$$\Rightarrow v(0) = -\omega_\gamma Be^{-\omega_\gamma 0} + C\left[1 - (\omega_\gamma \cdot 0)\right]e^{-\omega_\gamma 0} = -\omega_\gamma B + C$$

According to the problem statement, $v_0 = 0$, which yields $C = \omega_\gamma B$, and $x_0 = +5.00\ \text{cm}$, which determines B. We have already calculated $\omega_\gamma = 1.00\ \text{s}^{-1}$. Thus, we have

$$\begin{aligned} x(t) &= (5.00\,\text{cm})(1+\omega_\gamma t)e^{-\omega_\gamma t} \\ &= (5.00\,\text{cm})\left(1+\left(1.00\,\text{s}^{-1}\right)t\right)e^{-(1.00/\text{s})t}. \end{aligned}$$

We now calculate the position of the mass after 1.75 s:

$$x(1.75\,\text{s}) = (5.00\,\text{cm})(1+1.75)e^{-1.75} = 2.39\,\text{cm}.$$

Page 452

Figure 14.23 shows a plot of the displacement of this critically damped oscillator as a function of time. It also includes the curve from Figure 14.22 for the overdamped oscillator, which has the same mass and spring constant but a larger damping constant, $b = 3.0\,\text{kg/s}$. Note that the critically damped oscillator approaches zero displacement more quickly than the overdamped oscillator does.

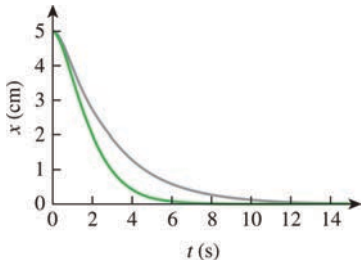

FIGURE 14.23 The displacement of a critically damped oscillator versus time. The gray line reproduces the curve for the overdamped oscillator from Figure 14.22.

To compare underdamped, overdamped, and critically damped motion, Figure 14.24 graphs position against angular speed times time for each type of motion. In all three cases, the oscillator started from rest at time $t = 0$. The green line represents the underdamped

case; you can see that oscillation continues. The red line reflects large damping above the critical value, and the blue line reflects critical damping.

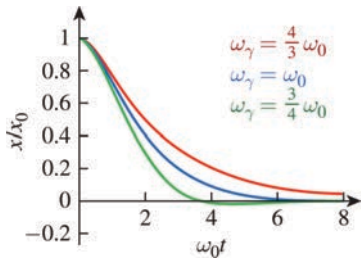

FIGURE 14.24
Position versus time for underdamped motion (green line), overdamped motion (red line), and critically damped motion (blue line).

An engineering solution providing a damped oscillation that returns as fast as possible to the equilibrium position and has no oscillations needs to use the condition of critical damping. Examples of such an application are the shock absorbers in cars, motorcycles (Figure 14.25), and bicycles. For maximum performance, they need to work at the critical damping limit or just slightly below. As they get worn, the damping effect becomes weaker, and the shock absorbers provide only small damping. This results in a "bouncing" sensation for riders, indicating that it is time to change the vehicle's shock absorbers.

SOLVED PROBLEM 14.3 Determining the Damping Constant

PROBLEM

A 1.75-kg block is connected to a vertical spring with spring constant $k = 3.50\ \text{N/m}$. The block is pulled upward a distance $d = 7.50\ \text{cm}$ and released from rest. After 113 complete oscillations, the amplitude of the oscillation is half the original amplitude. The damping of the block's motion is proportional to the speed. What is the damping constant, b?

SOLUTION

THINK

Because the block executes 113 oscillations and the amplitude decreases by a factor of 2, we know we are dealing with small damping. After an integral number of oscillations, the cosine term will be 1 and the sine term will be zero in equation 14.20. Knowing that the amplitude has decreased by a factor of 2 after 113 oscillations, we can get an expression for ω_γ in terms of the time required to complete 113 oscillations, from which we can obtain the damping constant.

SKETCH

Figure 14.26 shows the position of the block at $t = 0$ and at $t = 113T$, where T is the period of oscillation.

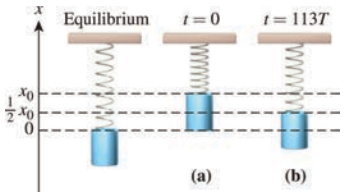

FIGURE 14.26 Position of the oscillating block at (a) $t = 0$ and (b) $t = 113T$.

RESEARCH

Because we know that we are dealing with small damping, we can apply equation 14.20:

$$x(t) = Be^{-\omega_\gamma t}\cos(\omega' t) + Ce^{-\omega_\gamma t}\sin(\omega' t).$$

At $t = 0$, we know that $x = x_0$ and so $B = x_0$. After 113 complete oscillations, the cosine term will be 1, the sine term will be zero, and $x = x_0/2$. Thus, we can write

$$\frac{x_0}{2} = \left(x_0 e^{-\omega_\gamma(113T)} \cdot 1\right) + 0, \qquad \text{(i)}$$

where $T = 2\pi/\omega'$ is the period of oscillation. We can express equation (i) as

$$0.5 = e^{-\omega_\gamma[113(2\pi/\omega')]}. \qquad \text{(ii)}$$

Taking the natural logarithm of both sides of equation (ii) gives us

$$\ln 0.5 = -\omega_\gamma\left[113\left(\frac{2\pi}{\omega'}\right)\right].$$

Remembering that $\omega' = \sqrt{\omega_0^2 - \omega_\gamma^2}$, where $\omega_0 = \sqrt{k/m}$ (k is the spring constant and m is the mass), we can write

$$-\frac{\ln 0.5}{113(2\pi)} = \frac{\omega_\gamma}{\omega'} = \frac{\omega_\gamma}{\sqrt{\omega_0^2 - \omega_\gamma^2}}. \qquad \text{(iii)}$$

We can square equation (iii) to obtain

$$\frac{\omega_\gamma^2}{\omega_0^2 - \omega_\gamma^2} = \left(-\frac{\ln 0.5}{113(2\pi)} \right)^2. \qquad \text{(iv)}$$

SIMPLIFY

In order to save a little effort in writing the constants on the right-hand side of equation (iv), we use the abbreviation

$$c^2 = \left(-\frac{\ln 0.5}{113(2\pi)} \right)^2.$$

Then we can write

$$\omega_\gamma^2 = (\omega_0^2 - \omega_\gamma^2)c^2 = \omega_0^2 c^2 - \omega_\gamma^2 c^2.$$

We can now solve for ω_γ:

$$\omega_\gamma = \sqrt{\frac{\omega_0^2 c^2}{1 + c^2}}.$$

Remembering that $\omega_\gamma = b/2m$, we can write an expression for the damping constant, b:

$$b = 2m\sqrt{\frac{\omega_0^2 c^2}{1 + c^2}}.$$

Substituting $\omega_0 = \sqrt{k/m}$, we obtain

$$b = 2m\sqrt{\frac{(k/m)c^2}{1 + c^2}} = 2\sqrt{\frac{mkc^2}{1 + c^2}}.$$

CALCULATE

We first put in the numerical values to find c^2:

$$c^2 = \left(-\frac{\ln 0.5}{113(2\pi)}\right)^2 = 9.53091 \cdot 10^{-7}.$$

We can now calculate the damping constant:

$$b = 2\sqrt{\frac{(1.75\,\text{kg})(3.50\,\text{N/m})\left(9.53091 \cdot 10^{-7}\right)}{1 + 9.53091 \cdot 10^{-7}}} = 0.0048322$$

ROUND

We report our result to three significant figures:

$$b = 4.83 \cdot 10^{-3}\,\text{kg/s}.$$

DOUBLE-CHECK

We can check that the calculated damping constant is consistent with small damping by verifying that $b < 2\sqrt{mk}$:

$$4.83 \cdot 10^{-3}\,\text{kg/s} < 2\sqrt{(1.75\,\text{kg})(3.50\,\text{N/m})} = 4.95\,\text{kg/s}.$$

Thus, the damping constant is consistent with small damping.

Energy Loss in Damped Oscillations

Damped oscillations are the result of the velocity-dependent (and thus nonconservative) damping force, $F_\gamma = -bv$, and are described by the differential equation (compare to equation 14.19)

$$\frac{d^2x}{dt^2} + 2\omega_\gamma \frac{dx}{dt} + \omega_0^2 x = 0, \qquad \textbf{(14.25)}$$

where $\omega_0 = \sqrt{k/m}$ (k is the spring constant and m is the mass) is the angular speed of the harmonic oscillation without damping and $\omega_\gamma = b/2m$ is the damping angular speed. The nonconservative damping force must result in a loss of total mechanical energy. We'll examine the energy loss for small damping only, because this case is by far of the greatest technological importance. However, large and critical damping can be treated in an analogous manner.

Self-Test Opportunity 14.5

Consider a pendulum whose motion is underdamped by a term given by the product of a damping constant, a, and the speed of the moving mass. Making the small-angle approximation, we can write the differential equation

$$\frac{d^2\theta}{dt^2} + \alpha\frac{d\theta}{dt} + \frac{g}{\ell}\theta = 0.$$

By analogy with a mass on a spring, give expressions for the angular speeds characterizing this angular motion: ω_γ, ω', and ω_0.

Concept Check 14.4

A mass on a spring oscillates in an oil bath and experiences critical damping. What happens to the motion of the mass when the spring is replaced with one that has a spring constant twice as large?

a) The motion becomes underdamped.

b) The motion becomes overdamped.

c) The damping remains critical, but it takes the mass longer to get to the equilibrium position.

d) The damping remains critical, but it takes the mass less time to get to the equilibrium position.

e) The damping remains critical, and the motion of the mass does not change.

For small damping, we saw that the displacement as a function of time can be written in terms of a single sinusoidal function with a phase shift (see equation 14.22):

$$x(t) = Ae^{-\omega_\gamma t}\sin\left(\omega' t + \theta_0\right). \qquad \textbf{(14.26)}$$

This solution can be understood as a sinusoidal oscillation in time with angular speed $\omega' = \sqrt{\omega_0^2 - \omega_\gamma^2}$ and with exponentially decreasing amplitude.

