\mathrm{s}}(N,Z) + B_{\mathrm{c}}(N,Z) + B_{\mathrm{a}}(N,Z) + B_{\mathrm{p}}(N,Z) \\ &= a_{\mathrm{v}}A - a_{\mathrm{s}}A^{2/3} - a_{\mathrm{c}}\frac{Z^2}{A^{1/3}} - a_{\mathrm{a}}\frac{(Z-\frac{1}{2}A)^2}{A} + a_{\mathrm{p}}\frac{(-1)^Z + (-1)^N}{\sqrt{A}} \end{aligned}$$

Dividing this expression by the mass number, the binding energy per nucleon is

$$\frac{B(N,Z)}{A} = a_{\mathrm{v}} - a_{\mathrm{s}}A^{-1/3} - a_{\mathrm{c}}\frac{Z^2}{A^{4/3}} - a_{\mathrm{a}}\left(\frac{Z}{A} - \frac{1}{2}\right) + a_{\mathrm{p}}\frac{(-1)^Z + (-1}{A^{3/2}}$$

The constants in this expression can be used as fit parameters to obtain the best agreement with all binding energies for all nuclei. This procedure to explain the systematic trends in the binding energy per nucleon as a function of mass number was first developed by the German physicists Hans Bethe and Carl Friedrich von Weizsäcker in 1935, and the resulting **empirical mass formula** (equation 40.37) carries their name. Several successful fits have been published in the literature. We use the values obtained by Bertulani and Schechter (2002):

$$\begin{aligned} &a_{\mathrm{v}} = 15.85 \text{ MeV},\ a_{\mathrm{s}} = 18.34 \text{ MeV},\ a_{\mathrm{c}} = 0.71 \text{ MeV}, \\ &a_{\mathrm{a}} = 92.86 \text{ MeV}, a_{\mathrm{p}} = 11.46 \text{ MeV}. \end{aligned} \quad \textbf{(40.38)}$$

Figure 40.25 displays the same experimental values of the binding energies as Figure 40.7, but only for the nuclei with odd values of A. For these, the last term in equation 40.37 is zero, and so the effect of the other terms in the equation can be compared to the experimental data as a function of the mass number A. (The curve is more complicated for nuclei with even values of A, because they can have either an even number of protons and an even number of neutrons or an odd number of neutrons and an odd number of protons, which changes the sign of the term in equation 40.36 and thus does not produce a single curve like the one

shown in Figure 40.7.) The yellow line in Figure 40.25 plots the (constant) volume term. Adding the surface term to it leads to the orange line, which shows very good agreement with the experimental data for low mass numbers. Adding the Coulomb term leads to the red line, which is close to the experimental data, showing that the Coulomb interaction becomes important for large nuclei. Finally, adding the asymmetry term leads to the green line, which gives a very good overall description of all binding energies of all odd-mass nuclei, at least at the resolution of the plot shown here.

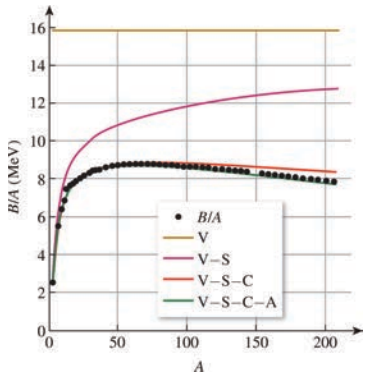

FIGURE 40.25 Binding energy per nucleon for nuclei with odd values of *A*. Black dots: experimental data. Lines are fits that include different numbers of terms in the Bethe-Weizsäcker formula (V: volume, S: symmetry, C: Coulomb, A: asymmetry).

The success of the Bethe-Weizsäcker formula (equation 40.37) for the binding energy is conventionally interpreted as strong support for the liquid-drop model of the nucleus. However, it is really only a consequence of the approximately spherical shape of nuclei, combined with the fact that the strong interaction is short-range and of the order of the nearest-neighbor spacing of the nucleons inside a nucleus.

Self-Test Opportunity 40.2

Figure 40.13 shows that the masses of the $A = 82$ nuclei with odd charge numbers lie on a parabola (dashed line), and the masses of the $A = 82$ nuclei with even charge numbers lie on another parabola. Explain.

Fermi Gas Model

Judging from the success of the liquid-drop model of the nucleus in reproducing the binding energies of nuclei, one might be tempted to think about nucleons as resting in a fixed and approximately spherical arrangement inside the nucleus. However, the Heisenberg uncertainty relation (see Chapter 36) imposes constraints on quantum particles (waves) confined to such a small volume. Since $\Delta p_x \cdot \Delta x \geq \frac{1}{2}\hbar$ and since a nucleon inside a nucleus is localized to within a few femtometers, there is a high uncertainty in momentum, on the order of $100\ \text{MeV}/c$. (If you remember the handy rule $\hbar c = 197.33\ \text{MeV/fm}$, this is easy to see.) That means that nucleons inside the nucleus cannot be considered to be resting in some fixed configuration, but rather they have fairly high momentum uncertainty and thus momentum.

The **Fermi gas model** of the nucleus (proposed by the Italian-American physicist Enrico Fermi, 1901–1953) takes this momentum into consideration and assumes that nucleons can move freely inside the nucleus like particles of a gas (Figure 40.26).

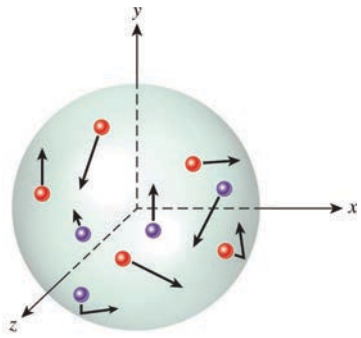

FIGURE 40.26 The Fermi gas model of the nucleus. Protons (purple) and neutrons (red) move independently and freely throughout the interior of the nucleus and are reflected off the nuclear surface that confines them.

Chapter 37 showed that a particle with mass m and momentum k confined to a cubic box of width a in three dimensions, but able to move freely inside the box, has a total energy of

$$E = \frac{\hbar^2}{2m}k^2 = \frac{\hbar^2}{2m}\left(k_x^2 + k_y^2 + k_z^2\right) = \frac{\hbar^2\pi^2}{2ma^2}\left(n_x^2 + n_y^2 + n_z^2\right). \quad \textbf{(40.39)}$$

The Pauli Exclusion Principle allows each quantum state to be occupied by exactly four nucleons (one spin-up and one spin-down proton and one spin-up and one spin-down neutron, for each state).

We can use this information to calculate the density of states, $dN(E)$, which will tell us how many quantum states reside in an interval dE around a given energy E, for the Fermi gas model.

Figure 40.27 illustrates the possible momentum states that can be occupied by the nucleons in the Fermi gas model. Each possible quantum state occupies a volume of $(\pi/a)^3$. Then the number of states, $dN(k)$, between the absolute value of the momentum k and $k + dk$ is given by the ratio of the volume of the spherical shell with radius k and thickness dk and the volume occupied by each quantum state:

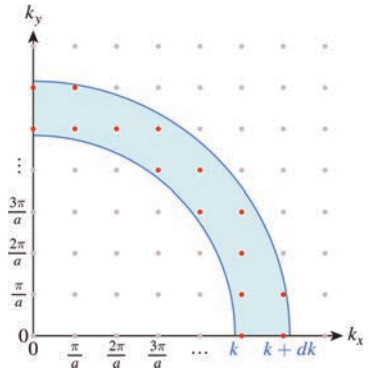

FIGURE 40.27 Density of states in the Fermi gas model. Each dot represents a possible quantum state. The third momentum coordinate is not shown.

$$dN(k) = \frac{\frac{1}{8}4\pi k^2 dk}{(\pi/a)^3} = \frac{a^3 k^2}{2\pi^2} dk. \qquad \textbf{(40.40)}$$

(The factor $\frac{1}{8}$ appears in this equation because we are considering only the octant of the three-dimensional sphere in which all three momentum coordinates are positive. Negative values of the momentum coordinates do not add additional solutions, because the energy is proportional to k^2.)

Now we need to convert the density of momentum states, $dN(k)$, which we just calculated, into a density of states, $dN(E)$. Equation 40.39 shows that $E = \hbar^2 k^2/2m$, and therefore $k = \sqrt{2mE/\hbar}$, so the derivative of the energy with respect to the wave number can be calculated: $dE/dk = \hbar^2 k/m$. The differential dk can be expressed in terms of the differential dE as follows:

$$dk = \frac{dE}{\hbar\sqrt{2E/m}}.$$

Combining this result with equation 40.40 gives the density of states as a function of energy:

$$dN(E) = \frac{a^3 m^{3/2}}{2^{1/2}\pi^2\hbar^3} E^{1/2} dE. \qquad \textbf{(40.41)}$$

The maximum energy required to accommodate all A nucleons in a nucleus according to the Fermi gas model is called the **Fermi energy,** E_{F}. To find the Fermi energy, we need to integrate the density of states (equation 40.41) up to that energy and set this number equal to $\frac{1}{4}A$. (Remember that each quantum state can be occupied by four nucleons.)

Self-Test Opportunity 40.3

Derive equation 40.41.

$$\int_0^{n(E_{\mathrm{F}})} dN(E) = \tfrac{1}{4}A \Rightarrow$$

$$\int_0^{E_{\mathrm{F}}} \frac{a^3 m^{3/2}}{2^{1/2}\pi^2\hbar^3} E^{1/2} dE = \frac{2^{1/2} a^3 m^{3/2}}{3\pi^2\hbar^3} E_{\mathrm{F}}^{3/2} = \tfrac{1}{4}A \Rightarrow \qquad \textbf{(40.42)}$$

$$E_{\mathrm{F}} = \frac{\hbar^2}{2m}\left(\frac{3A\pi^2}{2a^3}\right)^{2/3} = \frac{\hbar^2}{2m}\left(\frac{3\pi^2}{2}n\right)^{2/3},$$

where $n = A/a^3$ is the nucleon density inside the nucleus. Using $n = 0.17\ \mathrm{fm}^{-3}$ for the nucleon density (Example 40.1), a value of $938.9\ \mathrm{MeV}/c^2$ as the average of the proton and neutron mass, and $\hbar c = 197.33\ \mathrm{MeV\ fm}$, we arrive at the numerical value of the Fermi energy:

$$E_{\mathrm{F}} = \frac{(197.33\ \mathrm{MeV\ fm}/c)^2}{2(938.9\mathrm{MeV}/c^2)}\left(\frac{3\pi^2}{2}(0.17\ \mathrm{fm}^{-3})\right)^{2/3} = 38\ \mathrm{MeV}.$$

$2(938.9\text{MeV}/c^2)$ \ 2)

The density of the states occupied by nucleons inside the nuclear potential well is sketched in Figure 40.28 as a function of the energy relative to the bottom of the well. You can see that the largest probability of finding a nucleon inside a nucleus corresponds to an energy just below the Fermi energy. Note that the case displayed here is for the temperature $T = 0$ eV; for nonzero temperatures, the vertical drop-off at the Fermi energy is replaced by a more gradual decline.

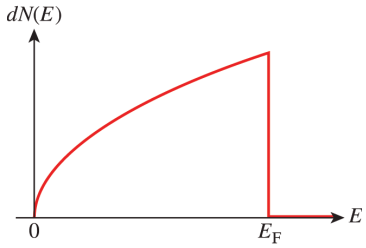

FIGURE 40.28 Density of states as a function of energy in the Fermi gas model. Here the energy is measured relative to the bottom of the potential well.

The *Fermi momentum,* p_F, is the momentum (magnitude) that corresponds to the Fermi energy:

$$p_F = \sqrt{2mE_F} = 270 \text{ MeV}/c$$
$$k_F = p_F/\hbar = 1.36 \text{ fm}^{-1}.$$

Dividing the Fermi momentum by the nucleon mass gives the maximum velocity with which nucleons move around inside the nucleus: $v_F = p_F/m = 0.29c$. That is, nucleons move around inside the nucleus with speeds of up to almost 30% of the speed of light!

Are these nucleon momentum values inside the nucleus real, or are they an artifact of a false interpretation of a quantum result in terms of classical physics? The answer is that they are real. This can be shown via particle production in heavy ion collisions, where the maximum energy of the particles produced can exceed the beam energy, a result that can be traced back directly to the Fermi momentum of the nucleons inside the nucleus.

The picture of the nucleus that emerges in this model can be illustrated as shown in Figure 40.29: Nucleons inside the nucleus are bound by a potential of depth V_0, which is the sum of the Fermi energy and the separation energy of the least-bound nucleon (S_n or S_p). Separation energies are typically on the order of 8 MeV. Thus, the depth of the nuclear well is approximately $V_0 = 8 \text{ MeV} + 38 \text{ MeV} = 46 \text{ MeV}$. This result is valid for all nuclei with A

larger than about 12, because from then on the nucleon density is a constant $n = 0.17\text{fm}^{-3}$.

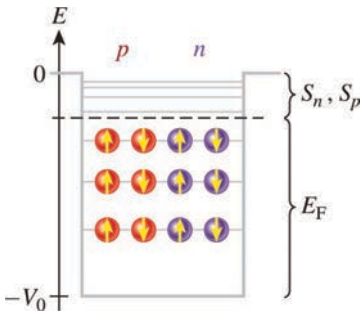

FIGURE 40.29
Approximation for the nuclear potential in the Fermi gas model.

This picture can be refined by introducing a separate Fermi energy for neutrons and protons. This gives rise to the asymmetry term (equation 40.35) in the Bethe-Weizsäcker formula (compare also Figure 40.24).

Shell Model

Chapter 38 showed that the electrons in atoms arrange themselves in shells because of the combined effects of their Coulomb interactions with the positively charged nucleus, quantum mechanics, and the Pauli Exclusion Principle. One essential piece of experimental evidence that supports the existence of electron shells is the separation (ionization) energy of the outermost electron as a function of the charge number, which shows a pronounced maximum for a filled shell. In Example 40.2, we calculated the two-neutron separation energies for a series of tin isotopes and found a pronounced jump of the separation energy at a neutron number of 82. Figure 40.30 shows a compilation of two-neutron separation energies for all known isotopes. It is clear that it becomes harder to remove neutron pairs from nuclei with a given charge number Z and fewer neutrons N. This observation is a consequence of the asymmetry term (equation 40.35) for the liquid-drop model. However, the color coding in Figure 40.30 shows sudden jumps at certain neutron numbers, which are superimposed on the general trend of rising two-neutron separation energies as we move from right to left in a given isotope chain. It is clear from this figure that the neutron numbers 50, 82, and 126 are special, because they exhibit these sudden jumps. When two-proton separation energies are compiled, a similar picture emerges, with sudden jumps at 50 and 82 as we move along lines of constant neutron number. (There is no nucleus with charge number $Z = 126$.)

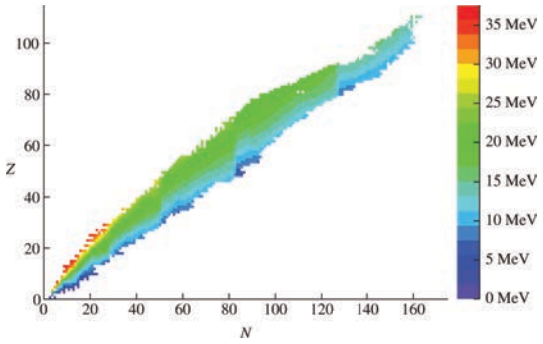

FIGURE 40.30 Experimentally measured two-neutron separation energies.

These and other data indicate that when certain numbers of protons or neutrons occur in a nucleus, a shell is filled. These numbers are called **magic numbers.** The magic numbers indicate that shell closures exist in nuclei just as they exist for the electron configurations in atoms. The magic numbers of either neutrons or protons in nuclei are

$$2, 8, 20, 28, 50, 82, 126.$$

For comparison, the magic numbers for the electron configurations are the charge numbers of the noble gases:

$$2, 10, 18, 36, 54, 86.$$

These sets of numbers are similar, but obviously not identical. Chapter 38 showed that the magic numbers of electrons indicate filled shells. The shells are formed by maximally occupying states with a given orbital angular momentum ℓ, where the maximum occupation of a given state is $2\ell + 1$. In the case of the electrons in an atom, the potential is provided by the Coulomb potential of the nucleus.

The potential for the nucleons inside the nucleus, on the other hand, is provided by the collective action of the other nucleons. Nevertheless, the quantum numbers of the nucleons inside the nuclear potential can also be calculated. Figure 40.31 shows the energy levels of neutrons inside the lead nucleus, calculated for three different potentials. The left side represents the harmonic oscillator potential, for which the solutions were calculated in Chapter 37. These energy levels are equally spaced. Interestingly, this simple harmonic oscillator potential reproduces the three lowest magic numbers. A similar agreement is achieved by using the Woods-Saxon potential, $V(r)$, which has the same dependence on the radial coordinate r as the nucleon density has (equation 40.4):

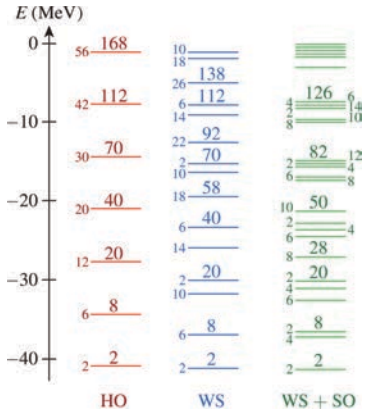

FIGURE 40.31 Energy levels for neutrons in a lead nucleus, calculated for three different potentials: harmonic oscillator (HO), Woods-Saxon (WS), and Woods-Saxon with strong spin-orbit coupling (WS + SO). The small numbers to the left of the levels indicate the maximum occupation for each level, and the larger numbers above the states indicate the cumulative sum of the occupation numbers.

$$V(r) = -\frac{V_0}{1 + e^{(r - R(A))/a}}. \tag{40.43}$$

Again, the surface thickness constant is $a = 0.54$ fm, and the radius is given by equation 40.3 as $R(A) = R_0 A^{1/3}$. The depth of the potential is $V_0 = 50$ MeV, close to that obtained for the Fermi gas model. The energy levels in this potential cannot be calculated analytically, but only with the aid of a computer. It is still possible to assign angular momentum quantum numbers to these numerical solutions, though, and so the maximum occupation numbers for the Woods-Saxon potential can be calculated. The results of this calculation are shown in blue in Figure 40.31. The maximum occupation number is given for each level. The cumulative occupation numbers are shown only where there is a larger-than-average energy gap to the next level.

The decisive insight into the nuclear shell model was achieved in 1949 by the Germans Maria Goeppert Mayer, Otto Hahn, J. Hans, D. Jensen, and Hans Suess. They realized that an essential part of the nuclear interaction is the coupling between the spin and the orbital angular momentum. (We will not derive this interaction term here, but merely state that it exists; a course on advanced quantum physics will fill this gap.) This spin-orbit coupling is also present for electrons, but it is much larger for nucleons. If a spin-orbit interaction potential with the correct strength is added to the Woods-Saxon potential, we obtain the energy levels shown in green on the right-hand side of Figure 40.31. Now we see that the large energy gaps between the levels occur at the magic numbers observed in experiment.

This simple shell model has been refined repeatedly since it was introduced, and it remains the main workhorse of low-energy nuclear structure calculations. Because the numerical solution of the shell model for heavy nuclei involves inversion of extremely large matrices, it cannot be achieved exactly, even using the largest available computers. Research on the nuclear shell model is thus a vibrant field, focusing on novel approximation techniques and steady refinement of nuclear interactions.

Other Models of the Nucleus

The three models of the nucleus presented so far are by no means the only ones. Nuclei are a very interesting testing ground for many theoretical models, in particular for understanding collisions of nuclei, in which they can be heated and compressed. Models of nuclear collisions involve several subfields of physics: quantum physics, fluid dynamics, thermodynamics, and electromagnetism. Nuclei can even undergo thermodynamic phase transitions between liquid-like and gas-like phases. The ongoing study of these phenomena, their technical applications, and their interdisciplinary relevance promises to yield interesting results in the coming decades.

As one example of a current nuclear model, we show a result from our own research on a nuclear transport model. Figure 40.32 shows the time sequence of a computer simulation of a collision of krypton-86 with niobium-93. The nuclei experience an off-center collision at an impact parameter of 5 fm. The time between two successive frames is $8.0\ \mathrm{fm}/c = 2.7 \cdot 10^{-23}\mathrm{s}$. Displayed is the nuclear density, which is color-coded according to the scale on the right-hand side of the figure. The compression, deformation, and sideways deflection of the nuclei are clearly visible. From the comparison of these and other model simulations to experimental data, we are able to draw conclusions about the dynamics and thermodynamics of nuclei and the properties of nuclear matter.

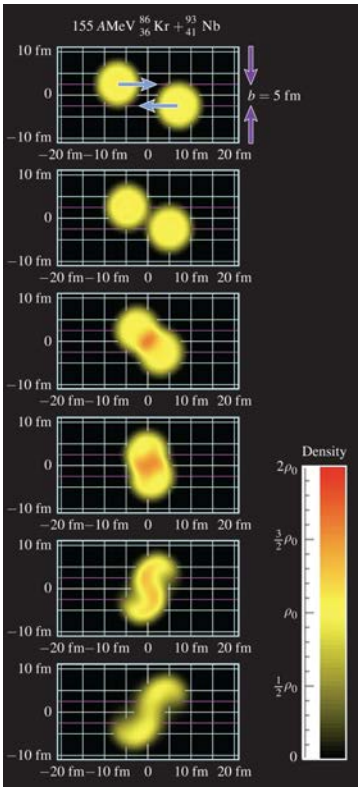

FIGURE 40.32 Time sequence of a nuclear collision, as calculated with a nuclear transport model.