We know that the damping force is nonconservative, and so we can be sure that mechanical energy is lost over time. Since the energy of harmonic oscillation is proportional to the square of the amplitude, $E = \frac{1}{2}kA^2$, we might be led to conclude that the energy decreases smoothly and exponentially for a damped oscillation. However, this is not quite the case, which we can demonstrate as follows.

First, we can find the velocity as a function of time by taking the time derivative of equation 14.26:

$$v(t) = \omega' A e^{-\omega_\gamma t} \cos\bigl(\omega' t + \theta_0\bigr) - \omega_\gamma A e^{-\omega_\gamma t} \sin\bigl(\omega' t + \theta_0\bigr).$$

Next, we know the potential energy stored in the spring as a function of time, $U = \frac{1}{2}kx^2(t)$, as well as the kinetic energy due to the motion of the mass, $K = \frac{1}{2}mv^2(t)$. We can plot these energies and the displacement and velocity as functions of time, as shown in the graphs in Figure 14.27, where $k = 11.00\,\mathrm{N/m}$, $m = 1.800\,\mathrm{kg}$, and $b = 0.500\,\mathrm{kg/s}$. These parameters result in an angular speed of $\omega' = 2.468\,\mathrm{s}^{-1}$, compared to an angular speed of $\omega_0 = 2.472\,\mathrm{s}^{-1}$ for the case without damping, and a damping angular speed of $\omega_\gamma = 0.139\,\mathrm{s}^{-1}$. The amplitude is $A = 5\,\mathrm{cm}$, and $\theta_0 = 1.6$.

Figure 14.27 shows that the total energy does not decrease in a smooth exponential way but instead declines in a stepwise fashion. This energy loss can be represented in a straightforward way by writing an expression for the power, that is, the rate of energy loss:

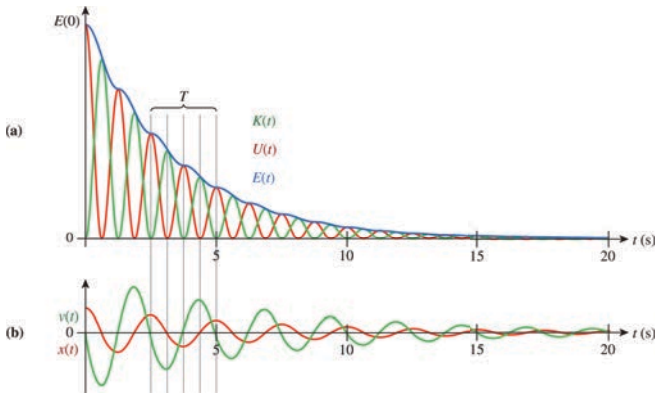

FIGURE 14.27 (a) Potential energy (red), kinetic energy (green), and total energy (blue). (b) Displacement (red) and velocity (green) for a weakly damped harmonic oscillator. The five thin vertical lines mark one complete oscillation period, *T*.

$$\frac{dE}{dt} = -bv^2 = vF_\gamma.$$

Thus, the rate of energy loss is largest wherever the velocity has the largest absolute value, which happens as the mass passes through the equilibrium position. When the mass reaches the points where the velocity is zero and is about to reverse direction, all energy is potential energy and there is no energy loss at these points.

DERIVATION 14.3 Energy Loss

We can derive the formula for the energy loss in damped oscillation by taking the time derivatives of the expressions for kinetic and potential energies:

$$\frac{dE}{dt} = \frac{dK}{dt} + \frac{dU}{dt} = \frac{d}{dt}\left(\tfrac{1}{2}mv^2\right) + \frac{d}{dt}\left(\tfrac{1}{2}kx^2\right) = mv\frac{dv}{dt} -$$

We use $v = dx/dt$ and factor out the common factor, $m\,dx/dt$:

$$\frac{dE}{dt} = m\frac{dx}{dt}\frac{d^2x}{dt^2} + kx\frac{dx}{dt} = m\frac{dx}{dt}\left(\frac{d^2x}{dt^2} + \frac{k}{m}x\right).$$

Now we can use $\omega_0^2 = k/m$ to obtain

$$\frac{dE}{dt} = m\frac{dx}{dt}\left(\frac{d^2x}{dt^2} + \omega_0^2 x\right). \qquad \text{(i)}$$

We can reorder equation 14.25 by moving the damping term to the right-hand side:

$$\frac{d^2x}{dt^2} + \omega_0^2 x = -2\omega_\gamma\frac{dx}{dt} = -\frac{b}{m}\frac{dx}{dt}.$$

Because the left-hand side of this differential equation is equal to the term inside the parentheses in equation (i) for the rate of energy loss, we obtain

$$\frac{dE}{dt} = m\frac{dx}{dt}\left(-\frac{b}{m}\frac{dx}{dt}\right) = -b\left(\frac{dx}{dt}\right)^2 = -bv^2.$$

The damping force is $F_\gamma = -bv$, and so we have shown that the rate of energy loss is indeed $dE/dt = vF_\gamma$.

Practical applications require consideration of the **quality** of the oscillator, *Q,* which specifies the ratio of total energy, *E,* to the energy loss, Δ*E,* over one complete oscillation period, *T:*

$$Q = 2\pi \frac{E}{|\Delta E|}. \qquad \textbf{(14.27)}$$

In the limit of zero damping, the oscillator experiences no energy loss, and $Q \to \infty$. In the limit of small damping, the quality of the oscillator can be approximated by

$$Q \approx \frac{\omega_0}{2\omega_\gamma}. \qquad \textbf{(14.28)}$$

Combining these two results provides a handy formula for the energy loss during a complete period of weakly damped oscillatory motion:

$$|\Delta E| = E\frac{2\pi}{Q} = E\frac{4\pi\omega_\gamma}{\omega_0}. \qquad \textbf{(14.29)}$$

For the harmonic oscillation graphed in Figure 14.27, equation 14.28 results in $Q = 2.472\,\mathrm{s}^{-1}/2(0.139)\,\mathrm{s}^{-1} = 8.89$. Substituting this value of *Q* into equation 14.29 gives an energy loss of $|\Delta E| = 0.71E$ during each oscillation period. We can compare this to the exact result for Figure 14.27 by measuring the energy at the beginning and end of the interval indicated in the figure. We find for the energy difference divided by the average energy a value of 0.68, in fairly good agreement with the value of 0.71 obtained by using the approximation of equation 14.28.

SOLVED PROBLEM 14.4 Grandfather Clock

PROBLEM

A grandfather clock has a pendulum of length 0.994 m that oscillates to a maximum angle of $\pm 6.25^\circ$ relative to the vertical. The pendulum bob has mass $m_1 = 0.750\,\text{kg}$ and is sufficiently compact to be considered a point mass. A pendulum loses energy because of friction and air resistance and thus has to be supplied with energy to keep going. In a grandfather clock, this is usually done by means of a weight, which hangs from a chain over a pulley, slowly descends in time, and occasionally has to be lifted manually to rewind the clock. For this clock, the weight has mass $m_2 = 1.550\,\text{kg}$, and it can descend through $h = 1.35\,\text{m}$ before it reaches the ground. If the quality of the pendulum is $Q = 2.95 \cdot 10^3$, what is the maximum time that can pass between successive rewindings of the clock?

SOLUTION

THINK

The period, T, is solely a function of the length of the pendulum and can thus be found easily since that information is given. The quality, Q, specifies the ratio of the total energy of an oscillation to the energy lost in one period. Since we are given the angular amplitude and the length and mass of the pendulum, we can calculate the energy lost in one oscillation, ΔE. The energy lost has to be supplied by work done on the mass m_2 by gravity. The maximum total work done on this mass before it hits the ground is m_2gh, which is equal to some number n times the energy lost per oscillation, ΔE. Therefore, at most, a time t equal to n periods of the oscillation can pass before the clock needs rewinding.

SKETCH

A sketch of the grandfather clock is shown in Figure 14.28. Usually the fulcrum of the pendulum and the pulley for the winding mechanism are right behind the center of the clock face,

but they are separated in the sketch for easier visualization of the various parameters.

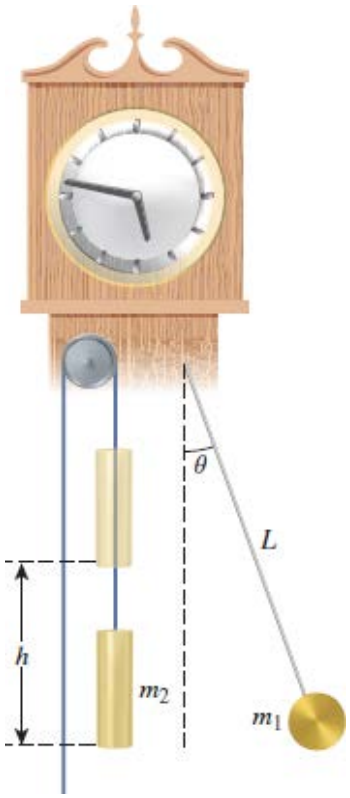

FIGURE 14.28 The workings of a grandfather clock, with the pendulum on the right and the winding mechanism on the left.

RESEARCH

The maximum time between successive rewindings of the clock is $t = nT$, and the period is given by $T = 2\pi\sqrt{L/g}$. The number n is the ratio of the total work done on the mass m_2 to the energy lost by the pendulum in one oscillation, $n = m_2gh/\Delta E$. The energy lost during one period is $\Delta E = 2\pi E/Q$ (see equation 14.29), and the energy of the pendulum is the difference in potential energy between the highest and lowest points of the oscillation, $E = m_1gL(1 - \cos\theta_{\max})$.