40.4 Nuclear Energy: Fission and Fusion

Let's return once again to Figure 40.7, which shows the binding energy per nucleon as a function of the mass number for stable isotopes. The iron and nickel nuclei have the largest binding energies per nucleon and are thus most strongly bound. Any other arrangement of nucleons into nuclei, lighter or heavier, is less strongly bound. This suggests that very heavy nuclei can be split into two more strongly bound medium-mass nuclei, with the reaction showing a positive Q-value (Figure 40.33). Such a reaction yields useful energy, in a process called **nuclear fission**. In the same way, very light nuclei can be combined into heavier ones in reactions that have positive Q-values and associated useful energy output, in the process of **nuclear fusion**. This is the entire physical basis for the energy production by the Sun and almost all other stars, for fission and fusion reactor power plants, as well as nuclear weapons.

Page 1294

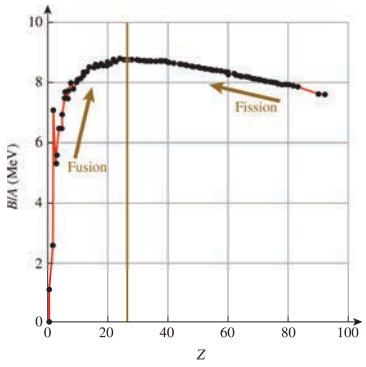

FIGURE 40.33 Energy gain through fission and fusion reactions.

Nuclear Fission

The nuclear fission process represents the splitting of an atomic nucleus into two smaller nuclei, often with the emission of one or more neutrons. The two smaller nuclei have mass numbers close to half that of the parent nucleus. As we will see, nuclei that undergo fission typically have mass numbers of 230 or greater, so isotopes resulting from nuclear fission typically have mass numbers ranging from 100 to 150. Important examples of fission fragments are the isotopes of krypton through barium and some isotopes of the lanthanides. These fission fragments tend to undergo subsequent radioactive decays, sometimes with very long half-lives. Many of them are easily ingested and accumulated in our bodies, so they pose great health risks. Examples are technetium-99 (more on this isotope later), cesium-137 (30-year half-life), and iodine-131 (8-day half-life), which is stored in the human thyroid.

A nucleus that is undergoing fission has to pass through a deformed configuration not unlike that in alpha decay (see Figure 40.11). A quantitative understanding of the onset of spontaneous fission in heavy nuclei requires a criterion in terms of mass number and charge number. To develop this criterion, we first parameterize the deformation of the nucleus (Figure 40.34) in terms of an ellipsoid with a semimajor axis of length $R(1+\epsilon)$, where R is the radius of the same nucleus if it were spherical and ϵ is the **deformation parameter**.

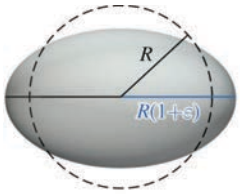

FIGURE 40.34 Nuclear deformation and definition of the deformation parameter.

When a nucleus is deformed from its spherical configuration, how is the binding energy per nucleon (equation 40.37) affected? The volume term is not changed, because it depends only on the number of nucleons, which stays the same. Since the charge-to-mass ratio is not changed, the symmetry term should also not be affected by deformation. The numbers of neutron pairs and proton pairs, and therefore the pairing term in equation 40.37, also remain constant. However, the surface is slightly increased when the sphere is deformed, so the surface term increases as a function of deformation. In addition, the protons are on average farther apart in the deformed nucleus, so the Coulomb term decreases. Niels Bohr (1885–1962) and John Archibald Wheeler (1911–2008) showed in 1939 that the change in the surface term as a function of deformation is (to leading order) given by $\Delta B_s(\epsilon) = \frac{2}{5}\epsilon^2 B_s(N,Z) = -\frac{2}{5}\epsilon^2 a_s A^{2/3}$, and the change in the Coulomb term by $\Delta B_c(\epsilon) = -\frac{1}{5}\epsilon^2 B_c(N,Z) = \frac{1}{5}\epsilon^2 a_c A^{-1/3} Z^2$. Therefore, the total change in the binding energy is

$$\begin{aligned}\Delta B(\epsilon) &= \Delta B_{\mathrm{c}}(\epsilon) + \Delta B_{\mathrm{s}}(\epsilon) \\ &= \tfrac{1}{5}\epsilon^2 a_{\mathrm{c}} A^{-1/3} Z^2 - \tfrac{2}{5}\epsilon^2 a_{\mathrm{s}} A^{2/3} \\ &= \tfrac{1}{5}\epsilon^2 \left(a_{\mathrm{c}} A^{-1/3} Z^2 - 2a_{\mathrm{s}} A^{2/3}\right).\end{aligned}$$

If $\Delta B(\epsilon) > 0$, energy can be gained by deforming a nucleus, and it can fission instantaneously. This transition point to spontaneous fission is reached when

$$\begin{gathered}\Delta B(\epsilon) = 0 \Rightarrow a_{\mathrm{c}} A^{-1/3} Z^2 - 2a_{\mathrm{s}} A^{2/3} = 0 \Rightarrow \\ \frac{Z^2}{A} = \frac{2a_{\mathrm{s}}}{a_{\mathrm{c}}} = \frac{2(18.34\,\mathrm{MeV})}{0.71\,\mathrm{MeV}} \approx 5.17,\end{gathered}$$

using the values given in equation 40.38.

Concept Check 40.4

Which of the following isotopes has the largest fissionability?

a) $^{235}_{92}\mathrm{U}$

b) $^{240}_{94}\mathrm{Pu}$

c) $^{254}_{98}\mathrm{Cf}$

d) $^{258}_{100}\mathrm{Fm}$

The quantity Z^2/A is called the *fissionability parameter*. Higher fissionability means a higher likelihood of fission and thus a shorter lifetime for the isotope.

In Figure 40.16, you can see that spontaneous fission is the dominant decay mode for some of the heaviest isotopes. However, in almost all cases where spontaneous fission dominates, the half-life of the isotope is so short that it does not exist in nature. Much more important for the use of nuclear fission in nuclear reactors and nuclear weapons is the very long-lived isotope $^{235}_{92}\mathrm{U}$, which has a half-life of 700 million years and which can be found in natural uranium deposits at 0.7% abundance. The most abundant uranium isotope is $^{238}_{92}\mathrm{U}$, with a natural abundance of 99.3% and a half-life of 4.5 billion years. Both isotopes decay overwhelmingly via emission of an alpha particle and have only a very small probability of undergoing spontaneous fission. However, $^{235}_{92}\mathrm{U}$ fissions almost instantaneously after being hit by a neutron of fairly low energy. This process releases two or three neutrons, which can then trigger further induced fission reactions in other $^{235}_{92}\mathrm{U}$ nuclei. A typical neutron-induced fission reaction of $^{235}_{92}\mathrm{U}$ is

$$n + {}^{235}_{92}\mathrm{U} \rightarrow {}^{141}_{56}\mathrm{Ba} + {}^{92}_{36}\mathrm{Kr} + 3n,$$

which releases 173.3 MeV of energy.

If sufficient $^{235}_{92}\mathrm{U}$ is present, the resulting **chain reaction** will exponentially multiply the number of neutrons in the sample and cause a nuclear explosion. However, for this to happen, the uranium needs to be predominantly composed of $^{235}_{92}\mathrm{U}$ and not $^{238}_{92}\mathrm{U}$ (which does not show induced fission when bombarded with low-energy neutrons). Thus, for nuclear weapons, the concentration of $^{235}_{92}\mathrm{U}$ needs to be *enriched*. Uranium is said to be *weapons-grade* if it contains 80% or more $^{235}_{92}\mathrm{U}$. Enrichment can be done by various means, but the dominant technique is to use gas centrifuges for separating the isotopes.

How much weapons-grade uranium is needed to make a nuclear weapon, that is, what is the **critical mass**? The optimum geometrical arrangement of the uranium is in the shape of a sphere. Within the sphere, the neutrons trigger further induced fission reactions, whereas on the surface of the sphere, on average, half of the neutrons escape. The critical mass of a sphere of $^{235}_{92}\mathrm{U}$ is approximately 50 kg. Since uranium has a mass density 19.2 times that of water, the radius of a sphere of uranium $^{235}_{92}\mathrm{U}$ with the critical mass is only approximately 8.6 cm. In a nuclear weapon, a sufficient quantity of $^{235}_{92}\mathrm{U}$ is kept separated in several pieces and then detonated by pushing these pieces together via the use of conventional chemical explosives. The exact details of this process are closely guarded military secrets.

Quantities of $^{235}_{92}\mathrm{U}$ can also be used for power production in nuclear fission reactors. The uranium needed for this is much less enriched than that used for nuclear weapons. The key to reactor construction is to keep the chain reaction controlled and thus avoid runaway reactions. This is achieved by using moderator materials, which capture neutrons and thus make them unavailable to induce further fission reactions. The disastrous reactor core meltdown at the Ukrainian city of Chernobyl on April 26, 1986, was the result of such a runaway reaction when the moderator system failed. The second biggest nuclear disaster happened on March 11, 2011, when an earthquake and subsequent tsunami caused a series of catastrophic equipment failures at the Fukushima Daiichi nuclear power plant complex in Japan. The resulting nuclear meltdown released significant amounts of radioactive materials into the environment.

A second isotope that is very important for nuclear weapons is plutonium-239. $^{239}_{94}\mathrm{Pu}$ is produced in reactors from $^{238}_{92}\mathrm{U}$ via neutron capture and subsequent β^- decays:

$$\begin{aligned} {}^{238}_{92}\mathrm{U} + n &\rightarrow {}^{239}_{92}\mathrm{U} + \gamma \\ {}^{239}_{92}\mathrm{U} &\rightarrow {}^{239}_{93}\mathrm{Np} + e^- + v_e \\ {}^{239}_{93}\mathrm{Np} &\rightarrow {}^{239}_{94}\mathrm{Pu} + e^- + v_e. \end{aligned}$$

The process of producing $^{239}_{94}\mathrm{Pu}$ is often referred to as **breeding**. $^{239}_{94}\mathrm{Pu}$ also undergoes neutron-induced fission and gives a higher yield of neutrons than

$^{235}_{92}$U. Thus, its critical mass is only 10 kg, and it is much more valuable for nuclear weapons than $^{235}_{92}$U. However, breeding weapons-grade plutonium is not easy because $^{239}_{94}$Pu can easily capture another neutron and turn into $^{240}_{94}$Pu, which does not show spontaneous fission. Too high a fraction of $^{240}_{94}$Pu will lead to precritical detonation (fizzle) of a warhead, so the $^{239}_{94}$Pu needs to be sufficiently pure to be useful in weapons.

Clearly, nuclear weapons pose a great threat, and increasing numbers of countries are acquiring this dangerous technology. After the United States and Russia in the 1950s, China, France, Great Britain, Israel, India, Pakistan, and perhaps others (such as North Korea, Iran, and South Africa) have become nuclear powers. With every additional country that is able to produce nuclear weapons, the danger increases that the weapons could fall into the wrong hands. Small nuclear warheads fit into suitcases, and terrorists have turned their attention to them. Even detonating a bomb of conventional explosives mixed with radioactive material, called a *dirty bomb,* could have devastating consequences.

Equally clearly, the peaceful use of nuclear power from fission reactions is a way to avoid the greenhouse gas emissions associated with the burning of fossil fuels in conventional power plants. However, the storage of radioactive wastes with very long half-lives is still a problem that is not completely solved. Countries such as Germany, for example, have sworn off the use of fission reactors and are turning their attention to alternative carbon-neutral energy sources (wind, biofuels, hydroelectric, photovoltaics, and others) to solve the greenhouse gas problem. However, with global energy consumption on a very steep rise, it remains to be seen if these alternatives to fission power can satisfy the world's energy needs.

EXAMPLE 40.5 Fission Energy Yield

PROBLEM

What is the energy yield per kilogram of uranium for the neutron-induced fission reaction of ${}^{235}_{92}\mathrm{U}$ to form ${}^{92}_{36}\mathrm{Kr}$ and three neutrons, if ${}^{235}_{92}\mathrm{U}$ is at 20% enrichment in the reactor?

SOLUTION

First, we need to write the equation for this fission reaction. This will tell us what the second fission fragment is. The reactants (a uranium nucleus and a proton) have 92 protons, the charge number of uranium. Since one of the fission fragments is krypton with 36 protons, the other fission fragment has $Z = 92 - 36 = 56$ protons. This means that it is a barium nucleus. For the total mass number for the reactants, we find $A = 236$. Subtracting the mass number total for the three neutrons and the mass number 92 of the krypton isotope, we find the mass number of the barium isotope: $A = 236 - 3 - 92 = 141$. Thus, the induced fission reaction equation is

$$n + {}^{235}_{92}\mathrm{U} \rightarrow {}^{141}_{56}\mathrm{Ba} + {}^{92}_{36}\mathrm{Kr} + 3n.$$

The mass of uranium-235 is 235.0439299 u, the mass of barium-141 is 140.914411 u, the mass of krypton-92 is 91.92615621 u, and the mass of a neutron is 1.008664916 u. Therefore, the mass difference between the reactants and the products is

$$235.0439299 - (140.914411 + 91.92615621 + 2 \cdot 1.008664916) = 0.186033 \text{ u}.$$

In electron-volts, the mass-energy difference between the initial and final states is 173.3 MeV. This is also the sum of the kinetic energies of the three emitted neutrons plus the two fission fragments minus the kinetic energy of the initial neutron.

This energy output can be converted into joules:

$$\Delta E = (173.3\,\text{MeV})\left(1.602 \cdot 10^{-13}\ \text{J/MeV}\right) = 2.776 \cdot 10^{-11}\ \text{J}.$$

A mixture of 80% ${}^{238}_{92}\mathrm{U}$ and 20% ${}^{235}_{92}\mathrm{U}$ has an average mass number of $0.8(238) + 0.2(235) = 237.4$. Thus, 237.4 g of uranium at the given enrichment has $6.022 \cdot 10^{23}$ uranium atoms (Avogadro's number, see Chapter 13). Of these atoms, 20% are uranium-235 and can undergo neutron-induced fission. Therefore, 237.4 g of the enriched uranium mixture contains $0.2\left(6.022 \cdot 10^{23}\right) = 1.2044 \cdot 10^{23}$ uranium-235 atoms, and consequently 1 kg of the mixture contains $1.2044 \cdot 10^{23}/0.2374 = 5.073 \cdot 10^{23}$ uranium-235 atoms.

All that is left to do is to multiply the number of atoms times the energy yield per atom to obtain the total energy yield from fission of a kilogram of the enriched uranium:

$$\left(2.776 \cdot 10^{-11}\ \text{J}\right)\left(5.073 \cdot 10^{23}\right) = 14.08 \cdot 10^{12}\ \text{J}.$$

Keep in mind that not all of this energy is available for feeding into the electric grid. Some uranium-235 will always be left nonfissioned, and some of the neutrons released will hit uranium-238 and breed it into plutonium.

For comparison, the combustion of 1 kg of gasoline yields a maximum of $4.6 \cdot 10^{7}$ J. This means that the nuclear fission of enriched uranium yields more than 300,000 times more energy than the combustion of the same mass of gasoline.

Thorium Fission Cycle

Uranium also has the isotope $^{233}_{92}\mathrm{U}$, which can decay via spontaneous fission (or via neutron-induced fission) and has a half-life of 159,200 years. It can be produced from thorium via a neutron-capture reaction:

$$
\begin{aligned}
&^{232}_{90}\mathrm{Th} + n \rightarrow ^{233}_{90}\mathrm{Th} + \gamma \\
&^{233}_{90}\mathrm{Th} \rightarrow ^{233}_{91}\mathrm{Pa} + e^{-} + v_e \\
&^{233}_{91}\mathrm{Pa} \rightarrow ^{233}_{92}\mathrm{U} + e^{-} + v_e.
\end{aligned}
$$

The spontaneous fission of $^{233}_{92}\mathrm{U}$ releases 198 MeV of energy, and this isotope is thus useful as a fuel for fission reactors. The dominant decay mode of $^{233}_{92}\mathrm{U}$ is alpha decay to $^{229}_{90}\mathrm{Th}$. This thorium isotope can then capture three neutrons and become $^{232}_{90}\mathrm{Th}$, and the thorium fission cycle can repeat, until, in principle, all of the fuel has undergone fission. In theory, the fission of $^{233}_{92}\mathrm{U}$ should provide enough neutrons to keep this cycle going as a chain reaction, but in practice even small losses of neutrons prevent this from occurring.

The protactinium isotope $^{233}_{91}\mathrm{Pa}$ is the key to the neutron balance of the thorium fission cycle, because it can capture neutrons before it has a chance to undergo beta decay to $^{233}_{92}\mathrm{U}$ (with a mean lifetime of 27 days). One strategy is to chemically remove the $^{233}_{91}\mathrm{Pa}$ from the reactor core, to prevent it from capturing the neutrons. This can be accomplished using a molten-salt reactor design. Another strategy, implemented by an accelerator-driven reactor design, is to supply additional neutrons to the reactor via an external particle accelerator. Both of these reactor designs are significantly more challenging to develop than designs based on the fission of $^{235}_{92}\mathrm{U}$. However, they have several advantages: less radioactive waste, significantly improved fuel utilization, and increased safety due to the impossibility of runaway reactions like those responsible for the meltdowns at Chernobyl and Fukushima.

Thorium is approximately four times more abundant on Earth than uranium; there are approximately 400,000 tons of minable thorium dioxide in the United States alone. Successful utilization of the thorium fission cycle could therefore satisfy the world's energy needs for the next few thousand years. Several countries, most notably China, have started large-scale efforts to utilize this thorium resource.

Nuclear Fusion

The nuclear fusion process merges light nuclei into heavier ones and thus also increases the binding energy per nucleon, as long as the end product of the fusion process is lighter than iron.

Stellar Fusion

Nuclear fusion is the basic process of energy production in stars. Two main reaction chains, discovered in 1938 by Hans Bethe, accomplish this. The first is the proton-proton chain, and the second is the CNO cycle. Both of these serve to fuse four hydrogen atomic nuclei into one helium nucleus.

The **proton-proton chain** starts with two protons forming a deuteron plus a positron. This is a weak interaction process and takes a long time, approximately 10 billion years on average (half-life). This explains why the Sun has already existed for approximately 5 billion years and did not explode right after it formed. The deuteron from the initial reaction can quickly capture another proton and form helium-3; the positron from the initial reaction annihilates almost instantaneously with an electron:

$$\begin{aligned} p + p &\rightarrow d + e^{-} + v_e \quad & Q &= 0.42\,\text{MeV} \\ d + p &\rightarrow {}^{3}_{2}\text{He} + \gamma & Q &= 5.49\,\text{MeV} \\ e^{+} + e^{-} &\rightarrow 2\gamma & Q &= 1.02\,\text{MeV}. \end{aligned}$$

The net result of these three reactions is the fusion of three protons into one helium-3 nucleus plus three photons and one neutrino. The combined Q-value of the three reactions is $Q_{\text{net}} = (0.42 + 5.49 + 1.02)\ \text{MeV} = 6.93\,\text{MeV}$.

The next step involves three different reactions through which fusion can proceed toward helium-4. In the Sun, 86% of the time, two helium-3 nuclei undergo a fusion reaction that has a Q-value of 12.86 MeV:

$$ {}^{3}_{2}\text{He} + {}^{3}_{2}\text{He} \rightarrow {}^{4}_{2}\text{He} + p + p. $$

Adding the Q-value of this reaction to the Q-values for the formation of the two helium-3 nuclei gives

$$ Q_{\text{net}} = (2 \cdot 6.93 + 12.86)\,\text{MeV} = 26.7\,\text{MeV}. $$

This is exactly the mass difference between four protons and one helium-4 nucleus, as expected from conservation of energy.

Alternatively, 14% of the time, a helium-3 nucleus fuses with an existing helium-4 nucleus in the Sun:

$$ {}^{3}_{2}\text{He} + {}^{4}_{2}\text{He} \rightarrow {}^{7}_{4}\text{Be} + \gamma. $$

This beryllium-7 nucleus then captures an electron to form lithium-7, which in turn undergoes a fusion reaction to form two helium-4 nuclei:

$$
\begin{aligned}
&{}^{7}_{4}\mathrm{Be} + e^{-} \rightarrow {}^{7}_{3}\mathrm{Li} + \nu_e \\
&{}^{7}_{3}\mathrm{Li} + p \rightarrow 2\,{}^{4}_{2}\mathrm{He}.
\end{aligned}
$$

The production of 26.7 MeV of kinetic energy from the fusion of four protons into one helium-4 nucleus is the basic reason why the Sun shines. What happens to this energy? Part of it is carried away by neutrinos. Due to the low cross sections for their interactions, these neutrinos can leave the Sun right away on straight paths. The photons, on the other hand, scatter off the electrons and ions in the Sun, become absorbed and re-emitted in random directions, and take, on average, approximately 50,000 years to reach the Sun's surface.

The name of the **CNO cycle** incorporates the chemical symbols of the elements carbon, nitrogen, and oxygen. This cycle is dominant in stars that are significantly more massive than the Sun. In the CNO cycle, a carbon nucleus serves as a catalyst (meaning that it is regenerated by the end of the cycle) to fuse four protons into one helium-4 nucleus:

$$
\begin{aligned}
{}^{12}_{6}\mathrm{C} + p &\rightarrow {}^{13}_{7}\mathrm{N} + \gamma && Q = 1.95\ \mathrm{MeV} \\
{}^{13}_{7}\mathrm{N} &\rightarrow {}^{13}_{6}\mathrm{C} + e^{+} + \nu_e && Q = 1.20\ \mathrm{MeV} \\
e^{+} + e^{-} &\rightarrow 2\gamma && Q = 1.02\ \mathrm{MeV} \\
{}^{13}_{6}\mathrm{C} + \mathrm{P} &\rightarrow {}^{14}_{7}\mathrm{N} + \gamma && Q = 7.54\ \mathrm{MeV} \\
{}^{14}_{7}\mathrm{N} + p &\rightarrow {}^{15}_{8}\mathrm{O} + \gamma && Q = 7.35\ \mathrm{MeV} \\
{}^{15}_{8}\mathrm{O} &\rightarrow {}^{15}_{7}\mathrm{N} + e^{+} + \nu_e && Q = 1.73\ \mathrm{MeV} \\
e^{+} + e^{-} &\rightarrow 2\gamma && Q = 1.02\ \mathrm{MeV} \\
{}^{15}_{7}\mathrm{N} + p &\rightarrow {}^{12}_{6}\mathrm{C} + {}^{4}_{2}\mathrm{He} && Q = 4.96\ \mathrm{MeV} \\
\text{net: } 4\mathrm{p} &\rightarrow {}^{4}_{2}\mathrm{He} + 7\gamma + 2\nu_e && Q_{\mathrm{net}} = 26.8\ \mathrm{MeV}
\end{aligned}
$$

These fusion processes need to overcome the Coulomb repulsions between positively charged atomic nuclei. Thus, fusion is restricted to the inner core of the Sun, which extends from the center to about 20% of the solar radius. The core contains about 10% of the mass of the Sun. In the core, the density is up to 150 tons per cubic meter, and the temperature is approximately 13.6 million K. The high temperatures and densities in the Sun's core are sufficient for the proton-proton fusion chain to proceed. By contrast, the CNO cycle requires somewhat higher temperatures than the Sun provides, and so contributes relatively little to the Sun's total energy output. However, as the Sun ages, it will reach stages of stellar evolution when the densities and temperatures in its core will be high enough for the CNO cycle to proceed.

EXAMPLE 40.6 Fusion in the Sun

As noted at the beginning of this chapter, nuclear fusion reactions are responsible for almost all of the energy resources at our disposal on Earth. Let's see how the numbers work out.

PROBLEM

The Sun radiates approximately $1370\,\mathrm{W/m^2}$ onto Earth. How much total energy do fusion reactions inside the solar core need to produce per second, and how many protons does it take per second to generate this much power?

SOLUTION

The Sun is an almost perfect sphere and radiates its power uniformly over the 4π solid angle. Thus, if we calculate the surface area of a sphere with the radius of the Earth's orbit around the Sun, we can calculate the total power output. The orbital radius is 1 astronomical unit, 149.6 million km. Therefore, the area of the surface of the sphere with a radius equal to Earth's orbit is

$$A = 4\pi r^2 = 4\pi\left(1.496 \cdot 10^{11}\ \mathrm{m}\right)^2 = 2.812 \cdot 10^{23}\mathrm{m}^2.$$

Given that each square meter of this area receives approximately 1370 W of power, the total power output of the Sun is

$$p_{\mathrm{total}} = \left(1.370 \cdot 10^3 \mathrm{W/m^2}\right)\left(2.812 \cdot 10^{23}\mathrm{m}^2\right) = 3.85 \cdot 10^{26}\mathrm{W}(385\ \mathrm{yott}$$

As a reminder, $1\ \mathrm{W} = 1\ \mathrm{J/s}$ and $1\,\mathrm{eV} = 1.602178 \cdot 10^{-19}$ J. The energy released by the fusion of four protons into one helium-4 nucleus can be converted to joules:

$$26.7\,\mathrm{MeV} = \left(26.7 \cdot 10^6\right)\left(1.602178 \cdot 10^{-19}\ \mathrm{J}\right) = 4.28 \cdot 10^{-12}\ \mathrm{J}.$$

One-quarter of this energy is from each proton involved in the fusion cycle, $1.07 \cdot 10^{-12}$ J. Therefore, $\left(3.85 \cdot 10^{26}\mathrm{W}\right)/\left(1.07 \cdot 10^{-12}\ \mathrm{J}\right) = 3.60 \cdot 10^{38}$ protons need to fuse into helium-4 each second. With a proton mass of $1.6726 \cdot 10^{-27}\mathrm{kg}$, this means that a total mass of $\left(3.60 \cdot 10^{38}\right)\left(1.6726 \cdot 10^{-27}\mathrm{kg}\right) = 6.02 \cdot 10^{11}\mathrm{kg}$ (600 million metric tons) of protons are converted into helium each second!

Concept Check **40.5**

With that much hydrogen being converted into helium, how much longer can the Sun keep shining at the current burn rate? (*Hint:* The mass of the Sun is $1.99 \cdot 10^{30}$ kg, the core contains approximately 10% of that mass, and approximately half of the core mass is currently still hydrogen.)

a) 30,000 years

b) 2 million years

c) 100 million years

d) 5 billion years

e) $3.3 \cdot 10^{18}$ years,

Terrestrial Fusion

Can the power of fusion be harnessed on Earth? The answer is yes and maybe. In 1952, the first hydrogen bomb was detonated by the United States. Hydrogen bombs use nuclear fusion reactions to achieve maximum energy output. The high temperatures and compressions needed to achieve fusion are obtained by using a nuclear bomb of the fission type as a trigger. So yes, it is possible to achieve nuclear fusion reactions and to obtain a very large energy release. However, the detonation of a hydrogen bomb cannot be considered to be a harnessing, or controlling, of fusion. Controlled fusion as a means of production of useful energy could be the solution to global energy problems. During the past four or five decades, very large sums of money have been dedicated to achieving controlled fusion, so far with little success. The high pressures and temperatures needed for thermonuclear fusion have been an elusive goal.

Presently, two approaches hold promise. One is magnetic confinement technology, which an international collaboration called ITER is using in a thermonuclear fusion reactor being built in France. Figure 40.35 shows the central fusion reactor of the ITER facility. The toroidal vacuum chamber is lined with a shield that absorbs heat and neutrons produced in the fusion reactions. Magnet systems to confine the heated plasma surround the vacuum chamber. There is also a divertor to handle neutral particles that are not contained by the magnetic field.

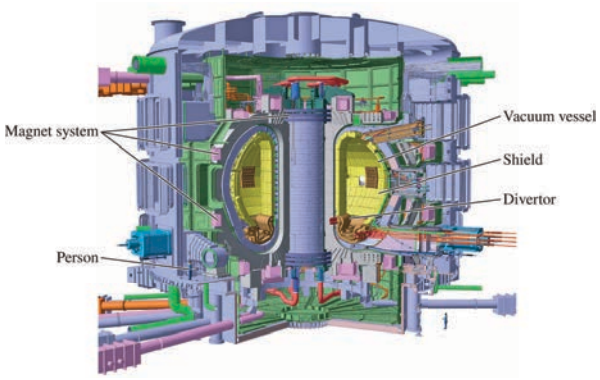

FIGURE 40.35 Cutaway drawing of the central fusion reactor of the ITER facility, now under construction in Cadarache, France.

ITER

In 2006, the European Union, the United States, China, Russia, Japan, India, and South Korea agreed to fund this project jointly and selected the construction site, Cadarache, in the south of France. It is expected that the ITER reactor will provide 500 MW of power sustained for approximately 10 minutes. This is an improvement of several orders of magnitude over what has been achieved with

earlier magnetic confinement fusion reactors and a big step toward a break-even point—that is, extracting at least as much power as has been put in. The current schedule for ITER is to achieve the first plasma operations in 2025 and the first deuterium-tritium sustained fusion in 2035.

The other very promising approach to fusion is laser fusion. In Livermore, California, the U.S. Department of Energy has constructed the National Ignition Facility (NIF). Here the world's most powerful lasers are shot into small hollow cylinders (called *hohlraum*), and the X-rays released from the interaction of the lasers with the hohlraum walls compress the nuclear fusion fuel in the interiors of the cylinders, causing fusion ignition. (The laser assembly at the NIF was shown in Figures 38.27 and 38.28.) Figure 40.36a presents an overview of the laser-induced fusion process, Figure 40.36b shows one of the hohlraum cylinders, and Figure 40.36c shows the target chamber, in which the target is ignited and the fusion energy that is released is recaptured.

40.5 Nuclear Astrophysics

The interface of nuclear physics, particle physics, and astrophysics is one of the most fascinating areas of current physics research. Laboratory experiments, computer simulations, model studies, and calculations can be performed to answer basic questions about the universe. Several aspects of this interdisciplinary field were discussed in Chapter 39. However, one of the most interesting topics is the origin of the chemical elements. We saw in Chapter 39 that the Big Bang created almost all of the hydrogen and most of the helium in the universe. Fusion reactions in stars, as we have just seen, generate helium as well. On the other hand, the elements that we observe around us are different. The Earth is predominantly composed of iron, silicon, oxygen, aluminum, sodium, and other elements. Elements as heavy as uranium can be found in sizable quantities. Our own bodies consist mainly of oxygen (at 65% of body weight), carbon (18%), hydrogen (3%), calcium (1.5%), phosphorus (1%), and traces of many other elements. Figure 40.37 shows the percent abundance by weight of the elements in the Solar System. Hydrogen and helium dominate, but all stable elements can be found, and even thorium and uranium exist in appreciable quantities.

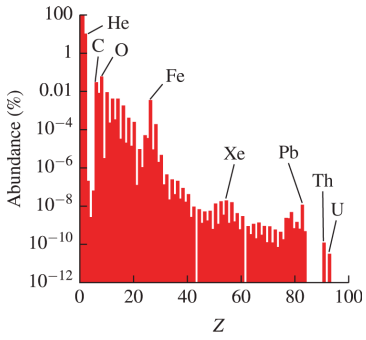

FIGURE 40.37
Abundance of the chemical elements in the Solar System by weight.

Where do the heavier elements come from? To answer this question, we have to examine the later stages in a star's life. For example, let's consider a star with a mass about 20 times the mass of the Sun. The combination of nuclear physics and stellar modeling shows that a star this massive uses up its hydrogen fuel much faster than the Sun does, and after only 10 million years, its core is predominantly composed of helium. The helium-4 nuclei then fuse to carbon-12 in what is called *triple-alpha process*:

$$
\begin{aligned}
&{}^{4}_{2}\mathrm{He} + {}^{4}_{2}\mathrm{He} \leftrightarrow {}^{8}_{4}\mathrm{Be} \\
&{}^{8}_{4}\mathrm{Be} + {}^{4}_{2}\mathrm{He} \rightarrow {}^{12}_{6}\mathrm{C} + \gamma.
\end{aligned}
$$

This two-step process is necessary because ${}^{8}_{4}\mathrm{Be}$ is not stable. It has a half-life of only $6.7 \cdot 10^{-17}$s and decays back into two helium-4 nuclei. Therefore, the density of helium-4 needs to be very high for this process to proceed. It then takes approximately 1 million years for much of the helium to be converted into carbon. As the core temperature rises, it eventually becomes sufficient to overcome the Coulomb repulsions between ever heavier nuclei. This leads to the production of nuclei of oxygen, neon, silicon, and then finally iron and nickel.

As we have seen, the stable iron and nickel isotopes have the highest binding energy per nucleon. The production of elements heavier than iron and nickel through fusion processes is thus not possible, which means that the core of the star can no longer produce energy through those processes. This iron core of the 20-solar-mass star has a mass of 1 solar mass. Once the fusion energy output ceases, the thermal pressure due to the fusion photons vanishes, and the core starts collapsing due to the force of gravity. Capture of a significant fraction of the electrons by protons, $p + e^{-} \rightarrow n + \nu_e$, accelerates the collapse. After only a few milliseconds, the center of the core has been compressed to the density of nuclear matter, and a shock wave begins to propagate radially outward through the core, causing the star to explode and become a **supernova.**

Exactly how the process from core collapse through explosion works in detail is still under intensive investigation. However, observations of supernovas show that the total energy emitted in the form of photons and neutrinos is on the order of 10^{44} J to 10^{45} J, which corresponds to the energy release of more than a billion billion billion (10^{27}) hydrogen bombs ignited simultaneously. What's left behind is a neutron star that is very small (radius of approximately 10 km) and incredibly dense (mass of approximately 1.5 solar masses at nuclear matter density). As the neutron star is formed, angular momentum is conserved, so it rotates very rapidly. As a neutron star spins, it can emit what are known as *lighthouse beams* of radio waves, light, and/or X-rays. Such a rotating neutron star is called a *pulsar*. Pulsars have been observed to rotate as fast as 40 times per second! The rotational speed of the Sun is $4.6 \cdot 10^{-7}$ rotations/s (one rotation every 25 days).

As a result of the supernova explosion, matter is thrown into interstellar space and forms clouds of dust and gas, which are some of the most picturesque objects in the universe. Figure 40.38 shows the famous Crab Nebula, which is the remnant of a supernova that exploded 6500 light-years from Earth and was observed in the year 1054. It was so bright that it could be seen during bright daylight, even though the explosion happened at a distance almost half a billion times greater than the distance from Earth to the Sun.

FIGURE 40.38 The Crab Nebula, a supernova remnant

ESA, J. Hester and A. Loll (Arizona State University)/NASA

During a supernova explosion, the isotopes that exist outside the core are bombarded by an incredibly high flux of neutrons. They capture these neutrons very rapidly and also undergo fast β^- decays, thus adding to their neutron and proton numbers. The path of this so-called *r-process* (*r* stands for "rapid") through the isotope chart is sketched in Figure 40.39. It takes only seconds to form the r-process isotopes, which then decay back toward the valley of stability. This process is understood qualitatively, but not in quantitative detail. However, astronomers generally agree that the elemental abundance observed in the Solar System (see Figure 40.37) is the result of a supernova explosion more than 5 billion years ago. The Solar System formed from the ashes of that supernova. The vast majority of the atoms around us and inside our bodies are thus at least 5 billion years old and have been recycled again and again.

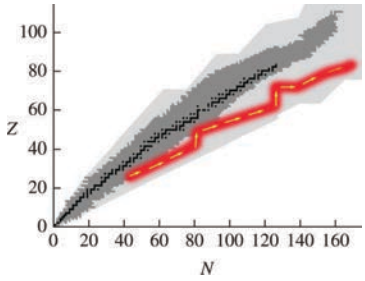

FIGURE 40.39 Path of the r-process (red with yellow arrows) through the isotope chart. Light gray: postulated isotopes. Gray: known isotopes. Black: stable isotopes.

40.6 Nuclear Medicine

Nuclear medicine is a flourishing subfield of medicine, where nuclear physics finds direct applications in diagnosis and treatment. Great progress continues to be made by using more precise tools for delivering radiation to the relevant areas of patients' bodies. There has also been steady improvement in detection equipment, resulting in the continual lowering of the minimum radiation doses needed for diagnostic tests. Progress in basic nuclear physics research thus translates directly into medical advances.

Radiation of various kinds is used for cancer treatment. The idea is straightforward: Concentrate the radiation on tumor cells that need to be destroyed, while at the same time trying to avoid irradiating healthy tissues. This treatment option is particularly attractive in cases where the tumor cannot be removed surgically or where the surgery area needs to be treated post-operatively. Brain cancers in particular have been successfully treated with radiation techniques, which are being refined steadily.

The most common radiation treatment of cancers uses gamma rays. In this technique, a very strong radioactive isotope, usually ${}^{60}_{27}\mathrm{Co}$, β^- decays into an excited state of nickel via ${}^{60}_{27}\mathrm{Co} \rightarrow {}^{60}_{28}\mathrm{Ni} + e^- + \nu_e$, with a Q-value of 318 keV. The half-life for this process is 5.27 years. Once populated, the excited state of ${}^{60}_{28}\mathrm{Ni}$ then decays promptly into the ground state via the emission of two high-energy gamma rays (Figure 40.40). Thus, the ${}^{60}_{27}\mathrm{Co}$ isotope delivers two high-energy gamma rays, but still has a very long half-life. Since ${}^{60}_{27}\mathrm{Co}$ is straightforwardly produced with 99% purity in reactors via neutron capture by the stable isotope ${}^{50}_{27}\mathrm{Co}$, it is ideal for medical purposes as well as other purposes, such as food irradiation.

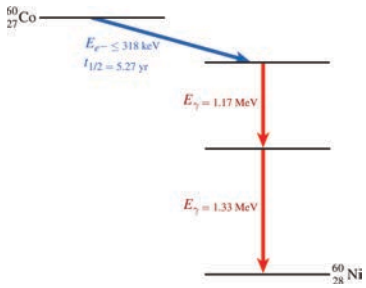

FIGURE 40.40 Decay process for cobalt-60.

The radioactive cobalt is contained behind thick shielding. Narrow channels in the shielding allow photons to escape in well-defined directions to be used as a beam for radiation. This is the basis for the treatment technique called **gamma knife** (invented in 1968), mainly used to treat inoperable brain cancers (Figure 40.41). For each patient, a custom radiation collimator in the shape of a very

thick helmet is designed; the many channels through the shielding all point to the point inside the patient's head where the cancer tumor is located.

FIGURE 40.41 Gamma-knife cancer treatment facility at Scripps Memorial Hospital, La Jolla, California.

Steve Goetsch

The last few years have seen a very strong increase in research into cancer treatment with heavy ion beams, which, like alpha particles, deposit most of their energy near their maximum penetration depth and so allow greater depth control of the deposited radiation dose. Great advances in radiation treatment can be expected from the use of this method.

In the field of imaging, the most important technology is based on nuclear magnetic resonance (NMR). The imaging technology based on NMR is called *magnetic resonance imaging* (MRI). How does MRI work? Particles such as protons have an intrinsic magnetic dipole moment, as discussed in Chapter 28. When protons are placed in a strong magnetic field, their spins and therefore their magnetic dipole moments can have only two directions: parallel or antiparallel to the external field. The difference in energy between the two states is the difference in magnetic potential energy, which is $2\mu B$, where μ is the component of the proton's magnetic moment along the direction of the external field. This potential energy difference was discussed in Chapter 27.

A time-varying electric field at the proper frequency can induce the dipole moments of some of the protons to flip their direction from parallel to antiparallel to the external field, and the protons thereby gain potential energy. Because the magnetic potential energy can have only two possible values, the energy required to flip the dipole moments is a discrete value, depending on the magnitude of the external field. Chapter 36 showed that the energy delivered by the field is proportional to the frequency. Thus, only one given oscillation frequency will cause the dipole moments to flip. If the time-varying electric field is switched off, the protons in the higher energy state, with dipole moments that are not aligned with the field, will flip to having their dipole moments parallel with the field, emitting photons of a well-defined energy that can be detected.

An MRI device applies this physical principle of nuclear magnetic resonance. Such a device can image the location of the protons in a human body by introducing a time-varying electric field and then varying the magnetic field in a known, precise manner to produce a three-dimensional picture of the distribution of tissue containing hydrogen. The quality of this imaging depends on the strength of the external magnetic field. Figure 40.42 shows results of an MRI scan.

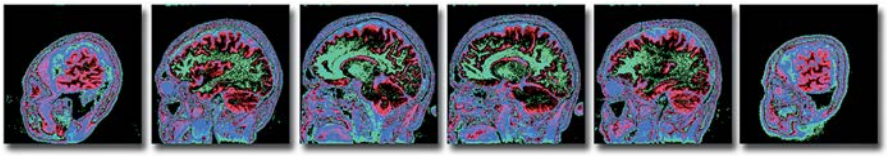

FIGURE 40.42 Image slices through a human head, obtained via MRI.

W. Bauer and G. D. Westfall

Finally, let's consider an example of the diagnostic use of nuclear radiation. The element technetium $(Z = 43)$ has no stable isotopes. The longest-lived technetium isotope is $^{99}_{43}\text{Tc}$, with a half-life of 4.2 million years. Its lowest energy levels, their angular momentum values, and their half-lives are shown in Figure 40.43. The state with angular momentum $\frac{1}{2}\hbar$ is an isomeric state, because its angular momentum is more than $1\hbar$ different from either of the two lower-energy states. Thus, it is relatively long-lived and decays with a half-life of 6.02 h into the $j = \frac{7}{2}\hbar$ state via the emission of a photon with an energy of 2.17 keV. This is followed by a very quick decay to the ground state, with a half-life of only 19 ns, via the emission of a 140.5-keV photon. Thus, the decay of $^{99}_{43}\text{Tc}$ delivers high-energy photons over several hours after the initial preparation of the isotope. Since a 140.5-keV photon easily penetrates biological tissue, this isotope is very valuable for diagnostic purposes.

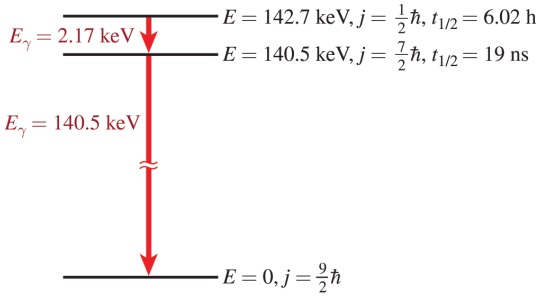

FIGURE 40.43 Lowest energy levels of technetium, their angular momenta in terms of Planck's constant, and their half-lives.