SIMPLIFY

We can insert our expressions for T and n into our expression for the time, t, and obtain

$$t = nT = n2\pi\sqrt{\frac{L}{g}} = \frac{m_2gh}{\Delta E}2\pi\sqrt{\frac{L}{g}}.$$

Next, substituting for ΔE and then for E and canceling out $2\pi g$ gives

$$\begin{aligned} t &= \frac{Qm_2gh}{2\pi E}2\pi\sqrt{\frac{L}{g}} = \frac{Qm_2gh}{2\pi m_1gL(1-\cos\theta_{\text{max}})}2\pi\sqrt{\frac{L}{g}} \\ &= \frac{Qm_2h}{m_1L(1-\cos\theta_{\text{max}})}\sqrt{\frac{L}{g}}. \end{aligned}$$

CALCULATE

We can now insert the given numbers:

$$t = \frac{\left(2.95\cdot 10^3\right)(1.550\,\text{kg})(1.35\,\text{m})}{(0.750\,\text{kg})(0.994\,\text{m})(1-\cos 6.25^\circ)}\sqrt{\frac{0.994\,\text{m}}{9.81\,\text{m/s}^2}} = 4.4$$

ROUND

We round our result to three significant digits:

$$t = 4.43\cdot 10^5\,\text{s}.$$

DOUBLE-CHECK

It's worth repeating occasionally that the first and easiest double-check is to make sure that the units are appropriate. We substituted quite a few quantities with different units into our equation for t, but all the units canceled out except for seconds, which are appropriate for measuring time. What about the order of magnitude of our solution? Since a day has 86,400 s, our

solution corresponds to a few days $\left(1\text{ week} = 6.048 \cdot 10^5\text{ s}\right)$. If you own a grandfather clock, then you know that it needs rewinding every few days, and our solution is consistent with that experience.

Concept Check 14.5

What could you do to increase the time between successive rewindings of the grandfather clock in Solved Problem 14.4?

a) increase the mass of the pendulum bob

b) increase the mass of the weight on the chain

c) increase the length of the pendulum

d) increase the pendulum's amplitude

e) All of the above would increase the time between rewindings.

f) None of the above would increase the time between rewindings, because *Q* does not change.

14.5 Forced Harmonic Motion and Resonance

If you are pushing someone sitting on a swing, you give the person periodic pushes, with the general goal of making him or her swing higher—that is, of increasing the amplitude of the oscillation. This situation is an example of **forced harmonic motion.** Periodically forced or driven oscillations arise in many kinds of problems in various areas of physics, including mechanics, acoustics, optics, and electromagnetism. To represent the periodic driving force, we use

$$F(t) = F_{\mathrm{d}} \cos(\omega_{\mathrm{d}} t), \tag{14.30}$$

where F_{d} and ω_{d} are constants.

To analyze forced harmonic motion, we start by considering the case of no damping. Using the driving force, $F(t)$, the differential equation for this situation is

$$\begin{aligned} m\frac{d^2x}{dt^2} &= -kx + F_{\mathrm{d}} \cos(\omega_{\mathrm{d}} t) \Rightarrow \\ \frac{d^2x}{dt^2} &+ \frac{k}{m}x - \frac{F_{\mathrm{d}}}{m}\cos(\omega_{\mathrm{d}} t) = 0. \end{aligned}$$

The solution to this differential equation is

$$x(t) = B \sin(\omega_0 t) + C \cos(\omega_0 t) + A_{\mathrm{d}} \cos(\omega_{\mathrm{d}} t).$$

The coefficients B and C for the part of the motion that oscillates with the intrinsic angular speed, $\omega_0 = \sqrt{k/m}$, can be determined from the initial conditions. However, much more interesting is the part of the motion that oscillates with the driving angular speed. It can be shown that the amplitude of this forced oscillation is given by

$$A_{\mathrm{d}} = \frac{F_{\mathrm{d}}}{m\left(\omega_0^2 - \omega_{\mathrm{d}}^2\right)}.$$

Self-Test Opportunity 14.6

Is a plucked guitar string an example of forced harmonic motion? If no, why not? If yes, what is the driver, and what resonates?

Thus, the closer the driving angular speed, ω_d, is to the intrinsic angular speed, ω_0, the larger the amplitude becomes. In the situation of pushing a person on a swing, this amplification is apparent. You can increase the amplitude of the swing's motion only when you push at approximately the same frequency with which the swing is already oscillating. If you push with that frequency, the person on the swing will go higher and higher.

If the driving angular speed is exactly equal to the intrinsic angular speed of the oscillator, the equation $A_d = F_d / \left[m\left(\omega_0^2 - \omega_d^2\right)\right]$ predicts that the amplitude will grow infinitely big. In real life, this infinite growth does not occur. Some damping is always present in the system. In the presence of damping, the differential equation to solve becomes

$$\frac{d^2x}{dt^2} + \frac{b}{m}\frac{dx}{dt} + \frac{k}{m}x - \frac{F_d}{m}\cos(\omega_d t) = 0. \qquad \textbf{(14.31)}$$

This equation has the steady-state solution

$$x(t) = A_\gamma \cos(\omega_d t - \theta_\gamma), \qquad \textbf{(14.32)}$$

where x oscillates at the driving angular speed and the amplitude is

$$A_\gamma = \frac{F_d}{m\sqrt{\left(\omega_0^2 - \omega_d^2\right)^2 + 4\omega_d^2\omega_\gamma^2}}. \qquad \textbf{(14.33)}$$

As you can see, the amplitude given by equation 14.33 cannot be infinite, because even at $\omega_\mathrm{d} = \omega_0$, it still has a finite value, $F_\mathrm{d}/(2m\omega_\mathrm{d}\omega_\gamma)$, which is also *approximately* its maximum. The driving frequency corresponding to the maximum amplitude can be calculated by taking the derivative of A_γ with respect to ω_d, setting that derivative equal to 0, and solving for ω_d, which gives the result that A_γ is maximum when $\omega_\mathrm{d} = \sqrt{\omega_0^2 - 2\omega_\gamma^2}$. Note that for $\omega_\gamma \ll \omega_0$,$\omega_\mathrm{d} \approx \omega_0$. The shape of the curve of the amplitude A_γ, as a function of the driving angular speed, ω_d, is called a **resonance shape,** and it is characteristic of all resonance phenomena. When $\omega_\mathrm{d} = \sqrt{\omega_0^2 - 2\omega_\gamma^2}$, the driving angular speed is called the **resonant angular speed;** A_γ is close to a maximum at this angular speed. In Figure 14.29, A_γ is plotted from equation 14.33 for $\omega_0 = 3\,\mathrm{s}^{-1}$ and three values of the damping angular speed, ω_γ. As the damping gets weaker, the resonance shape becomes sharper. You can see that in every case, the amplitude curve reaches its maximum at a value of ω_d slightly below $\omega_0 = 3\,\mathrm{s}^{-1}$.

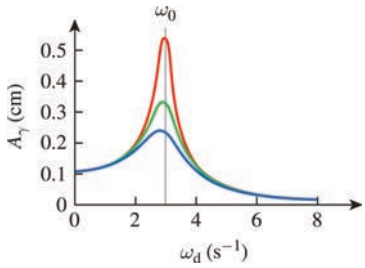

FIGURE 14.29 The amplitude of forced oscillations as a function of the angular speed of the driving force. The three curves represent different damping angular speeds: $\omega_\gamma = 0.3\,\mathrm{s}^{-1}$ (red curve), $\omega_\gamma = 0.5\,\mathrm{s}^{-1}$ (green curve), and $\omega_\gamma = 0.7\,\mathrm{s}^{-1}$ (blue curve).

The phase angle θ_γ in equation 14.32 depends on the driving angular speed as well as on the damping and intrinsic angular speeds:

$$\theta_\gamma = \frac{\pi}{2} - \tan^{-1}\left(\frac{\omega_0^2 - \omega_\mathrm{d}^2}{2\omega_\mathrm{d}\omega_\gamma}\right). \qquad \textbf{(14.34)}$$

The phase shift as a function of the driving angular speed is graphed in Figure 14.30 with the same parameters used in Figure 14.29. You can see that for small driving angular speeds, the forced oscillation follows the driving-in phase. As the driving angular speed increases, the phase difference begins to grow and reaches $\pi/2$ at $\omega_\mathrm{d} = \omega_0$. For driving angular speeds much larger than the resonant angular speed,

the phase shift approaches π. The lower the damping angular speed, ω_γ, the steeper the transition of the phase shift from 0 to π becomes.

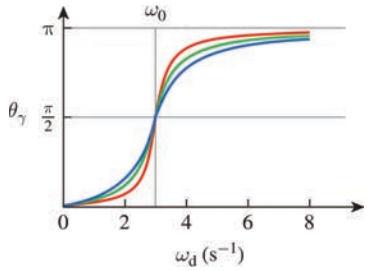

FIGURE 14.30
Phase shift as a function of driving angular speed with the same parameters as in Figure 14.29. The three curves represent different damping angular speeds: $\omega_\gamma = 0.3\,\mathrm{s}^{-1}$ (red curve), $\omega_\gamma = 0.5\,\mathrm{s}^{-1}$ (green curve), and $\omega_\gamma = 0.7\,\mathrm{s}^{-1}$ (blue curve).

A practical note is in order at this point: The solution presented in equation 14.32 is usually only reached after some time. The full solution for the differential equation for damped and driven oscillation (equation 14.31) is given by a combination of equations 14.20 and 14.32. During the transition time, the effect of the particular initial conditions for the system is damped out, and the solution given by equation 14.32 is approached asymptotically.

Figure 14.31 shows motion of a system that is driven with a driving angular speed of $\omega_\mathrm{d} = 1.2\,\mathrm{s}^{-1}$ and an acceleration of $F/m = 0.62\,\mathrm{m/s}^2$. The system has an intrinsic angular speed of $\omega_0 = 2.2\,\mathrm{s}^{-1}$ and a damping angular speed of $\omega_\gamma = 0.4\,\mathrm{s}^{-1}$ and starts at $x_0 = 0$ with a positive initial velocity. The unforced motion of the system follows equation 14.20 and is shown by the green

dashed curve. The motion according to equation 14.32 is shown in red. The full solution (blue curve) is the sum of the two. After some complicated-looking oscillations, during which the initial conditions are damped out, the full solution approaches the simple harmonic motion given by equation 14.32.

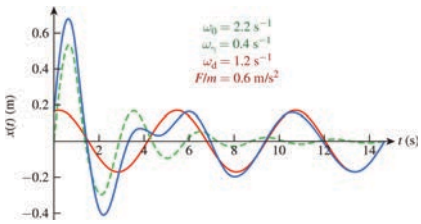

FIGURE 14.31 Position as a function of time for damped and driven harmonic oscillation: The red curve plots equation 14.32, and the green dashed curve shows the motion with damping (from equation 14.20). The blue curve is the sum of the red and green curves, giving the complete picture.

Driving mechanical systems to resonance has important technical consequences, not all of them desirable. Most worrisome are resonance frequencies in architectural structures. Builders have to be very careful, for example, not to construct high-rises in such a way that earthquakes can drive them into oscillations near resonance. Perhaps the most infamous example of a structure that was destroyed by a resonance phenomenon was the Tacoma Narrows Bridge, known as “Galloping Gertie,” in the state of Washington. It collapsed on November 7, 1940, only a few months after construction was finished (Figure 14.32). A 40-mph wind was able to drive the oscillations of the bridge into resonance, and catastrophic mechanical failure occurred.

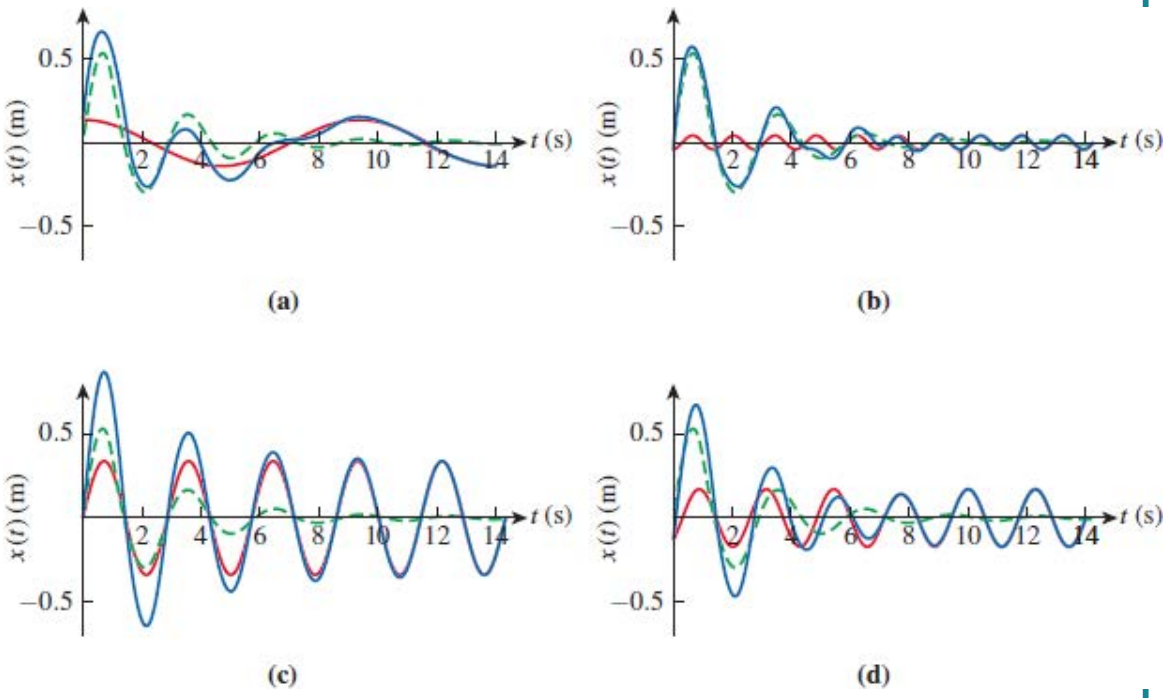
FIGURE 14.32
Collapse of the midsection of the Tacoma Narrows Bridge on November 7, 1940.

Smith Archive/Alamy Stock Photo

Columns of soldiers marching across a bridge are often told to fall out of lockstep to avoid creating a resonance due to the periodic stomping of their feet. However, a large number of walkers can get locked into phase through a feedback mechanism. On June 12, 2000, the London Millennium Bridge on the Thames River had to be closed after only three days of operation, because 2000 pedestrians walking over the bridge drove it into resonance and earned it the nickname "wobbly bridge." The lateral swaying of the bridge was such that it provided feedback and locked the pedestrians into a stepping rhythm that amplified the oscillations.

Concept Check 14.6

The system of Figure 14.31 is driven at four different driving angular speeds, and position versus time for all four cases are plotted in the figures below. Which of the four cases is closest to resonance? (The colors of the curves in each panel are the same as in Figure 14.31.)



Concept Check 14.7

Is forced harmonic motion produced by external sinusoidal driving periodic?

a) yes, always

b) only during the initial phase of the motion

c) only asymptotically during the later part of the motion

d) no, never

14.6 Phase Space

We will return repeatedly to the physics of oscillations during the course of this book. As mentioned earlier, the reason for this emphasis is that many systems have restoring forces that drive them back to equilibrium if they are nudged only a small distance from equilibrium. Many problem situations in physics can therefore be modeled in terms of a pendulum or a spring. Before we leave the topic of oscillations for now, let's consider one more interesting way of displaying the motion of oscillating systems. Instead of plotting displacement, velocity, or acceleration as a function of time, we can plot velocity versus displacement. A display of velocity versus displacement is called a **phase space.** Looking at physical motion in this way provides interesting insights.

Let's start with a harmonic oscillation without damping. Plotting an oscillation with time dependence given by $x(t) = A\sin(\omega t)$, amplitude $A = 4\,\text{cm}$, and angular speed $\omega = 0.7\,\text{s}^{-1}$ in a phase space gives an ellipse, the red curve in Figure 14.33. Other values of the amplitude, between 3 and 7 in steps of 1, yield different ellipses, shown in blue in Figure 14.33.

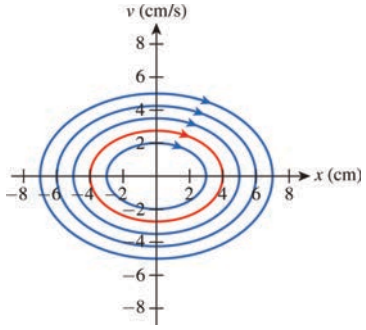


FIGURE 14.33
Velocity versus displacement for different amplitudes of simple harmonic motion.

Consider another example: Figure 14.34 shows a plot in a phase space of the motion of a weakly damped oscillator (with

$k = 11\,\text{N/m}, m = 1.8\,\text{kg}, b = 0.5\,\text{kg/s}, A = 5\,\text{cm}$, and $\theta_0 = 1.6$), the same oscillator whose position was plotted in Figure 14.20 as a function of time. You can see the starting point of the oscillatory motion, at $x(t = 0) = (5\,\text{cm})\sin(1.6)e^{-0}$ and $v(t = 0) = -1.05\,\text{cm/s}$. The trajectory in the phase space spirals inward toward the point (0,0). It looks as though the trajectory is attracted to that point. If the oscillation had different initial conditions, the plot would have spiraled inward to the same point, but on a different trajectory. A point to which all trajectories eventually converge is called a *point attractor*.

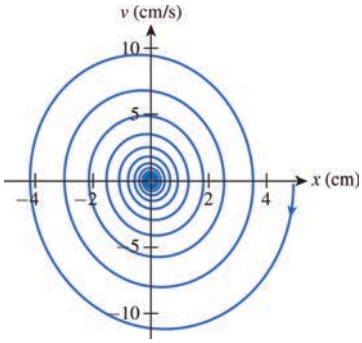

FIGURE 14.34
Velocity versus displacement for a damped oscillator.

14.7 Chaos

One field of research in physics has emerged only since the advent of computers. This field of **nonlinear dynamics,** including those of **chaos,** has yielded interesting and relevant results. If we look hard enough and under certain conditions, we can discover signs of chaotic motion even in the oscillators we have been dealing with in this chapter. In Chapter 7, we looked at chaos and billiards, noting the sensitivity of a system's motion to initial conditions; here we continue this examination in greater detail.

Concept Check 14.8

Suppose you start another weakly damped oscillator with the same initial conditions as in Figure 14.34 and with all parameters unchanged except for increased damping. How does the trajectory in the phase space change?

a) It remains unchanged.

b) It remains basically unchanged but spirals inward to a different point.

c) It spirals inward to the same point but does so faster; that is, it crosses the x-axis fewer times on its way in.

d) It spirals inward to the same point but does so more slowly; that is, it crosses the x-axis more times on its way in.

When we analyzed the motion of a pendulum, we used the small-angle approximation (Section 14.2). However, suppose we want to study large deflection angles. We can do this by using a pendulum whose string has been replaced with a thin solid rod. Such a pendulum can move through more than 180°, even through a full 360°. In this case, the approximation $\sin\theta \approx \theta$ does not work, and the sine function must be included in the differential equation. If a

periodic external driving force as well as damping is present for this pendulum, we cannot solve the equation of motion in an analytic fashion. However, we can use numerical integration procedures with a computer to obtain the solution. The solution depends on the given initial conditions. Based on what you have learned so far about oscillators, you might expect that similar initial conditions give similar patterns of motion over time. However, for some combinations of driving angular speed and amplitude, damping constant, and pendulum length, this expectation is not borne out.

Figure 14.35 shows plots of the pendulum's deflection angle as a function of time using the same equation of motion and the same value for the initial velocity. However, for the red curve, the initial angle is exactly zero radians. For the green curve, the initial angle is 10^{-3} rad. You can see that these two curves stay close to one another for a few oscillations, but then rapidly diverge. If the initial angle is 10^{-5} rad (blue curve), the curves do not stay close for much longer. Since the blue curve starts 100 times closer to the red curve, it might be expected to stay close to the red curve longer in time by a factor of 100. This is not the case. This behavior is called *sensitive dependence on initial conditions*. If a system is sensitively dependent on the initial conditions, a long-term prediction of its motion is impossible. This sensitivity is one of the hallmarks of chaotic motion.

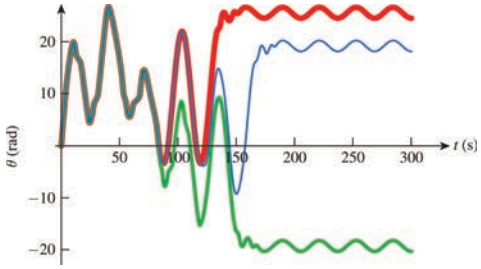

FIGURE 14.35 Deflection angle as a function of time for a driven pendulum with three different initial conditions: The red line resulted from an initial angle of zero. The green line resulted from an initial angle of 10^{-3} rad. The blue line resulted from an initial angle of 10^{-5} rad.