In a technetium scan, $^{99}_{43}\text{Tc}$ is injected into the patient. After a few minutes to a few hours, a picture can be taken of the patient with a gamma-ray camera to monitor where in the body the technetium has traveled. Certain tumors result in

an increased local concentration of $^{99}_{43}\mathrm{Tc}$ and appear as black areas in the gamma-ray picture. The patient shown in Figure 40.44 fortunately turned out to be cancer-free. (The black dot near the left elbow is the injection point.) $^{99}_{43}\mathrm{Tc}$ is thus a great example of the medical use of a specific isotope.

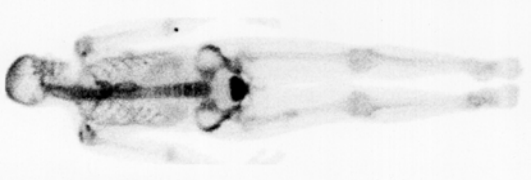

FIGURE 40.44 Technetium scan of a female patient. Dark areas show where there is increased concentration of the technetium-99 isotope in the body.

W. Bauer and G. D. Westfall

WHAT WE HAVE LEARNED EXAM STUDY GUIDE

- The atomic nucleus consists of protons and neutrons, collectively called *nucleons*. Nuclei with different numbers of neutrons but the same number of protons are isotopes of the same element. The mass number of an isotope is the sum of the number of protons and the number of neutrons: $A = Z + N$.
- The interaction between nucleons is short-range and can effectively be described by potentials based on pion exchange.
- Nuclei are approximately spherical in shape, with the radius of the sphere depending on the mass number: $R(A) = R_0 A^{1/3}$, where $R_0 = 1.12$ fm.
- The nucleon density in the interior of a nucleus is $n = 0.17\ \mathrm{fm}^{-3}$, and the mass density is $\rho = m_{\mathrm{nucleon}} n = 2.8 \cdot 10^{17} \mathrm{kg/m}^3$. The dependence of the density on the radial coordinate is given by the Fermi function: $n(r) = n_0 / \left[1 + e^{(r - R(A))/a}\right]$, with $a = 0.54$ fm.
- There are 251 stable isotopes and more than 2400 known unstable isotopes, with lifetimes from fractions of seconds to many times the age of the universe.
- Nuclear mass is measured in multiples of the atomic mass unit, $1\ \mathrm{u} = 1.660538782 \cdot 10^{-27}\ \mathrm{kg} = 931.494028\ \mathrm{MeV}/c^2$, which is defined as being 1/12 of the mass of the ${}^{12}_{6}\mathrm{C}$ atom.
- The mass of a nucleus with Z protons and N neutrons is smaller than the sum of the masses of the individual nucleons, and the binding energy is defined as that mass difference times c^2: $B(N,Z) = Zm(0,1)c^2 + Nm_n c^2 - m(N,Z)c^2$.
- The mass excess of a nucleus is defined as the difference between the mass of a nucleus expressed in atomic mass units and the mass number: $\text{mass excess} = m(N,Z) - (A)(1\ \mathrm{u})$.
- The binding energies of different isotopes can be reproduced well by the Bethe-Weizsäcker formula from the liquid-drop model, as the sum of volume, surface, Coulomb, asymmetry, and pairing contributions:

$$B(N,Z) = a_{\mathrm{v}} A - a_{\mathrm{s}} A^{2/3} - a_{\mathrm{c}} Z^2 A^{-1/3}$$
$$- a_{\mathrm{a}} \left(Z - \tfrac{1}{2}A\right)^2 + a_{\mathrm{p}} \left((-1)^Z + (-1)^N\right) A^{-1/2}.$$

- The Q-value of a given nuclear reaction is the difference between the sum of the mass-energies of the initial nuclei minus that of the final nuclei.
- The Fermi gas model proposes a quantum gas of nucleons that can move freely inside the nucleus but are confined by the nuclear surface. The density of states in the Fermi gas model is $dN(E) = m^{3/2} E^{1/2} dE / \left(2^{1/2} \pi^2 a^3 \hbar^3\right)$.

- The Fermi energy is

$$E_{\mathrm{F}} = \left(\hbar^2/2m\right)\left(\tfrac{3}{2}\pi^2 n_0\right)^{2/3} = 38\ \mathrm{MeV}.$$

- The nuclear shell model predicts angular momentum shells inside the nucleus similar to the electron shells in the atom. It reproduces the magic numbers of 2, 8, 20, 28, 50, 82, 126.
- Nuclear decays follow an exponential decay law: $N(t) = N_0 e^{-\lambda t}$. The decay constant λ, half-life $t_{1/2}$, and mean lifetime τ are related via $t_{1/2} = \ln 2/\lambda = \tau \ln 2$.
- In alpha decay, a heavier nucleus emits a helium-4 nucleus:

$${}^{A}_{Z}\mathrm{Nuc} \rightarrow {}^{4}_{2}\mathrm{He} + {}^{A-4}_{Z-2}\mathrm{Nuc}\prime.$$

  In a β^- decay, an electron and an anti-neutrino are emitted:

$${}^{A}_{Z}\mathrm{Nuc} \rightarrow {}^{A}_{Z+1}\mathrm{Nuc}' + e^- + v_e.$$

  A β^+ decay can proceed via a positron emission:

$${}^{A}_{Z}\mathrm{Nuc} \rightarrow {}^{A}_{Z-1}\mathrm{Nuc}' + e^+ + v_e.$$

  This type of decay can also occur via electron capture:

$$e^- + {}^{A}_{Z}\,\mathrm{Nuc} \rightarrow {}^{A}_{Z-1}\mathrm{Nuc}' + v_e.$$

  A gamma decay is the emission of a high-energy photon from an excited nucleus, a process that does not transmute the nucleus.
- The SI unit for radioactivity is the becquerel: $1\ \mathrm{Bq} = 1$ nuclear decay/s. The SI unit for the absorbed dose is the gray: $1\ \mathrm{Gy} = 1\ \mathrm{J/kg}$. The SI unit for the dose equivalent is the sievert: $1\ \mathrm{Sv} = w_{\mathrm{r}}(1\ \mathrm{Gy})$, where the radiation weight factor, w_{r}, varies between 1 and 20, depending on the type and energy of the emitted particle.
- Nuclear fission is the splitting of a very heavy nucleus into two medium-mass nuclei, usually with the associated emission of one or a few neutrons. This process is the physical basis for nuclear power plants, as well as nuclear weapons.
- Nuclear fusion is the merging of two light nuclei into a heavier one. Nuclear fusion is the basic process that powers the stars. The two most common fusion chains are the proton-proton chain and the CNO cycle.
- Nuclear astrophysics research is employed to explain, among other things, the abundance of the chemical elements in the Solar System.
- Nuclear medicine applies nuclear physics to medical diagnostics and cancer radiation treatment.

ANSWERS TO SELF-TEST OPPORTUNITIES

40.1

Particle	Mass (u)
d	2.014101778
${}^{12}_{6}\mathrm{C}$	12
p	1.007825032
${}^{13}_{6}\mathrm{C}$	13.00573861

$$\begin{aligned} Q = {} & (2.014101778\,\mathrm{u})c^2 + (12\,\mathrm{u})c^2 - \\ & ((1.007825032\,\mathrm{u})c^2 + (13.00573861\,\mathrm{u})c^2) = \\ & (0.000538128\,\mathrm{u})c^2 = 0.501263\,\mathrm{MeV}. \end{aligned}$$

Q is positive, so the reaction is exothermic.

40.2 In the empirical mass formula (equation 40.37), the nuclei with odd charge numbers have the same values for the volume term, surface term, and pairing term. The asymmetry term and the Coulomb term combine to yield the parabolic shape. The nuclei with even charge numbers form a similar parabola that is offset vertically relative to the other parabola by the pairing term.

40.3

$$dE = \frac{\hbar^2}{m}kdk = \frac{\hbar^2}{m}\frac{\sqrt{2mE}}{\hbar}dk = \hbar\sqrt{2E/m}dk \Rightarrow \frac{dE}{\hbar\sqrt{2E/m}} = dk$$

$$dN(E) = \frac{a^3k^2}{2\pi^2}\frac{dE}{\hbar\sqrt{2E/m}} = \frac{a^3 2mE/\hbar^2}{2\pi^2}\frac{dE}{\hbar^2\sqrt{2E/m}} = \frac{a^3 m^{3/2}}{2^{1/2}\pi^2\hbar^3}E^{1/2}dE.$$

PROBLEM-SOLVING GUIDELINES

1. Remember that the nucleus is the prototypical quantum system. The Pauli Exclusion Principle and the uncertainty relation provide essential tools for working out relationships of momenta, energies, and sizes.

2. When calculating binding energies, you should first consider using the Bethe-Weizsäcker formula.

3. To solve a problem involving nuclear decay, first make sure which decay process is involved. You can do this by comparing the initial and final nuclei involved in the decay. Then you need to make sure that the process obeys the conservation laws (lepton number, baryon number, momentum, energy, charge, etc.). Calculating the Q-value is a good idea, because it lets you find out whether a decay is possible.

MULTIPLE-CHOICE QUESTIONS

40.1 Radium-226 decays by emitting an alpha particle. What is the daughter nucleus?

a) Rd

b) Rn

c) Bi

d) Pb

40.2 Which of the following decay modes involves a transition between states of the same nucleus?

a) alpha decay

b) beta decay

c) gamma decay

d) none of the above

40.3 In neutron stars, which are roughly 90% neutrons and are held together almost entirely by nuclear forces, which of the following terms become(s) relatively dominant for the binding energy, compared to that energy in an ordinary nucleus?

a) the Coulomb term

b) the asymmetry term

c) the pairing term

d) all of the above

e) none of the above

40.4 When a target nucleus is bombarded by a beam of the appropriate particles, it is possible to produce

a) a less massive nucleus, but not a more massive one.

b) a more massive nucleus, but not a less massive one.

c) a nucleus with a smaller charge number, but not one with a larger charge number.

d) a nucleus with a larger charge number, but not one with a smaller charge number.

e) a nucleus with either a larger or smaller charge number.

40.5 The strong force

a) is only attractive.

b) does not act on electrons.

c) only acts over distances of a few femtometers.

d) All of the above are true.

e) None of the above are true.

40.6 Cobalt has a stable isotope, $^{59}_{27}\mathrm{Co}$, and 22 radioactive isotopes. The most stable radioactive isotope is $^{60}_{27}\mathrm{Co}$. What is the dominant decay mode of this isotope?

a) β^+

b) β^-

c) proton emission

d) neutron emission

40.7 The mass of an atom (atomic mass) is equal to

a) the sum of the masses of the protons.

b) the sum of the masses of protons and neutrons.

c) the sum of the masses of protons, neutrons, and electrons.

d) the sum of the masses of protons, neutrons, and electrons minus the atom's binding energy.

CONCEPTUAL QUESTIONS

40.8 What is more dangerous, a radioactive material with a short half-life or a long one?

40.9 Apart from fatigue, what is another reason the Federal Aviation Administration limits the number of hours that commercial jet pilots can fly each year?

40.10 Why are there magic numbers in the nuclear shell model?

40.11 The binding energy of ${}^{3}_{2}\mathrm{He}$ is lower than that of ${}^{3}_{1}\mathrm{H}$. Provide a plausible explanation, taking into consideration the Coulomb interaction between two protons in ${}^{3}_{2}\mathrm{He}$.

40.12 Which of the following quantities is conserved during a nuclear reaction, and how?

a) charge

b) the number of nucleons, A

c) mass-energy

d) linear momentum

e) angular momentum

40.13 Some food is treated with gamma radiation to kill bacteria. Why is it not a concern that people who eat such food are ingesting gamma radiation?

40.14 The subsection "Terrestrial Fusion" in Section 40.4 discussed how achieving controlled fusion would be the solution to the world's energy problems and how difficult it is to do this. Why is it so hard? The Sun does it all the time (see the subsection "Stellar Fusion"). Do we need to understand better how the Sun works to build a nuclear fusion reactor?

40.15 Why are atomic nuclei more or less limited in size and in neutron-proton ratio? That is, why are there no stable nuclei with 10 times as many neutrons as protons, and why are there no atomic nuclei the size of marbles?

40.16 A nuclear reaction of the kind ${}^{3}_{2}\mathrm{He} + {}^{12}_{6}\mathrm{C} \rightarrow \mathrm{X} + \alpha$ is called a *pick-up reaction*.

a) Why does it have this name, that is, what is picked up, what picked it up, and where did it come from?

b) What is the resulting nucleus, X?

c) What is the Q-value of this reaction?

d) Is this reaction endothermic or exothermic?

40.17 Isospin, or *isotopic spin,* is a quantum variable describing the relationship between protons and neutrons in nuclear and particle physics. (Strictly, it

describes the relationship between up and down quarks, as described in Chapter 39, but it was introduced before the advent of the quark model.) It has the same algebraic properties as quantum angular momentum: A proton and a neutron form an iso-doublet of states, with total isospin quantum number $\frac{1}{2}$; the proton is in the $t_z = +\frac{1}{2}$ state, and the neutron is in the $t_Z = -\frac{1}{2}$ state, where z refers to a direction in an abstract isospin space.

a) What isospin states can be constructed from two nucleons, that is, two particles with $t = \frac{1}{2}$? To what nuclei do these states correspond?

b) What isospin states can be constructed from three nucleons? To what nuclei do these correspond?

40.18 Before looking it up, predict intrinsic spin (i.e., actual angular momentum) of the deuteron, ${}^{2}_{1}\mathrm{H}$. Explain your reasoning. (*Hint:* Nucleons are fermions.)

40.19 ${}^{39}_{18}\mathrm{Ar}$ is an isotope with a half-life of 269 yr. If it decays through β^- decay, what isotope will result?

40.20 A neutron star is essentially a gigantic nucleus with mass 1.35 times that of the Sun, or a mass number of order 10^{57}. It consists of approximately 99% neutrons, the rest being protons and an equal number of electrons. Explain the physics that determines these features.

40.21 What is the nuclear configuration of the daughter nucleus associated with the alpha decay of $\mathrm{Hf}(A = 157, Z = 72)$?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 40.1

40.22 Estimate the volume of the uranium-235 nucleus.

40.23 Calculate the binding energies of the following nuclei.

a) ${}^{7}_{3}\mathrm{Li}$

b) ${}^{12}_{6}\mathrm{C}$

c) ${}^{52}_{26}\mathrm{Fe}$

d) ${}^{85}_{37}\mathrm{Rb}$

40.24 Give the numbers of protons, nucleons, neutrons, and electrons in an atom of ${}^{134}_{54}\mathrm{Xe}$.

•**40.25** Using the Fermi function, determine the relative change in density, $(dn(r)/dr)/n_0$, at the nuclear surface, $r = R(A)$.

•**40.26** Calculate the binding energy for the following two uranium isotopes (where $u = 1.66 \cdot 10^{-27}\mathrm{kg}$):

a) ${}^{238}_{92}\mathrm{U}$, which consists of 92 protons, 92 electrons, and 146 neutrons, with a total mass of 238.0507826 u

b) ${}^{235}_{92}\mathrm{U}$, which consists of 92 protons, 92 electrons, and 143 neutrons, with a total mass of 235.0439299 u

c) Which isotope is more stable (or less unstable)?

Section 40.2

40.27 Write equations for the β^- decay of the following isotopes:

a) $^{60}_{27}\text{Co}$

b) $^{3}_{1}\text{H}$

c) $^{14}_{6}\text{C}$

40.28 Write equations for the alpha decay of the following isotopes:

a) $^{212}_{86}\text{Rn}$

b) $^{241}_{95}\text{Am}$

40.29 How much energy is released in the beta decay of $^{14}_{6}\text{C}$?

40.30 A certain radioactive isotope decays to one-eighth of its original amount in 5.0 h

a) What is its half-life?

b) What is its mean lifetime?

40.31 A certain radioactive isotope decays to one-eighth of its original amount in 5.0 h. How long would it take for 10.0% of it to decay?

40.32 Determine the decay constant of radium-226, which has a half-life of 1600 yr.

40.33 A 1.00-g sample of radioactive thorium-228 decays via β^- decay, and 75 counts are recorded in one day by a detector that has 10.0% efficiency (that is, 10.0% of all events that occur are recorded by the detector). What is the lifetime of this isotope?

40.34 The half-life of a sample of 10^{11} atoms that decay by alpha particle emission is 10 min. How many alpha particles are emitted in the time interval from 100 min to 200 min?

•40.35 The specific activity of a radioactive material is the number of disintegrations per second per gram of radioactive atoms.

a) Given the half-life of $^{14}_{6}\text{C}$ of 5730 yr, calculate the specific activity of $^{14}_{6}\text{C}$. Express your result in disintegrations per second per gram, becquerel per gram, and curie per gram.

b) Calculate the initial activity of a 5.00-g piece of wood.

c) How many $^{14}_{6}\text{C}$ disintegrations have occurred in a 5.00-g piece of wood that was cut from a tree on January 1, 1700?

•**40.36** During a trip to an excavation site, an archeologist found a piece of charcoal. Analysis of the charcoal found the activity of ${}^{14}_{6}\mathrm{C}$ in the sample to be 0.42 Bq. If the mass of the charcoal is 7.2 g, estimate the approximate age of the site.

•**40.37** In 2008, crime scene investigators discover the bones of a person who appeared to have been the victim of a brutal attack that occurred a long time ago. They would like to know the year when the person was murdered. Using carbon dating, they determine that the rate of change of the ${}^{14}_{6}\mathrm{C}$ is 0.268 Bq per gram of carbon. The rate of change of ${}^{14}_{6}\mathrm{C}$ in the bones of a person who had just died is 0.270 Bq per gram of carbon. What year was the victim killed? The half-life of ${}^{14}_{6}\mathrm{C}$ is $5.73 \cdot 10^{3}$ yr.

•**40.38** Physicists blow stuff up better than anyone else. The measure for gauging the usefulness of blowing something up is the fraction of initial rest mass converted into energy in the process. Looking up the necessary data, calculate this fraction for the following processes:

a) chemical combustion of hydrogen: $2\mathrm{H}_2 + \mathrm{O}_2 \rightarrow 2\mathrm{H}_2\mathrm{O}$

b) nuclear fission: $n + {}^{235}_{92}\mathrm{U} \rightarrow {}^{89}_{36}\mathrm{Kr} + {}^{142}_{56}\mathrm{Ba} + 5n$

c) thermonuclear fusion: ${}^{6}_{3}\mathrm{Li} + {}^{2}_{1}\mathrm{H} \rightarrow {}^{7}_{4}\mathrm{Be} + n$

d) decay of free neutron: $n \rightarrow p + e^{-} + v_e$

e) decay of muon: $\mu^{-} \rightarrow e^{-} + v_\mu + v_e$

f) electron-positron annihilation: $e^{-} + e^{+} \rightarrow 2\gamma$

•• **40.39** An unstable nucleus A decays to an unstable nucleus B, which in turn decays to a stable nucleus. If at $t = 0$ s there are $N_{\mathrm{A}0}$ and $N_{\mathrm{B}0}$ nuclei present, derive an expression for $N_{\mathrm{B}0}$ the number of B nuclei present, as a function of time.

•• **40.40** In a simple case of *chain* radioactive decay, a *parent* radioactive nucleus, A, decays with a decay constant λ_1 into a *daughter* radioactive nucleus, B, which then decays with a decay constant λ_2 to a *stable* nucleus, C.

a) Write the equations describing the number of nuclei of each of the three types as a function of time, and derive expressions for the number of daughter nuclei, N_2, as a function of time and for the activity of the daughter nuclei, A_2, as a function of time.

b) Discuss the results in the case when $\lambda_2 > \lambda_1 (\lambda_2 \approx 10\ \lambda_1)$ and when $\lambda_2 >> \lambda_1 (\lambda_2 \approx 100\ \lambda_1)$.

Section 40.3

•**40.41** Show that for the case of nuclei with odd mass number, A, the Bethe-Weizsäcker formula can be written as a quadratic in Z—and thus, for any given A, the binding energies of the isotopes having that A take a quadratic form, $B = a + bZ + cZ^2$. Use your result to find the most strongly bound isotope (the most stable one) having $A = 117$.

•• **40.42** The *neutron drip line* is defined to be the point at which the neutron separation energy for any isotope of an element is negative. That is, the neutron is unbound. Using the Bethe-Weizsäcker formula, find the neutron drip line for the element Sn. Find this value using s_n and s_{2n}. Plot both s_n and $S_{2n}/2$ as a function of neutron number.

Section 40.4

40.43 A nuclear fission power plant produces about 1.50 GW of electrical power. Assume that the plant has an overall efficiency of 35.0% and that each fission event produces 200. MeV of energy. Calculate the mass of $^{235}_{92}\text{U}$ consumed each day.

40.44

a) What is the energy released in the fusion reaction $^{2}_{1}\text{H} + ^{2}_{1}\text{H} \rightarrow ^{4}_{2}\text{He} + Q$?

b) The Earth's oceans have a total mass of water of $1.50 \cdot 10^{16}$kg, and 0.0300% of this quantity is deuterium, $^{2}_{1}\text{H}$. If all the deuterium in the oceans were fused by controlled fusion into $^{4}_{2}\text{He}$, how many joules of energy would be released?

c) World power consumption is about $1.00 \cdot 10^{13}$W. If consumption stayed constant and all problems arising from ocean water consumption (including those of political, meteorological, and ecological nature) could be avoided, how many years would the energy calculated in part (b) last?