Precise long-range weather forecasts are impossible because of sensitive dependence on initial conditions. With the advent of computers in the 1950s, meteorologists thought they would be able to describe the future weather accurately if only they generated enough measurements of all the relevant variables—such as temperature and wind direction—at as many points as possible across the country. However, by the 1960s, it had become obvious that the basic differential equations for air masses moving in the atmosphere show sensitive dependence on initial conditions. Thus, the dream of precise long-range weather forecasting was ended.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- An object acting under Hooke's Law, $F = -kx$, undergoes simple harmonic motion, with a restoring force that acts in the opposite direction to the displacement from equilibrium.
- The equation of motion for a mass on a spring (with no damping) is $x(t) = B\sin(\omega_0 t) + C\cos(\omega_0 t)$, where $\omega_0 = \sqrt{k/m}$, or, alternatively, $x(t) = A\sin(\omega_0 t + \theta_0)$.
- The equation of motion for a pendulum (with no damping) is $\theta(t) = B\sin(\omega_0 t) + C\cos(\omega_0 t)$ with $\omega_0 = \sqrt{g/\ell}$.
- Velocity and acceleration for simple harmonic oscillations are given by

$$\begin{aligned} & x(t) = A\sin(\omega_0 t + \theta_0) \\ \Rightarrow\ & v(t) = \omega_0 A\cos(\omega_0 t + \theta_0) \\ \Rightarrow\ & a(t) = -\omega_0^2 A\sin(\omega_0 t + \theta_0). \end{aligned}$$

- The period of an oscillation is $T = 2\pi/\omega$.
- The frequency of an oscillation is $f = 1/T = \omega/2\pi$, or $\omega = 2\pi f$.
- The equation of motion for a mass on a spring with small damping $\left(b < 2\sqrt{mk}\right)$ is $x(t) = Be^{-\omega_\gamma t}\sin(\omega' t) + Ce^{-\omega_\gamma t}\cos(\omega' t)$, with $\omega_\gamma = b/2m$, $\omega' = \sqrt{k/m - (b/2m)^2} = \sqrt{\omega_0^2 - \omega_\gamma^2}$, and $\omega_0 = \sqrt{g/\ell}$.
- The equation of motion for a mass on a spring with large damping $\left(b > 2\sqrt{mk}\right)$ is $x(t) = Be^{-\left(\omega_\gamma + \sqrt{\omega_\gamma^2 - \omega_0^2}\right)t} + Ce^{-\left(\omega_\gamma - \sqrt{\omega_\gamma^2 - \omega_0^2}\right)t}$.

- The equation of motion for a mass on a spring with critical damping $\left(b = 2\sqrt{mk}\right)$ is $x(t) = (B + tC)e^{-\omega_\gamma t}$.
- For a damped harmonic oscillator, the rate of energy loss is $dE/dt = -bv^2 = vF_\gamma$.
- The quality of an oscillator is related to the energy loss during one complete oscillation period, $Q = 2\pi E/|\Delta E|$.
- If a periodic external driving force, $F(t) = F_\mathrm{d}\cos(\omega_\mathrm{d} t)$, is applied to an oscillating system, the equation of motion becomes (after some transient time) $x(t) = A_\gamma \cos(\omega_\mathrm{d} t - \theta_\gamma)$, with amplitude $A_\gamma = \dfrac{F_\mathrm{d}}{m\sqrt{\left(\omega_0^2 - \omega_\mathrm{d}^2\right)^2 + 4\omega_\mathrm{d}^2\omega_\gamma^2}}$. The graph of this amplitude displays a resonance shape in which the amplitude is a maximum when the driving angular speed approximately equals the intrinsic angular speed $(\omega_\mathrm{d} = \omega_0)$.
- A phase space displays a plot of the velocity of an object versus its position. Simple harmonic motion yields an ellipse in such a phase space. A plot of damped harmonic motion spirals in toward the point attractor at (0,0).
- With the right choice of parameters, a damped and driven rod pendulum can show chaotic motion, which is sensitively dependent on the initial conditions. In this case, the system's long-term behavior is not predictable.

ANSWERS TO SELF-TEST OPPORTUNITIES

14.1 $\frac{d^2x}{dt^2} + \frac{k}{m}x = 0$. Use the trial function $x(t) = A\sin(\omega_0 t + \theta_0)$ and take derivatives:

$$\frac{dx}{dt} = A\omega_0 \cos(\omega_0 t + \theta_0);$$
$$\frac{d^2x}{dt^2} = -A\omega_0^2 \sin(\omega_0 t + \theta_0).$$

Now insert the latter expression back into the differential equation with $\omega_0^2 = \frac{k}{m}$. We find $-A\omega_0^2 \sin(\omega_0 t + \theta_0) + A\omega_0^2 \sin(\omega_0 t + \theta_0) = 0$.

14.2 Use the trig identity $\sin(\alpha + \beta) = \sin(\alpha)\cos(\beta) + \cos(\alpha)\sin(\beta)$:

$$A\sin(\omega_0 t + \theta_0) = A\sin(\omega_0 t)\cos(\theta_0) + A\cos(\omega_0 t)\sin(\theta_0)$$
$$A\sin(\omega_0 t + \theta_0) = (A\cos(\theta_0))\sin(\omega_0 t) + (A\sin(\theta_0))\cos(\omega_0 t) =$$

$$B = A\cos(\theta_0)$$
$$C = A\sin(\theta_0).$$

Square and add these two equations:

$$B^2 + C^2 = A^2\sin^2(\theta_0) + A^2\cos^2(\theta_0) = A^2\left(\sin^2(\theta_0) + \cos^2(\theta_0\right.$$

$$A = \sqrt{B^2 + C^2}.$$

Now divide the same two equations:

$$\frac{C}{B} = \frac{A\sin(\theta_0)}{A\cos(\theta_0)} = \tan(\theta_0)$$
$$\theta_0 = \tan^{-1}\left(\frac{C}{B}\right).$$

14.3 The radial component of the gravitational force is $mg\cos\theta$, as indicated in Figure 14.10. Since the mass on the string is forced to move on a circular path, a centripetal force, $F_c = mv^2/\ell$, is required to keep the mass on that path. This force has to be supplied by the string tension, which also has to compensate for the radial component of the gravitational force. Therefore, in general, the relationship between the string tension and the radial component of the gravitational force is $T \geq mg\cos\theta$, where equality exists only at the turning points of the pendulum's motion.

14.4 $T_{\text{Moon}} = \sqrt{\frac{\text{g Earth}}{\text{g Moon}}}T = \sqrt{\frac{9.81\ \text{m/s}^2}{1.63\ \text{m/s}^2}}T = 2.45T.$

14.5 $\omega_\gamma = \frac{\alpha}{2};\ \omega_0 = \sqrt{\frac{g}{\ell}};\ \omega' = \sqrt{\omega_0^2 - \omega_\gamma^2}.$

14.6 Yes, a plucked guitar string is an example of forced harmonic motion. The oscillating string provides the harmonic driving force, and the air inside the guitar body resonates at the same frequency as the string's oscillation.

PROBLEM-SOLVING GUIDELINES

1. In oscillatory motion, some quantities are characteristic of the motion: position, x; velocity, v; acceleration, a; energy, E; phase angle, θ_0; amplitude, A; and maximum velocity, $v_{\max}$. Other quantities are characteristic of the particular system: mass, m; spring constant, k; pendulum length, ℓ; period, T; frequency, f; and angular frequency, ω; It is helpful to list the quantities you are looking for in a problem and the quantities you know or need to determine to find those unknowns.

2. All harmonic oscillations are produced by forces that depend linearly on the deflection from the equilibrium position and that always point toward the equilibrium position. Any time the given situation includes such a force, harmonic motion will result.

3. For harmonic oscillations, the kinetic energy is at a maximum when the oscillator is passing through the equilibrium position, and the potential energy is at a maximum (and the kinetic energy is zero) at the maximum displacement from equilibrium.

4. For problems involving damping, it is essential to first determine whether the system is weakly damped, critically damped, or overdamped, because the form of the equation of motion you should use depends on the type of damping.

MULTIPLE-CHOICE QUESTIONS

14.1 Two children are on adjacent playground swings with chains of the same length. They are given pushes by an adult and then left to swing. Assuming that each child on a swing can be treated as a simple pendulum and that friction is negligible, which child takes the longer time for one complete swing (has a longer period)?

a) the bigger child

b) the lighter child

c) neither child

d) the child given the bigger push

14.2 Identical blocks oscillate on the end of a vertical spring, one on Earth and one on the Moon. Where is the period of the oscillations greater?

a) on Earth

b) on the Moon

c) same on both Earth and Moon

d) cannot be determined from the information given

14.3 A mass that can oscillate without friction on a horizontal surface is attached to a horizontal spring that is pulled to the right 10.0 cm and is released from rest. The period of oscillation for the mass is 5.60 s. What is the speed of the mass at $t = 2.50$ s?

a) $-2.61 \cdot 10^{-1}$ m/s

b) $-3.71 \cdot 10^{-2}$ m/s

c) $-3.71 \cdot 10^{-1}$ m/s

d) $-2.01 \cdot 10^{-1}$ m/s

14.4 The spring constant for a spring-mass system undergoing simple harmonic motion is doubled. If the total energy remains

unchanged, what will happen to the maximum amplitude of the oscillation? Assume that the system is underdamped.

a) It will remain unchanged.

b) It will be multiplied by 2.

c) It will be multiplied by $\frac{1}{2}$.

d) It will be multiplied by $1/\sqrt{2}$.

14.5 With the right choice of parameters, a damped and driven physical pendulum can show chaotic motion, which is sensitively dependent on the initial conditions. Which statement about such a pendulum is true?

a) Its long-term behavior can be predicted.

b) Its long-term behavior is not predictable.

c) Its long-term behavior is like that of a simple pendulum of equivalent length.

d) Its long-term behavior is like that of a conical pendulum.

e) None of the above is true.