40.45 The Sun radiates energy at the rate of $3.85 \cdot 10^{26}$ W.

a) At what rate, in kilograms per second, is the Sun's mass converted into energy?

b) Why is this result different from the rate calculated in Example 40.6: $6.02 \cdot 10^{11}$ kg of protons being converted into helium each second?

c) Assuming that the current mass of the Sun is $1.99 \cdot 10^{30}$ kg and that it has radiated at the same rate for its entire lifetime of $4.50 \cdot 10^{9}$ yr, what percentage of the Sun's mass has been converted into energy during its entire lifetime?

40.46 Consider the following fusion reaction, through which stars produce progressively heavier elements: $^{3}_{2}\text{He} + ^{4}_{2}\text{ He} \rightarrow ^{7}_{4}\text{ Be} + \gamma$. The mass of $^{3}_{2}\text{He}$ is 3.016029 u, the mass of $^{4}_{2}\text{He}$, is 4.002603 u, and the mass of $^{7}_{4}\text{Be}$ is 7.0169298 u. The atomic mass unit is $1\text{ u} = 1.66 \cdot 10^{-27}$kg. Assuming that the Be atom is at rest after the reaction and neglecting any potential energy between the atoms and the kinetic energy of the He nuclei, calculate the minimum possible energy and maximum possible wavelength of the photon, γ that is emitted in this reaction.

•**40.47** Estimate the temperature that would be needed to initiate the fusion reaction $^{3}_{2}\text{He} + ^{3}_{2}\text{ He} \rightarrow ^{4}_{2}\text{ He} + p + p$.

•**40.48** Consider a hypothetical fission process in which a $^{120}_{52}\text{Te}$ nucleus splits into two identical $^{60}_{26}\text{Fe}$ nuclei without producing any other particles or radiation. The mass of $^{120}_{52}\text{Te}$ is 119.904040 u, and the mass of $^{60}_{26}\text{Fe}$ is 59.934078 u. At the moment when the two iron nuclei form, but before they start moving away due to Coulomb repulsion, how far apart are the two nuclei?

•**40.49** The *mass excess* of a nucleus is defined as the difference between the atomic mass (in atomic mass units, u), and the mass number of the nucleus, A. Using the mass-energy conversion $1\ \text{u} = 931.49\ \text{MeV}/c^2$, this mass excess is usually expressed in kilo-electron-volts (keV). The table below presents the mass excess for several nuclei (from the Berkeley National Lab *NuBase* database):

No.	Nucleus	Mass number, A	Mass excess, $\Delta m\left(\text{keV}/c^2\right)$	Atomic mass (u)
1	${}^{1}_{0}n$	1	8,071.3	1.00866491
2	${}^{252}_{98}\text{Cf}$	252	76,034	
3	${}^{256}_{100}\text{Fm}$	256	85,496	
4	${}^{140}_{56}\text{Ba}$	140	−83,271	
5	${}^{140}_{54}\text{Xe}$	140	−72,990	
6	${}^{112}_{46}\text{pd}$	112	−86,336	
7	${}^{109}_{42}\text{Mo}$	109	−67,250	

a) Calculate the atomic mass (in atomic mass units) for each of the nuclei in the table. For reference, the atomic mass of the neutron is given.

b) Using your results from part (a), determine the mass-energy difference between the initial and final states for the following possible fission reactions:

$$ {}^{252}_{98}\text{Cf} \rightarrow {}^{140}_{56}\text{Ba} + {}^{109}_{42}\text{Mo} + 3n \quad \text{Fm} \rightarrow {}^{140}_{54}\text{Xe} + {}^{112}_{46}\text{pd} + 4n $$

c) Will these reactions occur spontaneously?

Section 40.5

40.50 Neutron stars are sometimes approximated to be nothing more than large atomic nuclei (but with many more neutrons). Assuming that a neutron star is as dense as an atomic nucleus, estimate the number of nucleons in a 10.0-km-diameter star.

40.51 What is the average kinetic energy of protons at the center of a star, where the temperature is $1.00 \cdot 10^7$K? What is the average velocity of those protons?

•**40.52** Billions of years ago, the Solar System was created out of the remnants of a supernova explosion. Nuclear scientists believe that two isotopes of uranium, $^{235}_{92}\text{U}$ and $^{238}_{92}\text{U}$ were created in equal amounts at that time. However, today 99.28% of uranium is in the form of $^{238}_{92}\text{U}$ and only 0.72% is in the form of $^{235}_{92}\text{U}$ Assuming a simplified model in which all of the matter in the Solar System originated in a single exploding star, estimate the approximate time of this explosion.

Section 40.6

40.53 A drug containing $^{99}_{43}\mathrm{Tc}\left(t_{1/2} = 6.05\ \mathrm{h}\right)$ with an activity of 1.50 μCi is to be injected into a patient at 9.30 a.m. You are to prepare the drug 2.50 h before the injection (at 7:00 a.m.). What activity should the drug have at the preparation time (7:00 a.m.)?

40.54 A 42.58-MHz photon is needed to produce nuclear magnetic resonance in free protons in a magnetic field of 1.000 T. What is the wavelength of the photon, its energy, and the region of the spectrum in which it lies? Could it be harmful to the human body?

40.55 The radon isotope $^{222}_{86}\mathrm{Rn}$, which has a half-life of 3.825 days, is used for medical purposes such as radiotherapy. How long does it take until $^{222}_{86}\mathrm{Rn}$ decays to 10.00% of its initial quantity?

40.56 Radiation therapy is one of the techniques used for cancer treatment. Based on the approximate mass of a tumor, oncologists can calculate the radiation dose necessary to treat a patient. Suppose a patient has a 50.0-g tumor and needs to receive 0.180 J of energy to kill the cancer cells. What radiation absorbed dose should the patient receive?

Additional Exercises

40.57 The atom of sodium-22 $\left({}^{22}_{11}\mathrm{Na}\right)$ has a mass of 21.994435 u. How much work would be needed to take this nucleus completely apart into its constituent pieces (protons, neutrons, and electrons)?

40.58 A Geiger counter initially records 7210 counts/s from a sample of radioactive material. After 45 min, it records 4585 counts/s. Ignore any uncertainty in the counts and find the half-life of the material.

40.59 How close can a 5.00-MeV alpha particle get to a uranium-238 nucleus, assuming that the only interaction is Coulomb?

40.60 ${}^{239}_{94}\mathrm{Pu}$ decays with a half-life of 24,100 yr via emission of a 5.25-MeV alpha particle. If you have a 1.00 kg spherical sample of ${}^{239}_{94}\mathrm{Pu}$, find the initial activity in becquerels.

40.61 The activity of a sample of ${}^{210}_{83}\mathrm{Bi}$ (with a half-life of 5.01 days) is measured to be 1.000 μCi. What will the activity of this sample be after 1 yr?

40.62 Assuming that carbon makes up 14% of the mass of a human body, calculate the activity of a 75-kg person considering only the beta decays of carbon-14.

40.63 ${}^{8}_{3}\mathrm{Li}$ is an isotope that has a lifetime of less than a second. Its mass is 8.022485 u. Calculate its binding energy in MeV.

40.64 What is the total energy released in the decay $n \rightarrow p + e^{-} + v_e$?

40.65 A gallon of regular gasoline (density of 737 $\mathrm{kg/m^3}$) contains about 131 MJ of chemical energy. How much energy is contained in the rest mass of this gallon?

40.66 If 10^{30} atoms of a radioactive sample remain after 10 half-lives, how many atoms remain after 20 half-lives?

40.67 Calculate the binding energy per nucleon of

a) ${}^{4}_{2}\mathrm{He}(4.002603\ \mathrm{u})$.

b) ${}^{3}_{2}\mathrm{He}(3.016030\ \mathrm{u})$.

c) ${}^{3}_{1}\mathrm{H}(3.016050\ \mathrm{u})$.

d) ${}^{2}_{1}\mathrm{H}(2.014102\ \mathrm{u})$.

40.68 The mean lifetime for a radioactive nucleus is 4300 s. What is its half-life?

40.69 ${}^{214}_{82}\mathrm{Pb}$ has a half-life of 26.8 min. How many minutes must elapse for 90.0% of a given sample of ${}^{214}_{82}\mathrm{Pb}$ atoms to decay?

•• **40.70** The most common isotope of uranium, ${}^{238}_{92}\mathrm{U}$, produces radon, ${}^{222}_{86}\mathrm{Rn}$, through the following sequence of decays:

$$^{238}_{92}\mathrm{U} \rightarrow ^{234}_{90}\mathrm{Th} + \alpha,\ ^{234}_{90}\mathrm{Th} \rightarrow ^{234}_{91}\mathrm{Pa} + \beta^- + v_e,$$
$$^{234}_{91}\mathrm{Pa} \rightarrow ^{234}_{92}\mathrm{U} + \beta^- + v_e,\ ^{234}_{92}\mathrm{U} \rightarrow ^{230}_{90}\mathrm{Th} + \alpha,$$
$$^{230}_{90}\mathrm{Th} \rightarrow ^{226}_{88}\mathrm{Ra} + \alpha,\ ^{226}_{88}\mathrm{Ra} \rightarrow ^{222}_{86}\mathrm{Rn} + \alpha.$$

A sample of $^{238}_{92}\mathrm{U}$ will build up equilibrium concentrations of its daughter nuclei down to $^{226}_{88}\mathrm{Ra}$; the concentrations of each are such that each daughter is produced as fast as it decays. The $^{226}_{88}\mathrm{Ra}$ decays to $^{222}_{86}\mathrm{Rn}$, which escapes as a gas. (The alpha particles also escape, as helium; this is a source of much of the helium found on Earth.) Radon is a health hazard when it occurs in high concentrations in buildings built on soil or foundations containing uranium ores, as it can be inhaled.

a) Look up the necessary data, and calculate the rate at which 1.00 kg of an equilibrium mixture of $^{238}_{92}\mathrm{U}$ and its first five daughters produces $^{222}_{86}\mathrm{Rn}$ (mass per unit time).

b) What activity (in curies per unit time) of radon does this represent?

•40.71 After a tree has been chopped down and burned to ash, the carbon isotopes in the ash are found to have a $^{14}_{6}\mathrm{C}$ to $^{12}_{6}\mathrm{C}$ ratio of $1.300 \cdot 10^{-12}$. Experimental tests on the $^{14}_{6}\mathrm{C}$ atoms reveal that $^{14}_{6}\mathrm{C}$ is a beta emitter with a half-life of 5730 yr. At an archeological excavation, a skeleton is found next to some wood ash from a campfire. If 50.0 g of carbon from the ash emits electrons at a rate of 20.0 per hour, how long ago did the campfire burn?

•40.72 If your mass is 70.0 kg and you have a lifetime of 70.0 yr, how many proton decays will occur in your body during your life (assuming that your body is entirely composed of water)? Use a half-life of $1.00 \cdot 10^{30}$ yr.

•40.73 You have developed a grand unified theory that predicts the following things about the decay of protons: (1) protons never get any older, in the sense that their probability of decay per unit time never changes, and (2) half the protons in any given collection of protons will have decayed in $1.80 \cdot 10^{29}$ yr. You are given experimental facilities to test your theory: a tank containing $1.00 \cdot 10^{4}$ metric tons of water and sensors to record proton decays. You will be allowed access to this facility for 2 years. How many proton decays will occur in this period if your theory is correct?

•40.74 The precession frequency of the protons in a laboratory NMR spectrometer is 15.35850 MHz. The magnetic dipole moment of the proton is $1.410608 \cdot 10^{-26}$ J/T, while its spin angular momentum is $0.5272863 \cdot 10^{-34}$ J s. Calculate the magnitude of the magnetic field in which the protons are immersed.

•40.75 Two species of radioactive nuclei, A and B, each with an initial population N_0, start decaying. After a time of 100. s, it is observed that $N_\mathrm{A} = 100 N_\mathrm{B}$. If $\tau_\mathrm{A} = 2\tau_\mathrm{B}$, find the value of τ_B.

MULTI-VERSION EXERCISES

40.76 A 12.43-g fragment of charcoal is to be carbon dated. Measurements show that it has an activity of 105 decays/min. How many years ago did the tree from which the charcoal was produced die? (*Hint:* The half-life of ${}^{14}_{6}\mathrm{C}$ is 5730 yr, and the ${}^{14}_{6}\mathrm{C}/{}^{12}_{6}\mathrm{C}$ ratio in living organic matter is $1.20 \cdot 10^{12}$.)

40.77 A fragment of charcoal has been determined by carbon dating to be 4384 years old. Measurements show that it has an activity of 107 decays/min. What is the mass of the charcoal fragment? (*Hint:* The half-life of ${}^{14}_{6}\mathrm{C}$ is 5730 yr, and the ${}^{14}_{6}\mathrm{C}/{}^{12}_{6}\mathrm{C}$ ratio in living organic matter is $1.20 \cdot 10^{12}$)

40.78 A 13.83-g fragment of charcoal has been determined by carbon dating to be 4814 years old. How many decays per minute were measured in the carbon dating process? (*Hint:* The half-life of ${}^{14}_{6}\mathrm{C}$ is 5730 yr, and the ${}^{14}_{6}\mathrm{C}/{}^{12}_{6}\mathrm{C}$ ratio in living organic matter is $1.20 \cdot 10^{12}$.)

Example A.1 Mandelbrot Set

Notation:

The letters a, b, c, x, and y represent real numbers.

The letter n represents integer numbers.

The Greek letters α, β, and γ represent angles, which are measured in radians.

1. Algebra

1.1 Basics

Factors:

$$ax + bx + cx = (a + b + c)x \tag{A.1}$$

$$(a + b)^2 = a^2 + 2ab + b^2 \tag{A.2}$$

$$(a - b)^2 = a^2 - 2ab + b^2 \tag{A.3}$$

$$(a + b)(a - b) = a^2 - b^2 \tag{A.4}$$

Quadratic equation:
An equation of the form

$$ax^2 + bx + c = 0 \tag{A.5}$$

for given values of a, b, and c has the two solutions:

$$x = \frac{-b + \sqrt{b^2 - 4ac}}{2a}$$

and (A.6)

$$x = \frac{-b - \sqrt{b^2 - 4ac}}{2a}$$

These solutions of the quadratic equation are called *roots*. The roots are real numbers if $b^2 \geq 4ac$.

1.2 Exponents

If a is a number, a^n is the product of a with itself n times:

$$a^n = \underbrace{a \times a \times a \times \cdots \times a}_{n\,\text{factors}} \tag{A.7}$$

The number n is called the *exponent*. However, an exponent does not have to be a positive number or an integer. Any real number x can be used as an exponent.

$$a^{-x} = \frac{1}{a^x} \tag{A.8}$$

$$a^0 = 1 \tag{A.9}$$

$$a^1 = a \tag{A.10}$$

Roots:

$$a^{1/2} = \sqrt{a} \tag{A.11}$$

$$a^{1/n} = \sqrt[n]{a} \tag{A.12}$$

Multiplication and division:

$$a^x a^y = a^{x+y} \tag{A.13}$$

$$\frac{a^x}{a^y} = a^{x-y} \tag{A.14}$$

$$(a^x)^y = a^{xy} \tag{A.15}$$

1.3 Logarithms

The logarithm is the inverse function of the exponential function:

$$y = a^x \Leftrightarrow x = \log_a y \qquad \textbf{(A.16)}$$

The notation $\log_a y$ indicates the logarithm of y with respect to the base a. Since the exponential and logarithmic functions are inverses of each other, we can also write this identity:

$$x = \log_a (a^x) = a^{\log_a x} \qquad (\text{for any base } a) \qquad \textbf{(A.17)}$$

The two bases most commonly used are base 10, the common logarithm base, and base e, the natural logarithm base. The numerical value of e is

$$e = 2.718281828\ldots \qquad \textbf{(A.18)}$$

Base 10:

$$y = 10^x \Leftrightarrow x = \log_{10} y \qquad \textbf{(A.19)}$$

Base e:

$$y = e^x \Leftrightarrow x = \ln y \qquad \textbf{(A.20)}$$

This book follows the convention of using ln to indicate the logarithm with respect to the base e.

The rules for calculating with logarithms follow from the rules for exponents:

$$\log(ab) = \log a + \log b \tag{A.21}$$

$$\log \frac{a}{b} = \log a - \log b \tag{A.22}$$

$$\log(a^x) = x \log a \tag{A.23}$$

$$\log 1 = 0 \tag{A.24}$$

Since these rules are valid for any base, the subscript indicating the base has been omitted.

1.4 Linear Equations

The general form of a linear equation is

$$y = ax + b \tag{A.25}$$

where a and b are constants. The graph of y versus x is a straight line; a is the slope of this line, and b is the y-intercept. See Figure A.1.

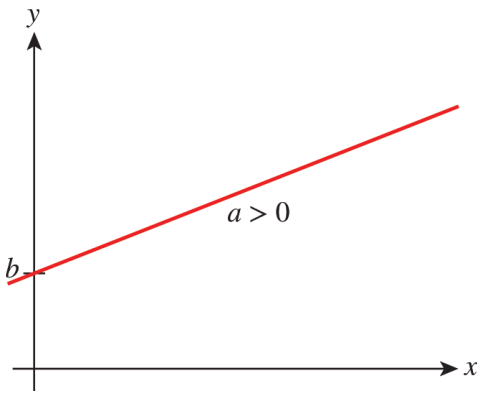

FIGURE A.1 Graphical representation of a linear equation.

The slope of the line can be calculated by inserting two different values, x_1 and x_2, into the linear equation and calculating the resulting values, y_1 and y_2:

$$a = \frac{y_2 - y_1}{x_2 - x_1} = \frac{\Delta y}{\Delta x} \tag{A.26}$$

If $a = 0$, then the line will be horizontal; if $a > 0$, then the line will rise as x increases, as shown in the example of Figure A.1; if $a < 0$, then the line will fall as x increases.

2. Geometry

2.1 Geometrical Shapes in Two Dimensions

Figure A.2 gives the area, A, and perimeter length (or circumference), C, of common two-dimensional geometrical shapes.

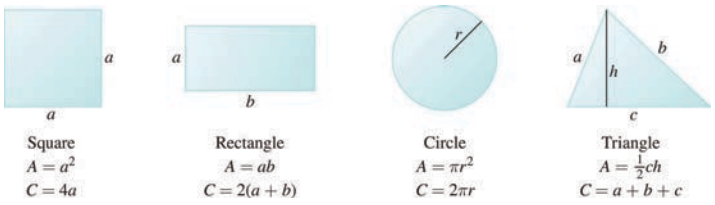

FIGURE A.2 Area, A, and perimeter length, C, for square, rectangle, circle, and triangle.

2.2 Geometrical Shapes in Three Dimensions

Figure A.3 gives the volume, V, and surface area, A, of common three-dimensional geometrical shapes.

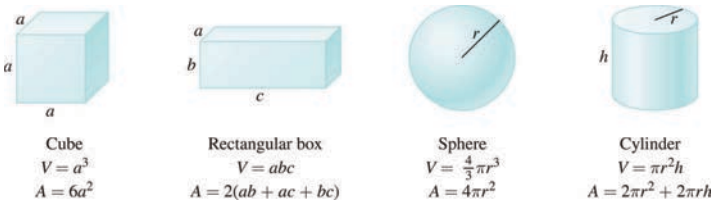

FIGURE A.3 Volume, V, and surface area, A, for cube, rectangular box, sphere, and cylinder.

3. Trigonometry

It is important to note that for the following all angles need to be measured in radians.

3.1 Right Triangles

A right triangle is a triangle for which one of the three angles is a right angle, that is, an angle of exactly $90^\circ (\pi/2 \text{ rad})$ (indicated by the small corner mark in Figure A.4). The hypotenuse is the side opposite the 90° angle. Conventionally, the letter c marks the hypotenuse.

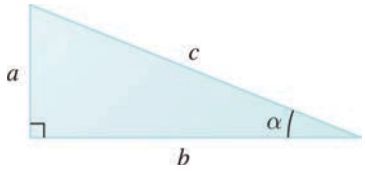

FIGURE A.4
Definition of the side lengths *a*, *b*, and *c* and the angles for the right triangle.