14.6 A spring is hanging from the ceiling with a mass attached to it. The mass is pulled downward, causing it to oscillate vertically with simple harmonic motion. Which of the following will decrease the frequency of the oscillation?

a) adding a second, identical spring with one end attached to the mass and the other to the ceiling

b) adding a second, identical spring with one end attached to the mass and the other to the floor

c) increasing the mass

d) adding both springs, as described in (a) and (b)

14.7 A child of mass M is swinging on a swing of length L to a maximum deflection angle of θ. A man of mass $4M$ is swinging on a similar swing of length L to a maximum angle of 2θ. Each swing can be treated as a simple pendulum undergoing simple harmonic motion. If the period for the child's motion is T, then the period for the man's motion is

a) T.

b) $2T$.

c) $T/2$.

d) $T/4$.

14.8 Object A is four times heavier than object B. Each object is attached to a spring, and the springs have equal spring constants. The two objects are then pulled from their equilibrium positions and released from rest. What is the ratio of the periods of the two oscillators if the amplitude of A is half that of B?

a) $T_{\mathrm{A}} : T_{\mathrm{B}} = 1 : 4$

b) $T_{\mathrm{A}} : T_{\mathrm{B}} = 4 : 1$

c) $T_{\mathrm{A}} : T_{\mathrm{B}} = 2 : 1$

d) $T_{\mathrm{A}} : T_{\mathrm{B}} = 1 : 2$

14.9 Rank the simple harmonic oscillators shown in the figure in order of their intrinsic frequencies, from highest to lowest. All the springs have identical spring constants, and all the blocks have identical masses.

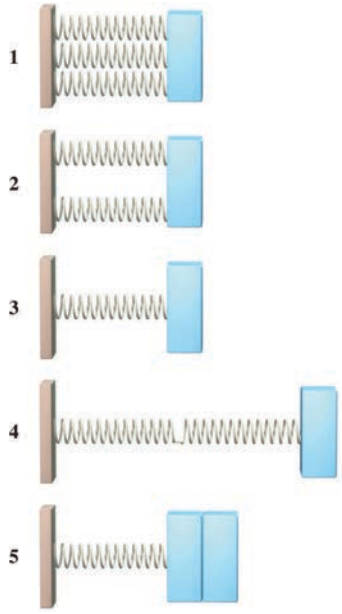
a) $1,\ 2,\ 3,\ 4 = 5$

b) $4 = 5,\ 3,\ 2,\ 1$

c) $1,\ 2,\ 3 = 4,\ 5$

d) $3, 4, 2, 1, 5$

e) $3,\ 2 = 5,\ 4,\ 1$



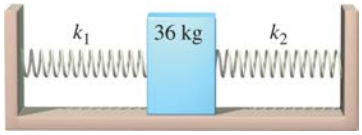
14.10 A pendulum is suspended from the ceiling of an elevator. When the elevator is at rest, the period of the pendulum is T. The elevator accelerates upward, and the period of the pendulum is then

a) still T.

b) less than T.

c) greater than T.

14.11 A 36-kg mass is placed on a horizontal frictionless surface and then connected to walls by two springs with spring constants $k_1 = 3.0\ \mathrm{N/m}$ and $k_2 = 4.0\ \mathrm{N/m}$, as shown in the figure. What is the period of oscillation for the 36-kg mass if it is displaced slightly to one side?



a) 11 s

b) 14 s

c) 17 s

d) 20. s

e) 32 s

f) 38 s

14.12 A spring with $k = 12.0\ \mathrm{N/m}$ has a mass $m = 3.00\ \mathrm{kg}$ attached to its end. The mass is pulled $+10.0\ \mathrm{cm}$ from the equilibrium position and released from rest. What is the velocity of the mass as it passes the equilibrium position?

a) $-0.125\ \mathrm{m/s}$

b) $+0.750\ \mathrm{m/s}$

c) $-0.200\ \mathrm{m/s}$

d) $+0.500\ \mathrm{m/s}$

e) $-0.633\ \mathrm{m/s}$

14.13 A grandfather clock keeps time using a pendulum consisting of a light rod connected to a small, heavy mass. How long should the rod be to make the period of the oscillations 1.00 s?

a) 0.0150 m

b) 0.145 m

c) 0.248 m

d) 0.439 m

e) 0.750 m

14.14 An automobile with a mass of 1640 kg is lifted into the air. During the lift, the suspension spring on each wheel lengthens by 30.0 cm. What damping constant is required for the shock absorber on each wheel to produce critical damping?

a) 101 kg/s

b) 234 kg/s

c) 1230 kg/s

d) 2310 kg/s

e) 4690 kg/s

14.15 Suppose you start another weakly damped oscillator with the same initial conditions as in Figure 14.34 and with all parameters unchanged except for a larger mass. How will the trajectory in the phase space change?

a) It remains unchanged.

b) It remains basically unchanged but spirals inward to a different point.

c) It spirals inward to the same point but does so faster; that is, it crosses the x-axis fewer times on its way in.

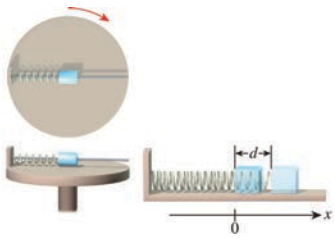
d) It spirals inward to the same point but does so more slowly; that is, it crosses the x-axis more times on its way in.

CONCEPTUAL QUESTIONS

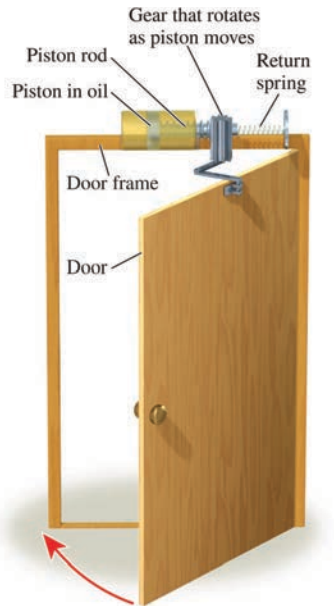
14.16 You sit in your SUV in a traffic jam. Out of boredom, you rock your body from side to side and then sit still. You notice that your SUV continues rocking for about 2 s and makes three side-to-side oscillations, before subsiding. You estimate that the amplitude of the SUV's motion must be less than 5% of the amplitude of your initial rocking. Knowing that your SUV has a mass of 2200 kg (including the gas, your stuff, and yourself), what can you say about the effective spring constant and damping of your SUV's suspension?

14.17 An astronaut, taking his first flight on a space shuttle, brings along his favorite miniature grandfather clock. At launch, the clock and his digital wristwatch are synchronized, and the grandfather clock is pointed in the direction of the shuttle's nose. During the boost phase, the shuttle has an upward acceleration whose magnitude is several times the value of the gravitational acceleration at the Earth's surface. As the shuttle reaches a constant cruising speed after completion of the boost phase, the astronaut compares his grandfather clock's time to that of his watch. Are the timepieces still synchronized? If not, which is ahead of the other? Explain.

14.18 A small cylinder of mass m can slide without friction on a shaft that is attached to a turntable, as shown in the figure. The shaft also passes through the coils of a spring with spring constant k, which is attached to the turntable at one end and to the cylinder at the other end. The equilibrium length of the spring (unstretched and uncompressed) matches the radius of the turntable; thus, when the turntable is not rotating, the cylinder is at equilibrium at the center of the turntable. The cylinder is given a small initial displacement, and, at the same time, the turntable is set into uniform circular motion with angular speed ω. Calculate the period of the oscillations performed by the cylinder. Discuss the result.



14.19 A door closer on a door allows the door to close by itself, as shown in the figure. The door closer consists of a return spring attached to an oil-filled damping piston. As the spring pulls the piston to the right, teeth on the piston rod engage a gear, which rotates and causes the door to close. Should the system be underdamped, critically damped, or overdamped for the best performance (where the door closes quickly without slamming into the frame)?



14.20 When the amplitude of the oscillation of a mass on a stretched string is increased, why doesn't the period of oscillation also increase?

14.21 Mass-spring systems and pendulum systems can both be used in mechanical timing devices. What are the advantages of using one type of system rather than the other in a device designed to generate reproducible time measurements over an extended period of time?

14.22 You have a linear (following Hooke's Law) spring with an unknown spring constant, a standard mass, and a timer. Explain carefully how you could most practically use these to measure masses *in the absence of gravity*. Be as quantitative as you can. Regard the mass of the spring as negligible.

14.23 Pendulum A has a bob of mass m hung from a string of length L; pendulum B is identical to A except its bob has mass $2m$. Compare the frequencies of small oscillations of the two pendulums.

14.24 A sharp spike in a plotted curve of frequency can be represented as a sum of sinusoidal functions of all possible frequencies, with equal amplitudes. A bell struck with a hammer rings at its natural frequency, that is, the frequency at which it vibrates as a free oscillator. Explain why, as clearly and concisely as you can.

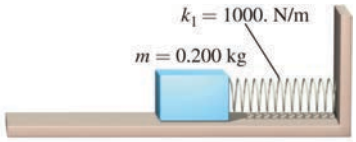
EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

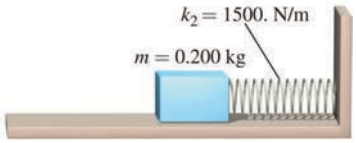
Section 14.1

14.25 A mass $m = 5.00$ kg is suspended from a spring and oscillates according to the equation of motion $x(t) = 0.500\ \cos(5.00t + \pi/4)$. What is the spring constant?

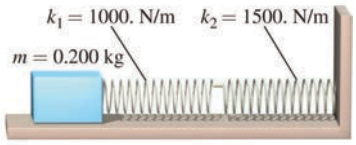
14.26 Determine the frequency of oscillation of a 200.-g block that is connected by a spring to a wall and sliding on a frictionless surface, for the three conditions shown in the figure.



(a)



(b)



(c)

• **14.27** A mass of 10.0 kg is hanging by a steel wire 1.00 m long and 1.00 mm in diameter. If the mass is pulled down slightly and released, what will be the *frequency* of the resulting oscillations? Young's modulus for steel is $2.0 \cdot 10^{11}$ N/m^2.

• **14.28** A 100.-g block hangs from a spring with $k = 5.00$ N/m. At $t = 0$ s, the block is 20.0 cm below the equilibrium position and moving upward with a speed of 200. cm/s. What is the block's speed when the displacement from equilibrium is 30.0 cm?

•**14.29** A block of wood of mass 55.0 g floats in a swimming pool, oscillating up and down in simple harmonic motion with a frequency of 3.00 Hz.