Pythagorean Theorem:

$$a^2 + b^2 = c^2 \tag{A.27}$$

Trigonometric functions (see Figure A.5):

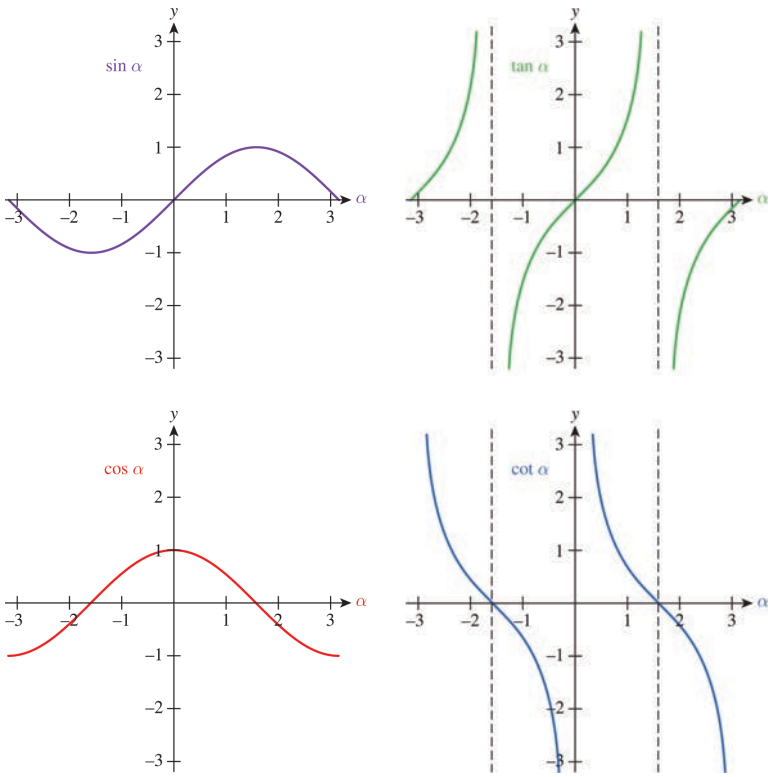

FIGURE A.5 The trigonometric functions sin, cos, tan, and cot.

$$\sin\alpha = \frac{a}{c} = \frac{\text{opposite side}}{\text{hypotenuse}} \tag{A.28}$$

$$\cos\alpha = \frac{b}{c} = \frac{\text{adjacent side}}{\text{hypotenuse}} \tag{A.29}$$

$$\tan\alpha = \frac{\sin\,\alpha}{\cos\,\alpha} = \frac{a}{b} \tag{A.30}$$

$$\cot\alpha = \frac{\cos\,\alpha}{\sin\,\alpha} = \frac{1}{\tan\,\alpha} = \frac{b}{a} \tag{A.31}$$

$$\csc\alpha = \frac{1}{\sin\alpha} = \frac{c}{a} \tag{A.32}$$

$$\sec\alpha = \frac{1}{\cos\alpha} = \frac{c}{b} \tag{A.33}$$

Inverse trigonometric functions (the notations $\sin^{-1}, \cos^{-1}$, etc., are used in this book):

$$\sin^{-1}\frac{a}{c} = \text{arc}\sin\frac{a}{c} = \alpha \tag{A.34}$$

$$\cos^{-1}\frac{b}{c} = \arccos\frac{b}{c} = \alpha \tag{A.35}$$

$$\tan^{-1}\frac{b}{c} = \arctan\frac{a}{b} = \alpha \tag{A.36}$$

$$\cot^{-1}\frac{b}{a} = \operatorname{arccot}\frac{b}{a} = \alpha \tag{A.37}$$

$$\csc^{-1}\frac{c}{a} = \operatorname{arccsc}\frac{c}{a} = \alpha \tag{A.38}$$

$$\sec^{-1}\frac{c}{b} = \operatorname{arcsec}\frac{c}{b} = \alpha \tag{A.39}$$

All trigonometric functions are periodic:

$$\sin(\alpha + 2\pi) = \sin\alpha \tag{A.40}$$

$$\cos(\alpha + 2\pi) = \cos\alpha \tag{A.41}$$

$$\tan(\alpha + \pi) = \tan\alpha \tag{A.42}$$

$$\cot(\alpha + \pi) = \cot\alpha \tag{A.43}$$

Other relations between trigonometric functions:

$$\sin^2\alpha + \cos^2\alpha = 1 \tag{A.44}$$

$$\sin\left(-\alpha\right) = -\sin\alpha \tag{A.45}$$

$$\cos\left(-\alpha\right) = \cos\alpha \tag{A.46}$$

$$\sin\left(\alpha \pm \pi/2\right) = \pm\cos\alpha \tag{A.47}$$

$$\sin\left(\alpha \pm \pi\right) = -\sin\alpha \tag{A.48}$$

$$\cos\left(\alpha \pm \pi/2\right) = \mp\sin\alpha \tag{A.49}$$

$$\cos\left(\alpha \pm \pi\right) = -\cos\alpha \tag{A.50}$$

Addition formulas:

$$\sin\left(\alpha \pm \beta\right) = \sin\alpha\cos\beta \pm \cos\alpha\sin\beta \tag{A.51}$$

$$\cos\left(\alpha \pm \beta\right) = \cos\alpha\cos\beta \mp \sin\alpha\sin\beta \tag{A.52}$$

Small-angle approximations:

$$\sin\alpha \approx \alpha - \tfrac{1}{6}\alpha^3 + \cdots \quad (\text{for } |\alpha| \ll 1) \tag{A.53}$$

$$\cos\alpha \approx 1 - \tfrac{1}{2}\alpha^2 + \cdots \quad (\text{for } |\alpha| \ll 1) \tag{A.54}$$

For small angles, that is, where $|\alpha| \ll 1$, it is often acceptable to use the small-angle approximations $\cos \alpha = 1$ and $\sin \alpha = \tan \alpha = \alpha$.

3.2 General Triangles

The three angles of any triangle add up to π rad (see Figure A.6):

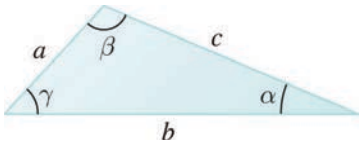

FIGURE A.6
Definition of the sides and angles for a general triangle.

$$\alpha + \beta + \gamma = \pi \tag{A.55}$$

Law of cosines:

$$c^2 = a^2 + b^2 - 2ab \cos \gamma \tag{A.56}$$

(This is a generalization of the Pythagorean Theorem for the case where the angle γ has a value that is not 90°, or $\pi/2$ rads.)

Law of sines:

$$\frac{\sin \alpha}{a} = \frac{\sin \beta}{b} = \frac{\sin \gamma}{c} \tag{A.57}$$

4. Calculus

4.1 Derivatives

Polynomials:

$$\frac{d}{dx}x^n = nx^{n-1} \tag{A.58}$$

Trigonometric functions:

$$\frac{d}{dx}\sin\left(ax\right) = a\,\cos\left(ax\right) \tag{A.59}$$

$$\frac{d}{dx}\cos\left(ax\right) = -a\,\sin\left(ax\right) \tag{A.60}$$

$$\frac{d}{dx}\tan\left(ax\right) = \frac{a}{\cos^2\left(ax\right)} \tag{A.61}$$

$$\frac{d}{dx}\cot\left(ax\right) = -\frac{a}{\sin^2\left(ax\right)} \tag{A.62}$$

Exponentials and logarithms:

$$\frac{d}{dx}e^{ax} = ae^{ax} \tag{A.63}$$

$$\frac{d}{dx}\ln(ax) = \frac{1}{x} \tag{A.64}$$

$$\frac{d}{dx}a^x = a^x \ln a \tag{A.65}$$

Product rule:

$$\frac{d}{dx}(f(x)g(x)) = \quad \frac{df(x)}{dx} \quad g(x) = f(x) \quad \frac{dg(x)}{dx} \tag{A.6}$$

Chain rule:

$$\frac{dy}{dx} = \frac{dy}{du}\frac{du}{dx} \tag{A.67}$$

4.2 Integrals

All indefinite integrals have an additive integration constant, c.
Polynomials:

$$x^n dx = \tfrac{1}{n+1} x^{n+1} + c \quad (\text{for } n \neq -1) \qquad (\text{A.72})$$

$$x^{-1} dx = \ln |x| + c \qquad (\text{A.72})$$

$$\frac{1}{a^2 + x^2} dx = \frac{1}{a} \tan^{-1} \frac{x}{a} + c \qquad (\text{A.72})$$

$$\frac{1}{\sqrt{a^2 + x^2}} dx = \ln \left| x + \sqrt{a^2 + x^2} \right| + c \qquad (\text{A.72})$$

$$\frac{1}{\sqrt{a^2 + x^2}} dx = \sin^{-1} \frac{x}{|a|} + c = \tan^{-1} \frac{x}{\sqrt{a^2 - x^2}} + c \qquad (\text{A.72})$$

$$\frac{1}{(a^2 + x^2)^{3/2}} dx = \frac{1}{a^2} \frac{x}{\sqrt{a^2 + x^2}} + c \qquad \textbf{(A.73)}$$

$$\frac{x}{(a^2 + x^2)^{3/2}} dx = -\frac{1}{\sqrt{a^2 + x^2}} + c \qquad \textbf{(A.74)}$$

Trigonometric functions:

$$\sin(ax)dx = -\frac{1}{a}\cos(ax) + c \tag{A.75}$$

$$\cos(ax)dx = \frac{1}{a}\sin(ax) + c \tag{A.76}$$

Exponentials:

$$e^{ax}dx = \frac{1}{a}e^{ax} + c \tag{A.77}$$

5. Complex Numbers

We are all familiar with real numbers, which can be sorted along a number line in order of increasing value, from $-\infty$ to $+\infty$. The real numbers are embedded in a much larger set of numbers, called the *complex numbers*. Complex numbers are defined in terms of their real part and their imaginary part. The space of complex numbers is a plane, for which the real parts form one axis, labeled (z) in Figure A.7. The imaginary parts form the other axis, labeled (z) in Figure A.7. (It is conventional to use the Old German script letters and to represent the real and imaginary parts of complex numbers.)

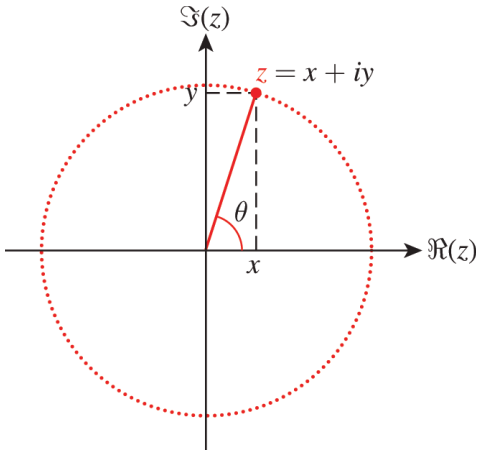

FIGURE A.7 The complex plane. The horizontal axis is formed by the real parts of complex numbers, and the vertical axis by the imaginary parts.

A complex number z is defined in terms of its real part, x, its imaginary part, y, and Euler's constant, i:

$$z = x + iy \tag{A.78}$$

Euler's constant is defined as follows:

$$i^2 = -1 \tag{A.79}$$

Both the real part, $x = \quad (z)$, and the imaginary part, $y = \quad (z)$, of a complex number are real numbers. Addition, subtraction, multiplication, and division of complex numbers are defined in analogy to those operations for real numbers, with $i^2 = -1$:

$$(a + ib) + (c + id) = (a + c) + i\,(b + d) \tag{A.80}$$

$$(a + ib) - (c + id) = (a - c) + i\,(b - d) \tag{A.81}$$

$$(a + ib)\,(c + id) = (ac - bd) + i\,(ad + bc) \tag{A.82}$$

$$\frac{a + ib}{c + id} = \frac{(ac + bd) + i\,(bc - ad)}{c^2 + d^2} \tag{A.83}$$

For each complex number z there exists a complex conjugate z^*, which has the same real part but an imaginary part with the opposite sign:

$$z = x + iy \Leftrightarrow z^* = x - iy \tag{A.84}$$

We can express the real and imaginary parts of a complex number in terms of the number and its complex conjugate:

$$(z) = \tfrac{1}{2}(z + z^*) \tag{A.85}$$

$$(z) = \tfrac{1}{2}i\,(z - z^*) \tag{A.86}$$

Just like a two-dimensional vector, a complex number $z = x + iy$ has the magnitude $|z|$ as well as an angle θ with respect to the horizontal axis of the complex plane, as indicated in Figure A.7:

$$|z|^2 = zz^* \tag{A.87}$$

$$\theta = \tan^{-1}\frac{(z)}{(z)} = \tan^{-1}\frac{i\,(z - z^*)}{(z + z^*)} \tag{A.88}$$

We can thus write the complex number $z = x + iy$ in terms of the magnitude and the "phase angle":

$$z = |z|(\cos\theta + i\sin\theta) \tag{A.89}$$

An interesting and most useful identity is *Euler's formula*:

$$e^{i\theta} = \cos\theta + i\sin\theta \tag{A.90}$$

With the aid of this identity, we can write, for any complex number, *z,*

$$z = |z|e^{i\theta} \tag{A.91}$$

We can thus take a complex number *z* to any power *n*:

$$z^n = |z|^n e^{in\theta} \tag{A.92}$$

EXAMPLE A.1 Mandelbrot Set

We can put our knowledge of complex numbers and their multiplication to good use by examining the *Mandelbrot set*, defined as the set of all points c in the complex plane for which the series of iterations

$$z_{n+1} = z_n^2 + c, \quad \text{with } z_0 = c,$$

does not escape to infinity, that is, for which $|z_n|$ remains finite for all iterations.

This iteration prescription is seemingly simple. For example, we can see that any number for which $|c| > 2$ cannot be part of the Mandelbrot set. However, if we plot the points of the Mandelbrot set in the complex plane, a strangely beautiful object emerges. In Figure A.8, the black points are part of the Mandelbrot set, and the remaining points are color-coded by how fast z_n escapes to infinity.

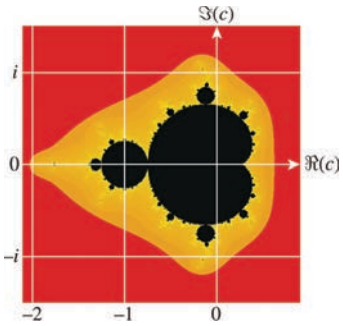

FIGURE A.8
Mandelbrot set in the complex plane.

Appendix B

Element Properties

Z	Charge number (number of protons in the nucleus = number of electrons)
ρ	Mass density at temperature $0\,^{\circ}\mathrm{C}$ ($= 273.15\ \mathrm{K}$) and pressure of 1 atmosphere
m	Standard atomic weight (average mass of an atom, abundance-weighted average of the isotope masses)
T_{melting}	Temperature of melting point (transition point between solid and liquid phase) at 1 atm pressure
T_{boiling}	Temperature of boiling point (transition point between liquid and gas phase) at 1 atm pressure
L_{m}	Heat of melting/fusion
L_{v}	Heat of vaporization
E_1	Ionization energy (energy to remove least bound electron)

Z	Sym	Name	Electron Configuration	$\rho\,(\mathrm{g/cm^3})$	$m\,(\mathrm{g/mol})$	$T_{\mathrm{melting}}\,(\mathrm{K})$	T_{boilin}

Answers to Selected Questions and Problems

Chapter 1: Overview

Multiple Choice

1.1 c.

1.3 d.

1.5 a.

1.7 b.

1.9 c.

1.11 d.

1.13 c.

1.15 e.

Exercises

1.35

(a) Three.
(b) Four.
(c) One.
(d) Six.
(e) One.
(f) Two.
(g) Three.

1.37 6.34.

1.39 1.10^{-7} cm.

1.41 $1.94822 \cdot 10^{6}$ inches.

1.43 $1 \cdot 10^{6}$ mm.

1.45 1 milliPascal.

1.47 $2420\ \text{cm}^2$.

1.49

(a) $356,000\ \text{km} = 221,000$ miles.
(b) $407,000\ \text{km} = 253,000$ miles.

1.51 $x_{\text{total}} = 5.50 \cdot 10^{-1}\ \text{m}; x_{\text{avg}} = 9.17 \cdot 10^{-2}\ \text{m}$.

1.53 120 millifurlongs/microfortnight.

1.55 76 times the surface area of Earth.

1.57 39 km.

1.59 1.56 barrels is equivalent to $1.51 \cdot 10^{4}$ cubic inches.

1.61

(a) $V_{\text{S}} = 1.41 \times 10^{27}\ \text{m}^3$.
(b) $V_{\text{E}} = 1.08 \times 10^{21}\ \text{m}^3$.
(c) $\rho_s = 1.41 \times 10^{3}\ \text{kg/m}^3$.
(d) $\rho_E = 5.52 \times 10^{3}\ \text{kg/m}^3$.

1.63 1.0×10^{2} cm.

1.65 $x = 21.8\ \text{m}$ and $y = 33.5\ \text{m}$.

1.67 $\overrightarrow{A} = 65.0\widehat{x} + 37.5\hat{y},\ \widehat{B} = -56.7\widehat{x} + 19.5\hat{y},\ \overrightarrow{C} = -15.4\widehat{x} - 19.7\hat{y},\ \overrightarrow{D} = 80.2\widehat{x} - 40.9\hat{y}$.

1.69 3.27 km.

1.71 $\overrightarrow{D} = -15\sqrt{2}\widehat{x} + \left(32 + 15\sqrt{2}\right)\hat{y} - 3\hat{z},\ \left|\widehat{D}\right| = 57$ paces.

1.73 $f = 16^\circ,\ \alpha = 41^\circ$. and $\theta = 140^\circ$.

1.75 $2 \cdot 10^8$

1.77 63.7 m at -57.1° or 303° (equivalent angles).

1.79

(a) $1.70 \cdot 10^3$ at 296°.
(b) $1.61 \cdot 10^3$ at 292°.

1.81 $1.00 \cdot 10^3$ N.

1.83

(a) 125 miles.
(b) 240° or -120° (from positive x-axis or E).
(c) 167 miles.

1.85 3.79 Km at 21.9° W of N.

1.87 $5.62 \cdot 10^7$ km.

1.89 9630. inches.

1.91 $1.4 \cdot 10^{11}$ m, 18° from the Sun.

Multi-Version Exercises

1.93 $\overrightarrow{A} = 2.5\widehat{x} + 1.5\hat{y},\ \widehat{B} = 5.5\widehat{x} - 1.5\hat{y},\ \overrightarrow{C} = -6\widehat{x} - 3\hat{y}$.

1.95 $(2, -3)$.

1.97 $\overrightarrow{D} = 2\widehat{x} - 3\hat{y}$.

1.99 $\left|\overrightarrow{A}\right| = 58.3\text{ m},\ \left|\overrightarrow{B}\right| = 58.3\text{ m}$.

1.103 $\overrightarrow{A} = 63.3$ at 68.7°; $\overrightarrow{B} = 175$ at -59.0°.

1.107 d

1.113

(a) 130.
(b) 11.4.
(c) $1.48 \cdot 10^3$.

where $E = \dfrac{\hbar^2\kappa^2}{2m}$.

(b) $\eta = \dfrac{\hbar}{\sqrt{2m(U_0 - E)}}$.

(c) 467 pm.

37.41 720 nm.

37.43 101 eV; 85.5 kN/m.

37.45

(a) $A = \dfrac{1}{\sqrt[4]{\pi}\sqrt{b}}$.

(b) 0.157.

37.47

(a) $A = \sqrt{\frac{2}{L}}$.

(b) 0.402

37.49 0.250.

37.51 $\Psi\left(\vec{r}, t\right) = Ae^{i\left(\vec{p}\cdot\vec{r}\right)/\hbar}e^{-ip^2t/2m\hbar}; A^2$.

37.53 $|\Psi(x,t)|^2 = \frac{1}{a}\sin^2\left(\frac{\pi x}{a}\right)\left[1 + 4\cos^2\left(\frac{\pi x}{a}\right) + 4\cos\left(\frac{\pi x}{a}\right)\cos\left(\frac{3\hbar\pi^2 t}{2ma^2}\right)\right]$.

37.55

(a) $\Delta t \geq 3.22 \cdot 10^{-22}$s.

(b) $\Delta t \geq 1.75 \cdot 10^{-25}$s.

37.57 $8.21 \cdot 10^{-4}$eV.

37.59

(a) $\psi = \left(\sqrt{\frac{2}{L}}\right)^3 \sin\frac{\pi x}{L}\sin\frac{\pi y}{L}\sin\frac{\pi z}{L}; 0 < x, y, z < L$.

(b) 14.

37.61 0.54 μm.

37.63

(a) 1.2 eV.

(b) 0.19 eV.

37.65 2.9 MeV.

37.67 $1.10 \cdot 10^3$nm.

37.69 38 eV.

37.71 (2,2) and (1,4).

Multi-Version Exercises

37.72 $4.95 \cdot 10^{-15}$.

37.76 $7.93 \cdot 10^{-21}$J.

Chapter 38: Atomic Physics

Multiple Choice

38.1 d.

38.3 d.

38.5 b.

38.7 b.

Exercises

38.19 91.2 nm.

38.21 2279 nm, 7458 nm;

38.23 -0.378 eV.

38.25

(a) $1.0968 \cdot 10^{7}\text{m}^{-1}$.

(b) $5.4869 \cdot 10^{6}\text{m}^{-1}$.

38.27 initial:$n = 6$; final: $n = 3$.

38.29 $r = \dfrac{\hbar^2}{GMm^2} n^2$; $2.523 \cdot 10^{74}$.

38.31 $4.716 \cdot 10^{-34}$J s and 0 J s.

38.33 65.9°.

38.35

(a) $\dfrac{e^{-1}}{4\pi a_0}$.

(b) The probability density includes an r^2 factor.

38.37 0.03432.

38.39 $a_0/2 = 0.0265$ nm.

38.41

(a) $\dfrac{0.200\, E_0}{\kappa^2}$.

(b) 27.2 meV.

38.43

(a) $r_n = \dfrac{a_0 n^2}{Z}$.

(b) $v_n = \dfrac{Z}{n}\sqrt{\dfrac{ke^2}{\mu a_0}}$.

(c) $E' = \dfrac{-Z^2}{n^2} E_0$.

38.45 656 nm; a laser with a wavelength 5.4 times bigger is needed.

38.47

(a) $2.86 \cdot 10^{-19}$J.

(b) $1.05 \cdot 10^{14}$ atoms.

38.49 91.16 nm.

38.51 $0.05442\%, \quad 4.555 \cdot 10^{-31}\text{kg}$.

38.53 $Z = 68.5$, so either erbium (68) or thulium (69).

38.55 $-2530\,\text{eV}, \quad -632\,\text{eV}, \quad -281\,\text{eV}$.

38.57 $-54.4\,\text{eV}, \quad -13.6\,\text{eV}, \quad -6.05\,\text{eV}$.

38.59 $-6.72\,\text{meV}$.

38.61 Yes. $v = 4.07\,\text{m/s}$.

38.63 0.3233.

Multi-Version Exercises

38.64 $1.078 \cdot 10^{6}\text{m/s}$.

38.67 $5.917 \cdot 10^{11}$.

Chapter 39: Elementary Particle Physics

Multiple Choice

39.1 a.

39.3 c.

39.5 d.

39.7 c.

Exercises

39.23 49.9 fm.

39.25 13.2 b/sr.

39.27 $r_{\min}/\lambda$ is proportional to $1/\sqrt{K}$.

39.29 120. particles per second.

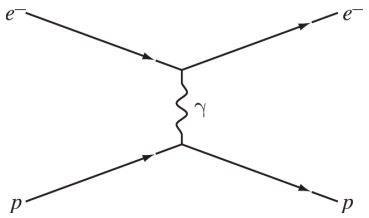
39.31

$$F^2(\Delta p) = \left| \frac{4\pi\rho\hbar^3}{Ze(\Delta p)^3}\left[\sin\left(\frac{\Delta pR}{\hbar}\right) - \left(\frac{\Delta pR}{\hbar}\right)\cos\left(\frac{\Delta pR}{\hbar}\right)\right]\right|^2$$

$$\frac{d\sigma}{d\Omega} = \frac{\left(2kZ_\mathrm{p}Z_\mathrm{t}e^2m_\mathrm{p}\right)^2}{(\Delta p)^4}\left|\frac{3\hbar^3}{\Delta p^3R^3}\left[\sin\left(\frac{\Delta pR}{\hbar}\right) - \left(\frac{\Delta pR}{\hbar}\right)\cos\left(\frac{\Delta pR}{\hbar}\right)\right]\right|^2$$

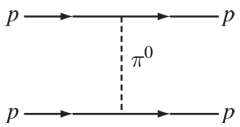
39.33 $2.2 \cdot 10^8$m/s.

39.35

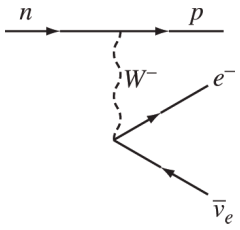


39.37

(a)

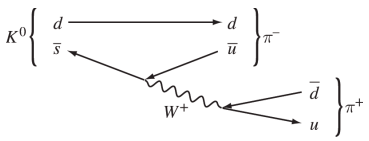


(b)



39.39 154.

39.41



39.43 $2.1 \cdot 10^{12}$ K;

39.45 (a) 9.10^5keV.

39.47

(a) $H = \left(\frac{1}{a}\frac{da}{dt}\right)_{\text{rec}}$.

(b) 420 Mpc.

39.49 (a) 0.036 eV compared to 8.3 keV, over 200,000 times smaller.

39.51 54. meV.

39.53 10^{-18}m.

39.55 9.10^{-4} m^2 .

39.57 (a) 316 ke^2/mv^2. (b) 48.8 fm.

39.59 13/32.

39.61

$F^2(\Delta p) = \left(\frac{\sin\left[(\Delta p\hbar)a/\hbar\right]}{(\Delta p)a/\hbar}\right)^2$;

$\frac{d\sigma}{d\Omega} = \left(\frac{2Ze^2m_e}{4\pi\epsilon_0}\right)\frac{1}{(\Delta p)^4}\left(\frac{\sin\left[(\Delta p\hbar)a/\hbar\right]}{(\Delta p)a/\hbar}\right)^2$; Yes.

Multi-Version Exercises

39.62 $9.7 \cdot 10^{-12}$.

39.65 3900 counts/s.

Chapter 40: Nuclear Physics

Multiple Choice

40.1 b.

40.3 b.

40.5 d.

40.7 d.

Exercises

40.23

(a) 39 MeV.

(b) 92 MeV.

(c) 493 MeV.

(d) 739 MeV.

40.25 $-0.46\ \text{fm}^{-1}$.

40.27

(a) ${}^{60}_{27}\text{Co} \rightarrow {}^{60}_{28}\text{ Ni} + \ {}^{0}_{-1}\text{e}^{-} + \overline{\nu}_e$.

(b) ${}^{3}_{1}\text{H} \rightarrow {}^{3}_{2}\text{ He} + \ {}^{0}_{-1}\text{e}^{-} + \overline{\nu}_e$.

(c) ${}^{14}_{6}\text{C} \rightarrow {}^{14}_{7}\text{ N} + \ {}^{0}_{-1}\text{e}^{-} + \overline{\nu}_e$.

40.29 0.352 MeV.

40.31 0.253 h.

40.33 $9.64 \cdot 10^{15}\text{yr}$.

40.35

(a) $1.65 \cdot 10^{11}\text{disint/(g s)} = 1.65 \cdot 10^{11}\ \text{Bq/g} = 4.46\ \text{Ci/g}$.

(b) 1.15 Bq.

(c) $1.12 \cdot 10^{10}$ disint.

40.37 1946 or 1947.

40.39 $N_{\text{B}}(t) = \dfrac{\lambda_{\text{A}}}{\lambda_{\text{B}} - \lambda_{\text{A}}} N_{\text{A}_0 e^{-\lambda_{\text{A}} t}} + \left(N_{\text{B0}} - \dfrac{\lambda_{\text{A}}}{\lambda_{\text{B}} - \lambda_{\text{A}}} N_{\text{A0}} \right) e^{-\lambda_{\text{B}} t}$.

40.41 ${}^{117}_{50}\text{Sn}$.

40.43 4.51 kg.

40.45

(a) $4.28 \cdot 10^{9}\text{kg/s}$.

(b) 0.0305%.

40.47 13.8 GK.

40.49

(a)

No.	Nuclide	Mass number, A	Mass excess, $\Delta m\left(\mathrm{keV/c^2}\right)$	Atomic mass (u)
1	${}^{1}_{0}n$	1	8,071.3	1.0087
2	${}^{252}_{98}\mathrm{Cf}$	252	76,034	252.08
3	${}^{256}_{100}\mathrm{Fm}$	256	85,496	256.09
4	${}^{140}_{56}\mathrm{Ba}$	140	−83,271	139.91
5	${}^{140}_{54}\mathrm{Xe}$	140	−72,990	139.92
6	${}^{112}_{46}\mathrm{Pd}$	112	−86,336	111.91
7	${}^{109}_{42}\mathrm{Mo}$	109	−67,250	108.93

(b) $\Delta E_{\mathrm{Cf}} = 202.34\,\mathrm{MeV}$ and $\Delta E_{\mathrm{Fm}} = 212.54\,\mathrm{MeV}$.

(c) Yes.

40.51 $2.07 \cdot 10^{-16}\mathrm{J}; 4.98 \cdot 10^{5}\mathrm{m/s}$.

40.53 2.00 μCi.

40.55 12.71 days.

40.57 174.147 MeV.

40.59 53.0 fm.

40.61 $1.13 \cdot 10^{-22}\mu\mathrm{Ci}$.

40.63 41.279 MeV.

40.65 $2.51 \cdot 10^{17}\mathrm{J}$.

40.67

(a) 7.074 MeV.

(b) 2.572 MeV.

(c) 2.827 MeV.

(d) 1.112 MeV.

40.69 89.0 min.

40.71 $6.38 \cdot 10^{4}$ yr.

40.73 $2.57 \cdot 10^{4}$ decays

40.75 10.9 s.

Multi-Version Exercises

40.76 4100 yr.

    corrective lenses, 1027–1028
    defined, 1014
    image formation and, 1014, 1014f
    overview of, 1014
    sign convention for, 1015
    system of two or more lenses, 1021–1026
Diving, angular momentum, 317–318, 317f
Domain, 874

Doppler effect, 512–518
    ambulance siren, 513–514
    Cherenkov radiation, 518, 518f
    Concorde and angle of Mach cone, 518, 518f
    defined, 512, 512f
    for electromagnetic radiation, 1091
    Mach cone and, 517–518
    trains and, 514–515, 514f
    in two-and three-dimensional space, 514–515
    ultrasound measurement of blood flow and, 516–517

weather reports and, 517
Dot product, 24
Double-slit diffraction, 1066
Double-slit experiment, 1132–1134
Double-slit interference, 1051–1053
Down quark, 661
Drag coefficient, 115
Drag force, 114
Drift velocity
in copper wire, 778–779
defined, 777
Driven AC circuits, 922–925
alternating driving emf, 922
with capacitors, 923–924
with inductor, 924–925
with resistor, 922–925
Driving emf, 922
DSL filter, 929
DVD, as diffraction gratings, 1068–1070
Dynamic equilibrium, 104
Dynamic range, 504
Dynamics, 94
Dynamo effect, 830
Dysnomia, 362

E

Earth, 358f
asteroid impact, 371, 371f
atmosphere and Maxwell speed distribution and, 611–612
average pressure at sea level, 403
as black body, 575
center of mass for Earth-Moon system, 233–234
centripetal acceleration due to Earth's rotation, 270
eccentricity of orbit around Sun, 374
electromagnetic force and, 96
escape speed and, 369–371
gases of, 598, 598t
geothermal power resource, 577–580
global warming and thermal energy transfer, 575
gravitational potential, 372
gravitation inside, 366–368
gravitation near surface of, 364–365
as infinite reservoir of charge, 664
internal thermal energy, 578
James Webb Space Telescope, distance of, 385–387
length scale for, 10
magnet field of, 829–830, 829f, 830f, 836
mass of, 11
measuring size of Earth's molten core, 482
orbit and relative size of, 362f
physical data for, 363t
revolution and rotation of, 267
rise in sea level, due to thermal expansion of, 545–546
rotational kinetic energy of, 300
Schwarzschild radius of, 1107
seismic waves and core of, 481–482

surface area of, 5
surface temperature of, 532–533, 532f, 544–546, 577
Van Allen radiation belts, 829–830, 829f
Earthquakes
seismic waves, 481–482, 481f
tsunami and, 480–481, 480f
Echolocation, 503, 503f
Eddington, Arthur, 1106
Eddy currents, 891–892
Efficiency
of Carnot engine, 629–630
diesel engine, 638
energy crisis and, 639–640, 639f
of engine, 626
of gasoline-powered internal combustion engine, 636–638
of hybrid car, 638
maximum efficiency of electric power plant, 631–632
of Otto cycle, 635–636
of refrigerator, 627
Efflux, speed of, 421
Egg drop, impulse and, 199–200
Eigenfunctions, 1181
Eigenvalue, 1181, 1214
Einstein, Albert, 1123, 1143
biographical perspective on, 1082
postulates and reference frames, 1082–1083
Einstein's Cross, 1080, 1080f
Elastic collisions, 200
average force on golf ball, 205
coefficient of restitution, 217–218
collision with walls, 205–206
curling, 208–209

defined, 202
equal masses, 203–204
in one dimension, 202–205
one object initially at rest, 204
in two/three dimensions, 205–209
Elasticity
modulus of, 399
of solids, 399
Elastic limit, 399
Electric charge, 659–662
conservation law of, 660, 804
Earth as infinite reservoir of charge, 664
electrostatic charging, 663–666
induced charge, 664
insulators and conductors, 662–663
law of, 659–660
negative charge, 659
net charge, 662
positive charge, 659
quantized, 660–662
symbol/equivalent/expression for, 8t
Electric circuits
ammeter and, 811–813
branches, 804
capacitors in, 752–755
defined, 748
direct current circuits, 803–820
energy and power in, 792–795
general observations on circuit networks, 810–811
junctions, 804
multiloop circuits, 808–811
overview of, 748

of pacemaker, 816–818
power source for, 748
RC circuits, 813–820
resistors in parallel, 788–791
resistors in series, 785–788
single-loop circuits, 806–808
symbols for, 748f
voltmeter and, 811
Wheatstone bridge, 809–810
Electric current. *See* Current
Electric dipole
defined, 688
in electric field, 695–698
electric field due to, 688
water and, 689
Electric dipole moment, 688
of water, 689
Electric energy density, 756
Electric field, 682–708
compared to magnetic field, 828
constant, and electric potential energy, 717–718
crossed fields, 838, 838f
cylindrical symmetry, 703
defined, 683
determining from electric potential, 726
dipole in, 695–698
due to dipole, 688–689
due to general charge distribution, 690–692
due to point charges, 686–687
electric flux of, 698–699
electromagnetic induction and, 886
equipotential surfaces and lines, 723–725

field lines, 683–686
finding from electric potential, 733–735
finite line of charge, 691–692
force due to, 693–698
Gauss's Law, 699–702, 951t, 952
graphical extraction of, 733–734

human physiology and, 697–698
induced, 898–899
induced magnetic field and, 948–949
Maxwell-Ampere Law, 949
nonpolar dielectrics in, 764
of parallel plate capacitor, 746–747, 747f
planar symmetry, 703–704
polar dielectrics in, 763–764
ring of charge, 691–692
rotational symmetry, 703
sharks and detecting, 682
sharp points and lighting rods, 707–708
shielding, 701–702
spherical symmetry and, 704–705
from sunlight, 961
superposition principle for total, 683
time projection chamber, 693–694
translational symmetry, 703
units of magnitude for, 718–719
water and, 689
Electric field lines, 683–686
defined, 683
general observations, 686
point charge, 684–685, 685f

two point charges of opposite sign, 685, 685f
two point charges with same sign, 685–686, 685f
Electric flux, 698–699
defined, 698
Gauss's Law and, 700
through a cube, 699
Electric generators, 897–898
as emf device, 783
Electricity, history of unification of fundamental forces, 658–659, 659f, 1248
Electric motor, 897–898
Electric permittivity
of dielectric, 760
of free space, 666–667, 858–859
Electric potential, 715–737
batteries, 720–721
battery-powered cars, 721
beam of oxygen ions, 722–723
charged disk, 731–732
continuous charge distribution, 730
defined, 718–719
determining from electric field, 726
electric potential energy, 716–718
energy gain of proton, 719
equipotential surfaces and lines, 723–725
finding electric field from, 733–735
finite line of charge, 731
of fixed and moving positive charges, 727–728
Kirchhoff's Loop Rule and, 805–806
minimum potential, 729–730
of parallel plate capacitor, 746–747, 747f
of point charge, 726–727

superposition of, 729
symbol/equivalent/expression for, 8t
of system of point charges, 728–729
Van de Graaff generator, 721–722, 721f, 722f
Electric potential energy
defined, 716
of four point charges, 737
of system of point charges, 735–737
of uniformly charged sphere, 736
Electric power, high-voltage direct current power transmission, 793–794
Electric power plant, maximum efficiency of, 631–632
Electric resistance, symbol/equivalent/expression for, 8t
Electrocardiogram, 816, 816f
Electrocorticography, 697–698
Electrolytic capacitors, 764–765
Electromagnetic force
defined, 96, 950
history of unification of fundamental forces, 658–659, 659f
unification energy scale and, 1249
Electromagnetic induction, 883–907
computer hard drives, 906–907
eddy currents, 891–892
energy of magnetic field and, 905–906
Faraday's experiments, 884–885
Faraday's Law of Induction, 885–890
in flat loop inside magnetic field, 887–888
Gauss's Law for Magnetic Fields, 886
generators and motors, 897–898
induced electric field, 898–899
inductance of solenoid, 899
Lenz's Law, 890–891

magnetic flux and, 886
metal detector, 892–893
mutual induction, 900–902
potential difference induced by changing magnetic field, 888
potential difference induced by moving loop, 889–890
potential difference induced on wire moving in magnetic field, 893–894
power from rotating rod, 895–896
pulled conducting rod, 894–895
pulse induction, 892
regenerative braking, 898
RL circuits and, 902–905
satellite tethered to Space Shuttle, 894
self-inductance, 900–901
Electromagnetic oscillations and currents
damped oscillations in RLC circuits, 920–922
defined, 916
driven AC circuits, 922–925
energy and power in AC circuits, 931–937
LC circuits, 916–920
overview of, 916–918
rectifiers, 939–940
series RLC circuit, 925–931
transformers, 937–939
Electromagnetic radiation, 133
Electromagnetic rail accelerator, 859–861
Electromagnetic spectrum, 955, 956f
Electromagnetic waves, 947–972
characteristics of, 469, 951
communication frequency bands, 957–958
defined, 951
displacement current, 949–950

Faraday's law of induction, 951t, 952–954
Gauss's law for electric fields, 951t, 952
Gauss's law for magnetic fields, 951t, 952
induced magnetic fields, 948–949
Maxwell-Ampere Law, 949, 951t, 954
Maxwell's equations and, 951–955, 972
momentum of, 961–962
plane wave, 951–952
polarization, 966–971
Poynting vector and energy transport, 959–960
radiation pressure, 961–963
root-mean-square electric and magnetic fields from sunlight, 961
solar panels to charge electric car, 960
solar stationary satellites, 963–964
spectrum of, 955–956, 955f, 956f
speed of light, 954–955
traveling, 958
Electromotive force, 783
Electrons, 1118
in atomic box, 1160
charge of, 660
de Broglie wavelength of, 1131
defined, 659
double-slit experiment for, 1132–1134
forces between, 676
mass of, 11
motion of, in solenoid, 869–870
moving over charged plate, 694–695
reduced mass of, 1199
spin, 872, 1216

    second law: conservation of angular momentum, 377–378
    third law: periods, 374–375
Ketterle, Wolfgang, 565, 1143
Kilocalorie, 555
Kilograms
    abbreviation for, 7t
    defined, 7, 10
Kilowatt-hour, 148
Kinematics, 35
Kinetic energy
    average, of air molecules, 602
    average, of gas molecules, 600–602
    catapult, 169–171
    characteristics of, 135

collisions and, 202, 206, 212
collision with parked car, 216–217
conservation of mechanical energy and, 168–172
decay of radon, 214–215
defined, 135
energy gain of proton, 719
examples of objects with various energies, 135, 135f
falling vase, 136–137
lost in totally inelastic collision, 212
Maxwell kinetic energy distribution, 612–613
momentum and, 196
object in rolling motion, 301–302
of particle, 1132
relativistic, 1099
of rotation, 293–294
rotational kinetic energy of Earth, 300
shot put, 141–143
trapeze artist's swing, 171–172
wave functions and, 1155, 1176–1178
work and, 136–137
work-kinetic energy theorem, 138–139
Kinetic friction
coefficient of, 111, 112t
defined, 111
overview of, 111–112
snowboarder with friction, 113–114
Kinetic theory of ideal gas
average kinetic energy of air molecules, 602
defined, 599–600
equipartition theorem, 599–602
Maxwell speed distribution, 610–613
Kirchhoff's Junction Rule, 804

general observations on circuit networks, 810–811
multiloop circuits and, 808–811
Kirchhoff's Loop Rule, 805–806
general observations on circuit networks, 810–811
multiloop circuits and, 808–811
RL circuits and, 903
Knipping, Paul, 1072
Kroto, Harold, 397
Krypton
as gas in Earth's atmosphere, 598t
molar specific heat of, 603t
speed of sound in, 502t
K-T (Cretaceous-Tertiary) extinction, 371
Kuiper Belt, 362, 362f, 376
Kyoto Protocol, 577

L

Ladder, person standing on, as static equilibrium problem, 341–342
Laminar flow
    defined, 414
    streamlines as, 414, 414f
Laplace, Marquis Pierre-Simon, 219
Laplace's Demon, 219
Large Hadron Collider, 536, 1231, 1231f, 1260
Laser cooling, 535–536, 536f
Laser fusion, 1300, 1300f
Laser pointer, 962–963
Laser-powered sailing, 964–965
Laser printers, 673
Lasers
    applications for, 1221
    as coherent light, 1049, 1050f
    helium-neon gas laser, 1221
    National Ignition Facility (NIF), 758, 758f
    number of photons in pulsed ruby laser, 1223
    origin of word, 1220
    overview of, 1195, 1220–1221
    photons from laser pointer, 1127
    research with, 1223–1224
    stimulated emission, 1221–1223
Laser tweezers, 1038–1039
LASIK surgery, 1028–1029
Latent heat of fusion, 564, 565t
Latent heat of vaporization, 564, 565t
Lattice QCD, 1256–1257
Law of Malus, 967
Lawrence, Ernest, 1240

Lawrence Livermore National Laboratory, 1224
LC circuits
    analysis of, 918–920
    characteristics of, 920
    defined, 916
    overview of, 916–918
LCD screen, 970–971
Lead, 396
    heat lost by, 562–563
    linear expansion coefficient, 537t
    magnetic susceptibility, 873t
    resistivity and temperature coefficient of, 780t
    specific heat of, 561t
    speed of sound in, 502t

    thermal conductivity of, 567t
    work function of, 1125t
Lederman, Leon, 1240

NANOGrav (North American Nanohertz Observatory for Gravitational Waves), 1108–1109
Nanotechnology, 397
NASA, 20*g* centrifuge, 262, 262f
NASCAR racing, 282–283
    length contraction of NASCAR race car, 1088
National Ignition Facility (NIF), 134, 758, 758f, 1224, 1224f, 1300
National Institute of Standards and Technology (NIST)
    research by, 10
    role of, 9
National Synchrotron Light Source, 1073
Near point, 1020–1021, 1020f, 1027
Negative charge, 659
Neon
    as gas in Earth's atmosphere, 598t
    helium-neon gas laser, 1221
    molar specific heat of, 603t
Neptune, 362
    eccentricity of orbit, 374
    orbit and relative size of, 362f
    physical data for, 363t
Nesjavellir Geothermal Power Station, 579, 579f
Net charge, 662
Net force
    defined, 99
    Newton's first law and, 100–101
    normal force and, 99, 99f
    static equilibrium and, 332
Net quark number, 1241
Net torque
    defined, 306

static equilibrium and, 332
Neutral equilibrium, 345
Neutralinos, 1251
Neutrino, 1241, 1242
Neutrino oscillations, 1242
Neutrons, 1118, 1244
charged particles of, 661, 662f
discovery of, 1239
isotopes and, 1267–1268
mass-energy equivalent for, 1272
mass for, 1272
spin, 872
tunneling, 1169
Neutron stars, 318
Newton, 8t, 97
Newton, Isaac, 94, 95, 97, 100, 373
Newton's first law
defined, 100
dynamic equilibrium, 101
kinetic friction, 112
as law of inertia, 101
overview of, 100–101
of rotation, 307
static equilibrium, 101
tug-of-war competition and, 103
two books on table, 106