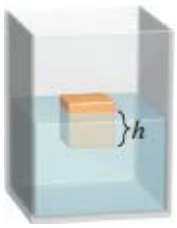
a) What is the value of the effective spring constant of the water?

b) A partially filled water bottle of almost the same size and shape as the block of wood but with mass 250. g is placed on the water's

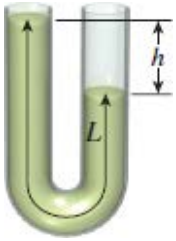
surface. At what frequency will the bottle bob up and down?

• **14.30** When a mass is attached to a vertical spring, the spring is stretched a distance *d*. The mass is then pulled down from this position and released. It undergoes 50.0 oscillations in 30.0 s. What was the distance *d*?

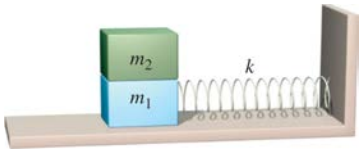
• **14.31** A cube of density ρ_c floats in a liquid of density ρ_1, as shown in the figure. At rest, an amount *h* of the cube's height is submerged in liquid. If the cube is pushed down, it bobs up and down like a spring and oscillates about its equilibrium position. Show that the frequency of its oscillations is given by $f = (2\pi)^{-1}\sqrt{g/h}$.



• **14.32** A U-shaped glass tube with a uniform cross-sectional area, *A*, is partly filled with fluid of density ρ. Increased pressure is applied to one of the arms, resulting in a difference in elevation, *h*, between the two arms of the tube, as shown in the figure. The increased pressure is then removed, and the fluid oscillates in the tube. Determine the period of the oscillations of the fluid column. (You have to determine what the known quantities are.)



•**14.33** The figure shows a mass $m_2 = 20.0$ g resting on top of a mass $m_1 = 20.0$ g, which is attached to a spring with $k = 10.0$ N/m. The coefficient of static friction between the two masses is 0.600. The masses are oscillating with simple harmonic motion on a frictionless surface. What is the maximum amplitude the oscillation can have without m_2 slipping off m_1?



••**14.34** Consider two identical oscillators, each with spring constant k and mass m, in simple harmonic motion. One oscillator is started with initial conditions x_0 and v_0; the other starts with slightly different conditions, $x_0 + \delta x$ and $v_0 + \delta v$.

a) Find the difference in the oscillators' positions, $x_1(t) - x_2(t)$, for all t.

b) This difference is *bounded;* that is, there exists a constant C, independent of time, for which $|x_1(t) - x_2(t)| \leq C$ holds for all t. Find an expression for C. What is the *best* bound, that is, the smallest value of C that works? (*Note:* An important characteristic of *chaotic* systems is exponential sensitivity to initial conditions; the difference in position of two such systems with slightly different initial conditions grows exponentially with time. You have just shown that an oscillator in simple harmonic motion is not a chaotic system.)

Section 14.2

14.35 What is the period of a simple pendulum that is 1.00 m long in each situation?

a) in the physics lab

b) in an elevator accelerating at 2.10 $\mathrm{m/s^2}$ upward

c) in an elevator accelerating 2.10 $\mathrm{m/s^2}$ downward

d) in an elevator that is in free fall

14.36 Suppose a simple pendulum is used to measure the acceleration due to gravity at various points on the Earth. If g varies by 0.16% over the various locations where it is sampled, what is the corresponding variation in the period of the pendulum? Assume that the length of the pendulum does not change from one site to another.

•**14.37** A 1.00-kg mass is connected to a 2.00-kg mass by a massless rod 30.0 cm long, as shown in the figure. A hole is then drilled in the rod 10.0 cm away from the 1.00-kg mass, and the rod and masses are free to rotate about this pivot point, P. Calculate the period of oscillation for the masses if they are displaced slightly from the stable equilibrium position.

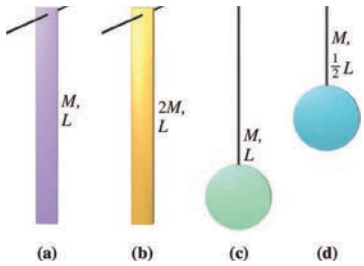
• **14.38** A torsional pendulum is a vertically suspended wire with a mass attached to one end that is free to rotate. The wire resists twisting as well as elongation and compression, so it is subject to a rotational equivalent of Hooke's Law: $\tau = -\kappa\,\theta$. Use this information to find the frequency of a torsional pendulum.

• **14.39** A physical pendulum consists of a uniform rod of mass M and length L. The pendulum is pivoted at a point that is a distance x from the center of the rod, so the period for oscillation of the pendulum depends on x: $T(x)$.

a) What value of x gives the maximum value for T?

b) What value of x gives the minimum value for T?

• **14.40** Shown in the figure are four different pendulums: (a) a rod has a mass M and a length L; (b) a rod has a mass 2 M and a length L; (c) a mass M is attached to a massless string of a length L; and (d) a mass M is attached to a massless string of length $\frac{1}{2}L$. Find the period of each pendulum when it is pulled 20° to the right and then released.



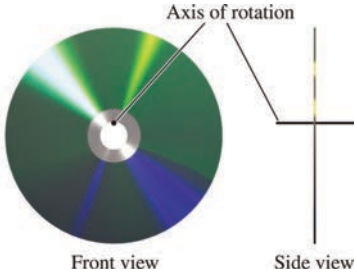
•**14.41** A grandfather clock uses a physical pendulum to keep time. The pendulum consists of a uniform thin rod of mass M and length L that is pivoted freely about one end, with a solid sphere of the same mass, M, and a radius of $L/2$ centered about the free end of the rod.

a) Obtain an expression for the moment of inertia of the pendulum about its pivot point as a function of M and L.

b) Obtain an expression for the period of the pendulum for small oscillations.

c) Determine the length L that gives a period of $T = 2.0$ s.

• **14.42** A standard CD has a diameter of 12 cm and a hole that is centered on the axis of symmetry and has a diameter of 1.5 cm. The CD's thickness is 2.0 mm. If a (very thin) pin extending through the hole of the CD suspends it in a vertical orientation, as shown in the figure, the CD may oscillate about an axis parallel to the pin, rocking back and forth. Calculate the oscillation frequency.



Section 14.3

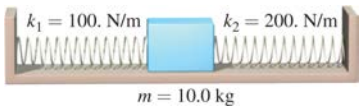
14.43 A massive object of $m = 5.00\,\text{kg}$ oscillates with simple harmonic motion. Its position as a function of time varies according to the equation $x(t) = 2\sin([\pi/2]t + \pi/6)$, where x is in meters.

a) What are the position, velocity, and acceleration of the object at $t = 0\,\text{s}$?

b) What is the kinetic energy of the object as a function of time?

c) At which time after $t = 0\,\text{s}$ is the kinetic energy first at a maximum?

14.44 The mass m shown in the figure is displaced a distance x to the right from its equilibrium position.



a) What is the net force acting on the mass, and what is the effective spring constant?

b) What will the frequency of the oscillation be when the mass is released?

c) If $x = 0.100\,\text{m}$, what is the total energy of the mass-spring system after the mass is released, and what is the maximum velocity of the mass?

•**14.45** A 2.00-kg mass attached to a spring is displaced 8.00 cm from the equilibrium position. It is released and then oscillates with a frequency of 4.00 Hz.

a) What is the energy of the motion when the mass passes through the equilibrium position?

b) What is the speed of the mass when it is 2.00 cm from the equilibrium position?

• **14.46** A Foucault pendulum is designed to demonstrate the effect of the Earth's rotation. A Foucault pendulum displayed in a museum is typically quite long, making the effect easier to see. Consider a Foucault pendulum of length 15.0 m with a 110.-kg brass bob. It is set to swing with an amplitude of 3.50°.

a) What is the period of the pendulum?

b) What is the maximum kinetic energy of the pendulum?

c) What is the maximum speed of the pendulum?

••14.47 A mass, $m_1 = 8.00$ kg, is at rest on a frictionless horizontal surface and connected to a wall by a spring with $k = 70.0\ \mathrm{N/m}$, as shown in the figure. A second mass, $m_2 = 5.00$ kg, is moving to the right at $v_0 = 17.0\ \mathrm{m/s}$. The two masses collide and stick together.

a) What is the maximum compression of the spring?

b) How long will it take after the collision to reach this maximum compression?

••14.48 A mass $M = 0.460$ kg moves with an initial speed $v = 3.20\ \mathrm{m/s}$ on a level frictionless air track. The mass is initially a distance $D = 0.250$ m away from a spring with $k = 840\ \mathrm{N/m}$, which is mounted rigidly at one end of the air track. The mass compresses the spring a maximum distance *d,* before reversing direction. After bouncing off the spring, the mass travels with the same speed *v,* but in the opposite direction.

a) Determine the maximum distance that the spring is compressed.

b) Find the total elapsed time until the mass returns to its starting point. (*Hint:* The mass undergoes a partial cycle of simple harmonic motion while in contact with the spring.)

••14.49 The relative motion of two atoms in a molecule can be described as the motion of a single body of mass m moving in one dimension, with potential energy $U(r) = A/r^{12} - B/r^6$, where r is the separation between the atoms and A and B are positive constants.

a) Find the equilibrium separation, r_0, of the atoms, in terms of the constants A and B.

b) If moved slightly, the atoms will oscillate about their equilibrium separation. Find the angular frequency of this oscillation, in terms of A, B, and m.

Section 14.4

14.50 A 3.00-kg mass attached to a spring with $k = 140.\ \mathrm{N/m}$ is oscillating in a vat of oil, which damps the oscillations.

a) If the damping constant of the oil is $b = 10.0\ \mathrm{kg/s}$, how long will it take the amplitude of the oscillations to decrease to 1.00% of its original value?

b) What should the damping constant be to reduce the amplitude of the oscillations by 99.0% in 1.00 s?

• **14.51** A vertical spring with a spring constant of $2.00\ \mathrm{N/m}$ has a 0.300-kg mass attached to it, and the mass moves in a medium with a damping constant of $0.0250\ \mathrm{kg/s}$. The mass is released from rest at a position 5.00 cm from the equilibrium position. How long will it take for the amplitude to decrease to 2.50 cm?