Newton's law of gravity, 359–364
Coulomb's Law and, 675–676
general relativity and, 1105–1106
gravitation inside Earth, 367–368

influence of celestial objects, 363–364
superposition of gravitational forces, 360–361
universal gravitational constant, 359
Newton's rings, 1056–1057
Newton's second law
center of mass, 236
collision of two vehicles, 110–111
conical pendulum and, 271
defined, 100
equipartition theorem and, 601
momentum and, 196
overview of, 101–102
for rotation, 306–307
simple harmonic motion and, 434
snowboarding, 107–108, 113
two blocks connected by rope, 109, 117
work-kinetic energy theorem and, 139
Newton's third law
airplane lift and, 418
center of mass, 236
collision of two vehicles, 110–111, 201, 210, 211
curveball in baseball and, 418
defined, 100
equipartition theorem and, 601
overview of, 102
recoil, 236
tug-of-war competition, 103
two books on table, 106
Niagara Falls, 158, 158f
power produced by, 160–161
Nichrome, 780, 782
Nickel, thermal conductivity of, 567t

Nighttime illumination, 132, 132f
Night-vision devices, 1126–1127, 1126f
Nitrogen
    as gas in Earth's atmosphere, 598t
    Maxwell speed distribution for, 610–611, 611f
    molar specific heat of, 603t
Noble gas, 1217
Nodes, of standing waves, 487
Nonconservative force, 161–164
    air resistance as, 164
    damping force as, 164
    defined, 162
    friction force as, 163–164, 178
    work-energy theorem and, 178–183
Nonlinear dynamics, 460
Non-ohmic resistors, 784
Nonpolar dielectrics, 764
Nonviscous fluid, 414
Normal force
    collisions with walls, 205–206
    defined, 95, 99, 99f
North magnetic pole, 828
    magnetic declination and, 830, 830f
Novoselov, Konstantin, 397
n-type semiconductor, 663
Nuclear astrophysics, 1300–1302
Nuclear decay, 1276–1288
    alpha decay, 1278–1280
    beta decay, 1280–1281
    carbon dating, 1283–1285
    exponential decay law, 1276–1278
    gamma decay, 1281–1282

other decays, 1282–1283
radiation exposure, 1286–1288
Roentgenium decay, 1279–1280
units of radioactivity, 1285–1286
Nuclear fission, 134, 1102–1103, 1294–1297
breeding, 1295
chain reaction, 1295
critical mass and, 1295
defined, 1293
deformation parameter, 1294
energy yield, 1296
nuclear power, 1295–1296
nuclear weapons, 1295–1296
overview of, 1294–1295
thorium fission cycle, 1297
Nuclear force
strong, 96
weak, 96
Nuclear fusion, 1297–1300
CNO cycle, 1298
defined, 1293
as energy source, 1299–1300
hydrogen bomb, 1299
laser fusion, 1300, 1300f
overview of, 134
proton-proton chain, 1297
stellar fusion, 1297–1298
Sun and, 1297–1298, 1299
Nuclear lifetimes, 1271–1272
Nuclear magnetic resonance (NMR), 1302–1303, 1303f
Nuclear medicine, 1302–1303, 1302–1303f
Nuclear physics, 185, 1267–1303

carbon dating, 1283–1285
isotopes, 1267–1268
models for, 1288–1293
nuclear and atomic mass, 1272–1274
nuclear astrophysics, 1300–1302
nuclear decay, 1276–1288
nuclear density, 1269–1270
nuclear fission, 1294–1297
nuclear fusion, 1297–1300
nuclear interactions, 1268–1269
nuclear lifetimes, 1271–1272
nuclear medicine, 1302–1303
nuclear radius, 1269–1270
nuclear reactions and Q-values, 1274–1276
nuclear surface, 1270–1271
separation energy, 1275–1276
Nuclear power, 1295–1296
worldwide power production by source, 150f
Nuclear reaction, 1274–1275
Nuclear weapons, 1295–1296
Nucleons, 1267, 1269
Nucleosynthesis, 1260–1261
Nucleus
empirical mass formula, 1289
Fermi gas model, 1290–1291
liquid-drop model of, 1288–1290
Shell model, 1291–1293

O

Objective lens, 1032
Occam's razor, 1231
Oersted, Hans, 854, 884
Ohm, 8t, 779
Ohm, Georg Simon, 779
Ohmic resistors, 784
Ohmmeter, 811
Ohm's Law
    defined, 779
    overview of, 784–785
    potential drop, 784–785
    resistance of human body and battery safety, 785
    resistors in parallel and, 788–789
    resistors in series and, 786
Omega/Swan Nebula (M17), 564, 564f
Omnidirectional dielectric mirror, 983
One-dimensional motion. *See* Straight-line motion
Optical fibers, 1000–1002
Optical instruments. *See also* Lenses
    laser tweezers, 1038–1039
Optical lattice clock, 9, 10f
Optic axis, 984
Optics. *See* Lenses
Orbital angular momentum number, 1212
Orbital magnetic moment, 871–872
Order, of the fringe, 1052
Oscillations
    chaotic motion, 460
    harmonic (See Harmonic oscillations)
    pendulum motion, 441–444

phase space, 459
point attractor, 459
Otto cycle, 634–636
compression ratio, 635
efficiency of, 635–636
overview of, 634–635, 634f
steps in, 634
Overdamping, 450
Oxygen, 396
beam of oxygen ions, 722–723
as gas in Earth's atmosphere, 598t
magnetic susceptibility, 873t
molar specific heat of, 603t

P

Pacemaker, 816–818
Parabolic mirrors, 993–994
Parabolic troughs, 995, 995f
Parallel-axis theorem, 300–301
Parallel connection
    capacitors in, 752
    resistors in, 788–791
Parallel plate capacitor, 746–747, 747f, 748–750
    area of, 750
    with dielectric, 760–761
Paramagnetism, 873
Partial pressure, 598
Particle in rigid box, 1159
Particle physics, 215–216. *See also* Elementary particle physics
Particles
    de Broglie wavelength of, 1132
    distinguishable, 1181–1182
    double-slit experiment for, 1132–1134
    energy of, in infinite potential well, 1159–1160
    kinetic energy of, 1132
Partition function, 1139
Pascal, 8t, 402
Pascal's Principle, 407–408
Paschen series for doubly ionized lithium, 1202–1203
Path-dependent process, 557
Pauli, Wolfgang, 1239
Pauli exclusion principle, 1138, 1216, 1218
Pendulum motion, 441–442
    chaotic motion and, 460
    energy of, 446–447

frequency, 442
overview, 441–442
period, 442
physical pendulum, 443–444
restricted, 442–443
Penzias, Arno, 546, 1258
Perihelion, 374
Period
pendulum motion, 442
in simple harmonic motion, 437–438
Periodic motion
defined, 433
simple harmonic motion, 433–441
Periodic table of chemical elements, 1217–1218, 1231, 1267
Period of rotation, 265
Permanent magnets, 828–831
Perpendicular encoding, 907
Phase changes, 563–567
Phase space, 459
Phase transitions
defined, 564
latent heat and, 563–567
warming ice to water and water to steam, 565–566
work done vaporizing water, 566–567
Phasor, 923
Phillips, William D., 536
Philosophiae Naturalis Principia Mathematica (Newton), 366
Photinos, 1251
Photoelectric effect, 1082, 1117
overview of, 1123–1125
photomultiplier tubes, 1126, 1126f
photosensor, 1123–1124

wave-particle duality light, 1126
work function, 1124–1125
Photomultiplier tubes, 1126, 1126f
Photons, 979, 1117
as bosons, 1138
defined, 1123, 1243
gamma decay and, 1281
from laser pointer, 1127
lasers and, 1221–1222
mass of, 11
momentum of, 1125–1126
photon decay, 1249
in pulsed ruby laser, 1223
wave-particle duality of light and, 1126
x-ray production and, 1220
Photosensor, 1123–1124
Photovoltaic cells, 134, 1117
to charge electric car, 960
Physical optics, 1046
Physical pendulum, 443–444
Piano, tuning, 488–489
Pions, 1239, 1252, 1253t
decay of positive, 1257
pion exchange potential theory, 1268–1269
Planar converging lens, 1017f
Planar diverging lens, 1017f
Planar symmetry, electric field and, 703–704
Planck, Max, 1120, 1249
Planck's constant, 321, 1120
Planck's radiation law, 1120, 1122
Planck units, 1249–1250
Plane mirror

full-length, 985–986
image formed by, 983–986
law of reflection and, 983
optic axis, 984
Plane-polarized wave, 966
Planetary nebula, pressure of, 594–595
Planets
Kepler's laws of planetary motion, 373–378
orbits and relative sizes of, 362f
physical data for, 363t
Plane waves, 480, 480f
electromagnetic waves, 951–952
Huygens construction for, 1047, 1047f
Plasma, 398
defined, 536, 564
in high-temperature research, 536
temperature of quark-gluon plasma, 612–613
Pleiades star cluster, 529, 529f
Pluto, 362
eccentricity of orbit, 374
Plutonium, 1272
Poincaré, Henry, 625
Poincaré recurrence time, 625
Point attractor, 459
Point charge
electric field due to, 686–687
electric field lines, 685, 685f
electric potential of, 726–727
equipotential surfaces and lines, 723–725
Point location of an object, 35
Poiseuille, 422
Poiseuille, Jean Louis Marie, 423

Polar coordinates
defined, 263–264
locating point with Cartesian and polar coordinates, 264
relationship to Cartesian coordinates, 263–264
Polar dielectrics, 763–764
Polarization
applications of, 970–971
Blu-ray discs and, 1070
electromagnetic waves and, 966–971
Law of Malus, 967
multiple polarization, 969–970
with polarizer, 966
by reflection, 1004–1005
three polarizers and, 969–970
Polarizer, 966–967
Pollux, 363–364
Polyatomic gases, 603
specific heat at, 605–606
Position graphs, 36
Position vector
angle between, 24
characteristics of, 35
defined, 35
symbol for, 35
Positive charge, 659
Positron, 1187
Potential drop, 784–785
across resistor in circuit, 790–791
Potential energy, 159–185
block pushed of table by spring, 179–181
bungee jumper, 175–176
catapult, 169–171

conservation of mechanical energy, 168–172
conservative forces and, 161–165
defined, 159
electric, 716–718
force and, 165–168
gravitational, 159–160, 164
human cannonball, 173–175
hydroelectric dams, 158, 160–161
Lennard-Jones potential, 166–168
for magnetic dipole moment, 844
nonconservative forces and, 161–164, 178–183
object hanging from spring, 176–178
power produced by Niagara Falls, 160–161
roller coasters and, 183–185

sledding down hill, 181–183
spring force, 165, 173–178
trapeze artist's swing, 171–172
weightlifting, 159–160
work and, 164–165
work-energy theorem and, 178
Potential energy curves
equilibrium points, 184
turning points, 185
Potential well, 185
finite, 1162–1170
infinite, 1156–1162
Powell, Cecil, 1239
Power, 148–152
for accelerating a car, 149
in AC circuits, 931–933

average, 148
average consumption of U.S. per person, 148–149
average mass, power and fuel efficiency of cars sold in U.S., 149–150
for constant force, 152
defined, 148
dissipated in RLC circuit, 934–935
in electric circuits, 792–795
high-voltage direct current power transmission, 793–794
produced by Niagara Falls, 160–161
riding bicycle, 152
sources of, and consumption rates, 148–149, 148f
symbol/equivalent/expression for, 8t
units for, 148
of wave, 483–484
wind power, 150–151
worldwide power production by source, 150f
Power factor, 932
Power lines, 794–795
Power stroke, 634, 634f

fire hose, 238
rocket motion, 239–244
Rectifier, 939–940
Recursion relation, 240
Red-shifted, 1091
Red-shift parameter, 1091
Reduced mass, 1199
Reductionism, 396
elementary particle physics and, 1230–1232
Reflecting telescope, 1035–1036
Reflection
diffuse, 982

law of, 983
plane mirrors and, 983–986
polarization by, 1004–1005
of sound waves, 503, 503f
specular, 982
total internal reflection, 999–1000
waves, 478–479
Refracting telescope, 1034–1035
angular magnification of, 1034–1035
magnification of, 1035
Refraction
apparent depth and, 997–998
chromatic dispersion, 1003–1004
defined, 996
displacement of light rays in transparent material, 998–999
Fermat's Principle, 997
human eye and, 1026–1027
index of, 995–996, 996t
mirages, 1002–1003
Snell's Law, 996–997
Refrigerators
coefficient of performance, 627
defined, 626
efficiency and, 639–640, 639f
freezing water in, 640–641
overview of, 626–627
Second Law of Thermodynamics and, 641–642
Regenerative brakes, 638–639
Relative magnetic permeability, 873
Relative motion, 82–87
airplane in crosswind, 83–85, 84f
driving through rain, 85

Galilean transformation, 83
moving deer, 86–87
moving walkway, 82, 82f
relative velocity, 82–85
Relative velocity, 82–85
Relativistic Doppler effect, 1091
Relativistic frequency shift, 1091–1092
Relativistic Heavy Ion Collider (RHIC), 425, 536, 613f, 1104, 1260
Relativistic velocity addition, 1095
Relativistic velocity transformation, 1095–1098
Relativity
beta and gamma, 1083
black holes and, 1106–1109
Einstein's Cross, 1080, 1080f
Einstein's postulates and reference frames, 1082–1083
Equivalence Principle, 1105
general theory of, 1081, 1105–1109
Global Positioning System (GPS) and, 1109
gravitational waves, 1107–1109
length contraction, 1087–1088
light cone, 1084
Lorentz transformation, 1092–1094
momentum and energy, 1098–1104
relativistic frequency shift, 1091–1092
relativistic velocity transformation, 1095–1098
search for aether and, 1081–1082
space-time intervals, 1085
special theory of, 1081
time dilation, 1085–1087
twin paradox, 1089–1091
velocity addition relationship, 1095–1096
Research

at high-temperature frontier, 536
at low-temperature frontier, 535–536
Resistance
brain probe and, 787–788
of copper wire, 781
defined, 779
of human body, 784–785
internal resistance of battery, 786–787
microscopic basis of conduction of solids, 783
overview of, 779–781
size convention for wires, 781, 781t
superconductors and temperature, 782
temperature and, 782
temperature dependence of light bulb's resistance, 792–793
Wheatstone bridge, 809–810
Resistivity
defined, 779
overview of, 779–781
temperature and, 782
temperature coefficient of, 780t, 782
of various metal conductors, 780t
Resistors
color codes for, 781–782, 782f
driven AC circuits, 922–923
electromotive force, 783
with nonconstant cross section, 787
ohmic and non-ohmic, 784
Ohm's Law and, 784
in parallel connection, 788–791
potential drop, 784–785, 791–792
RLC circuit, 920–922
in series connection, 785–788

in series RLC circuit, 925–928
symbol for, 784
Resolution, of telescope or camera, 1063–1064
Resolving power, of diffraction gratings, 1068
Resonance
circuit in, 927
forced harmonic motion and, 457–458
Resonance frequency, 487
Resonance shape, 458
Resonant angular frequency, 927
Resonant angular speed, 458
Rest mass, 1099
Restoring force, 145
Restricted pendulum, 442–443
Resultant vector, 21
Reversible processes
entropy and, 644
thermodynamic processes as, 624–625
Reynolds number, 424
Richter, Burton, 1240
Right-handed Cartesian coordinate system, 69
Right-hand rule 1
magnetic field and, 855, 855f
magnetic force and, 831, 831f, 841, 841f
Right-hand rule 2, magnetic force, 842, 842f
Right-hand rule 3, magnetic field, 856, 856f
Ring Nebula, 594f
RLC circuit
AM radio transmission and, 957
with capacitor, 923–924
defined, 920
frequency filters, 929–930

impedance, 926
with inductor, 924–925
overview of, 920–922
power dissipated in, 934–935
power factor, 932
quality factor, 935
with resistor, 922–923
resonance, 927
resonant angular frequency, 927
series of, 925–931
RL circuit, 902–905
Rochester, George, 1239
Rock concert, relative sound levels at, 504–505
Rocket motion, 239–244
rocket launch to Mars, 241
thrust, 242
thruster firing, 242–244
Roentgenium decay, 1279–1280
Rohrer, Heinrich, 1169
Roller coasters
linear speed at top of vertical loop, 272–273
potential energy and, 183–185
Rolling motion
ball rolling through loop, 304–305
race down incline, 303–304
sphere rolling down inclined plane, 302–303
without slipping, 301–305
Röntgen, 1286
Röntgen, Wilhelm, 1072, 1219
Roof insulation, 567, 568f

Root-mean-square (rms) current, 932
Root-mean-square speed, 600
Ropes and pulleys, 102–105
    Atwood machine, 109–110
    force multiplier, 105
    overview, 102–103
    still rings, 104
    tension, 102
    tug-of-war competition, 103
    two blocks connected by rope, 108–109, 117
    work and, 140–141
Rotation, 292–322
    about an axis through the center of mass, 295–296
    angular momentum, 314–319, 321
    Atwood machine, 309–310, 313–314
    axis of, 294
    driving screw, 312
    of Earth, 267
    falling roll of toilet paper, 307–308
    kinetic energy of, 293–294
    moment-of-inertia calculations, 294–301
    Newton's first law for, 307
    Newton's second law for, 306–307
    parallel-axis theorem, 300–301
    precession, 320–321
    rolling motion without slipping, 301–305
    rotational kinetic energy of Earth, 300
    tightening bold, 312
    torque and, 306
    work done by torque, 311–314
    yo-yo, 308–309
Rotational inertia, 294

Rotational motion, in static equilibrium, 332
Rotational symmetry, electric field and, 703
Rubber, thermal conductivity of, 567t
Rubbia, Carlo, 1244
Rutherford, Ernest, 1198, 1235, 1239
Rutherford scattering, 1235–1237
Rydberg, Johannes, 1197
Rydberg constant, 1197, 1201
Rydberg formula, 1197

work done by, 140
Weinberg, Steven, 1244
Weizsäcker, Carl Friedrich von, 1289
Weller, Ronny, 140
Wess, Julius, 1250
Wheatstone bridge, 809–810
Wheels, moment of inertia for, 296–297
Whirlpool Galaxy, 1011f
Wieman, Carl, 565, 1143
Wien, Wilhelm, 1119
Wien displacement law, 1119, 1121–1122
Wilkinson, Laura, 317f
Wilkinson Microwave Anisotropy Probe (WMAP) satellite, 546
Willis Tower, view from, 15–16
Wilson, Robert, 546, 1258
WIMP, 1251
Wind farms, 133, 133f, 151, 395, 395f
Wind instruments, half-open and open pipes, 519–522, 520f
Wind power, 150–151
annual average wind speed in U.S., 151f

worldwide power production by source, 150f
Wire
bead on a wire, 672
magnetic field due to current-carrying wire loop, 862–864
magnetic field from long straight, 855–856
magnetic field from two parallel, 856–857
magnetic field inside long, straight wire, 865
potential difference induced on wire moving in magnetic field, 893–894
size conventions for, 781, 781t
stretched, 401–402
Witten, Edward, 1251
WMAP (Wilkinson Microwave Anisotropy Probe) mission, 385, 1123
Wobbly bridge, 458
Wood, thermal conductivity of, 567t
Woofer, 931
Work
conservative force and, 163–164
constant force and, 137–143
defined, 137
done by Carnot engine, 629–630, 631
done by torque, 311–314
done in lifting and lowering an object, 139–140
by gravitational force, 139
harmonic oscillation, 444–447
heat and, 556–557
by ideal gas at constant temperature, 595–596
by ideal gas in adiabatic process, 609–610
kinetic energy and, 136–137
lifting with pulleys, 140–141
magnetic force and, 831

one-dimensional case, 138
potential energy and, 164–165
power and, 148–152
scalar product, 138
spring force, 146, 173–178
variable force and, 143–144
weightlifting, 140
work-kinetic energy theorem, 138–139
Work-energy theorem
nonconservative forces and, 178–183
potential energy and, 178
Work function, 1124–1125
Work-kinetic energy theorem
constant torque, 311–312
defined, 138
friction force and, 163
gravitational force and, 139
Newton’s second law and, 139
World line, 1084

X

X-rays
chest x-ray and radiation exposure, 1287–1288
Compton scattering, 1127–1131
defined, 956
diffraction of, 1072–1073
overview of, 1219–1220
production of, 1220–1221

Y

Young, John, 359f
Young, Thomas, 1051
Young's double-slit experiment, 1051–1053
Young's modulus, 400, 400t
    speed of sound and, 500–501
Yo-yo, 308–309
Yukawa, Hideki, 1239, 1268

Z

Z boson, 1244
Zeroth Law of Thermodynamics, 530
Zinos, 1251
Zoom lens, 1022–1023
Zumino, Bruno, 1250