14.52 A mass of 0.404 kg is attached to a spring with a spring constant of $206.9\ \mathrm{N/m}$. Its oscillation is damped, with damping constant $b = 14.5\ \mathrm{kg/s}$. What is the frequency of this damped oscillation?

•**14.53** Cars have shock absorbers to damp the oscillations that would otherwise occur when the springs that attach the wheels to the car's frame are compressed or stretched. Ideally, the shock absorbers provide critical damping. If the shock absorbers fail, they provide less damping, resulting in an underdamped motion. You can perform a simple test of your shock absorbers by pushing down on one corner of your car and then quickly releasing it. If this results in an up-and-down oscillation of the car, you know that your shock absorbers need changing. The spring on each wheel of a car has a spring constant of $4005\ \mathrm{N/m}$, and the car has a mass of 851 kg, equally distributed over all four wheels. Its shock absorbers have gone bad and provide only 60.7% of the damping they were initially designed to provide. What will the period of the underdamped oscillation of this car be if the pushing-down shock absorber test is performed?

• **14.54** In a lab, a student measures the unstretched length of a spring as 11.2 cm. When a 100.0-g mass is hung from the spring, its length is 20.7 cm. The mass-spring system is set into oscillatory motion, and the student observes that the amplitude of the oscillation decreases by about a factor of 2 after five complete cycles.

a) Calculate the period of oscillation for this system, assuming no damping.

b) If the student can measure the period to the nearest 0.05 s, will she be able to detect the difference between the period with no damping and the period with damping?

• **14.55** An 80.0-kg bungee jumper is enjoying an afternoon of jumps. The jumper's first oscillation has an amplitude of 10.0 m and a period of 5.00 s. Treating the bungee cord as a spring with no damping, calculate each of the following:

a) the spring constant of the bungee cord,

b) the bungee jumper's maximum speed during the oscillation, and

c) the time for the amplitude to decrease to 2.00 m (with air resistance providing the damping of the oscillations at $7.50\ \text{kg/s}$).

••**14.56** A small mass, $m = 50.0$ g, is attached to the end of a massless rod that is hanging from the ceiling and is free to swing. The rod has length $L = 1.00$ m. The rod is displaced 10.0° from the vertical and released at time $t = 0$. Neglect air resistance. What is the period of the rod's oscillation? Now suppose the entire system is immersed in a fluid with a small damping constant, $b = 0.0100\ \text{kg/s}$, and the rod is again released from an initial displacement angle of 10.0°. What is the time for the amplitude of the oscillation to reduce to 5.00°? Assume that the damping is small. Also note that since the amplitude of the oscillation is small and all the mass of the pendulum is at the end of the rod, the motion of the mass can be treated as strictly linear, and you can use the substitution $R\theta(t) = x(t)$, where $R = 1.0$ m is the length of the pendulum rod.

Section 14.5

14.57 A 3.00-kg mass is vibrating on a spring. It has a resonant angular speed of 2.40 rad/s and a damping angular speed of 0.140 rad/s. If the sinusoidal driving force has an amplitude of 2.00 N, find the maximum amplitude of the vibration if the driving angular speed is (a) 1.20 rad/s, (b) 2.40 rad/s, and (c) 4.80 rad/s.

• **14.58** A mass of 0.404 kg is attached to a spring with a spring constant of 204.7 N/m and hangs at rest. The spring hangs from a piston. The piston then moves up and down, driven by a force given by $(29.4\ \text{N})\ \cos\left[(17.1\ \text{rad/s})t\right]$.

a) What is the maximum displacement from its equilibrium position that the mass can reach?

b) What is the maximum speed that the mass can attain in this motion?

••**14.59** A mass, $M = 1.60$ kg, is attached to a wall by a spring with $k = 578$ N/m. The mass slides on a frictionless floor. The spring and mass are immersed in a fluid with a damping constant of 6.40 kg/s. A horizontal force, $F(t) = F_{\text{d}} \cos(\omega_{\text{d}} t)$, where $F_{\text{d}} = 52.0$ N, is applied to the mass through a knob, causing the mass to oscillate back and forth. Neglect the mass of the spring and of the knob and rod. At what frequency will the amplitude of the mass's oscillation be greatest, and what is the maximum amplitude? If the driving frequency is reduced slightly (but the driving amplitude remains the same), at what frequency will the amplitude of the mass's oscillation be half of the maximum amplitude?

Additional Exercises

14.60 When the displacement of a mass on a spring is half of the amplitude of its oscillation, what fraction of the mass's energy is kinetic energy?

14.61 A mass m is attached to a spring with a spring constant of k and set into simple harmonic motion. When the mass has half of its maximum kinetic energy, how far away from its equilibrium position is it, expressed as a fraction of its maximum displacement?

14.62 If you kick a harmonic oscillator sharply, you impart to it an initial velocity but no initial displacement. For a weakly damped oscillator with mass m, spring constant k, and damping force $F_\gamma = -bv$, find $x(t)$, if the total impulse delivered by the kick is J_0.

14.63 A mass $m = 1.00\ \text{kg}$ in a spring-mass system with $k = 1.00\ \text{N/m}$ is observed to be moving to the right, past its equilibrium position with a speed of $1.00\ \text{m/s}$ at time $t = 0$.

a) Ignoring all damping, determine the equation of motion.

b) Suppose the initial conditions are such that at time $t = 0$, the mass is at $x = 0.500\ \text{m}$ and moving to the right with a speed of $1.00\ \text{m/s}$. Determine the new equation of motion. Assume the same spring constant and mass.

14.64 The motion of a block-spring system is described by $x(t) = A\sin(\omega t)$. Find ω, if the potential energy equals the kinetic energy at $t = 1.00\ \text{s}$.

14.65 A hydrogen gas molecule can be thought of as a pair of protons bound together by a spring. If the mass of a proton is $1.7 \cdot 10^{-27}\ \text{kg}$ and the period of oscillation is $8.0 \cdot 10^{-15}\ \text{s}$, what is the effective spring constant for the bond in a hydrogen molecule?

14.66 A shock absorber that provides critical damping with $\omega_\gamma = 72.4\ \text{rad/s}$ is compressed by 6.41 cm. How far from the equilibrium position is it after 0.0247 s?

14.67 Imagine you are an astronaut who has landed on another planet and wants to determine the free-fall acceleration on that planet. In one of the experiments you decide to conduct, you use a pendulum 0.500 m long and find that the period of oscillation for

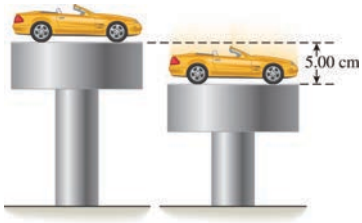
this pendulum is 1.50 s. What is the acceleration due to gravity on that planet?

14.68 A horizontal tree branch is directly above another horizontal tree branch. The elevation of the higher branch is 9.65 m above the ground, and the elevation of the lower branch is 5.99 m above the ground. Some children decide to use the two branches to hold a tire swing. One end of the tire swing's rope is tied to the higher tree branch so that the bottom of the tire swing is 0.470 m above the ground. This swing is thus a restricted pendulum. Starting with the complete length of the rope at an initial angle of 14.2° with respect to the vertical, how long does it take a child of mass 29.9 kg to complete one swing back and forth?

•14.69 Two pendulums with identical lengths of 1.000 m are suspended from the ceiling and begin swinging at the same time. One is at Manila, in the Philippines, where $g = 9.784\ \mathrm{m/s^2}$, and the other is at Oslo, Norway, where $g = 9.819\ \mathrm{m/s^2}$. After how many oscillations of the Manila pendulum will the two pendulums be in phase again? How long will it take for them to be in phase again?

• 14.70 Two springs, each with $k = 125\ \mathrm{N/m}$, are hung vertically, and 1.00-kg masses are attached to their ends. One spring is pulled down 5.00 cm and released at $t = 0$; the other is pulled down 4.00 cm and released at $t = 0.300$ s. Find the phase difference, in degrees, between the oscillations of the two masses and the equations for the vertical displacements of the masses, taking upward to be the positive direction.

• 14.71 A piston that has a small toy car sitting on it is undergoing simple harmonic motion vertically, with amplitude of 5.00 cm, as shown in the figure. When the frequency of oscillation is low, the car stays on the piston. However, when the frequency is increased sufficiently, the car leaves the piston. What is the maximum frequency at which the car will remain in place on the piston?



• **14.72** The period of a pendulum is 0.24 s on Earth. The period of the same pendulum is found to be 0.48 s on planet X, whose mass is equal to that of Earth. (a) Calculate the gravitational acceleration at the surface of planet X. (b) Find the radius of planet X in terms of that of Earth.

•**14.73** A grandfather clock uses a pendulum and a weight. The pendulum has a period of 2.00 s, and the mass of the bob is 250. g. The weight slowly falls, providing the energy to overcome the damping of the pendulum due to friction. The weight has a mass of 1.00 kg, and it moves down 25.0 cm every day. Find Q for this clock. Assume that the amplitude of the oscillation of the pendulum is 10.0°.

• **14.74** A cylindrical can of diameter 10.0 cm contains some ballast so that it floats vertically in water. The mass of can and ballast is 800.0 g, and the density of water is $1.00\ \mathrm{g/cm^3}$. The can is lifted 1.00 cm from its equilibrium position and released at $t = 0$. Find its vertical displacement from equilibrium as a function of time. Determine the period of the motion. Ignore the damping effect due to the viscosity of the water.

• **14.75** The period of oscillation of an object in a frictionless tunnel running through the center of the Moon is $T = 2\pi/\omega_0 = 6485$ s, as shown in Example 14.2. What is the period of oscillation of an object in a similar tunnel through the Earth ($R_\mathrm{E} = 6.37 \cdot 10^6$ m; $R_\mathrm{M} = 1.74 \cdot 10^6$ m; $M_\mathrm{E} = 5.98 \cdot 10^{24}$ kg; $M_\mathrm{M} = 7.35 \cdot 10^{22}$ kg)?

• **14.76** The motion of a planet in a circular orbit about a star obeys the equations of simple harmonic motion. If the orbit is observed edge-on, so the planet's motion appears to be one-dimensional, the analogy is quite direct: The motion of the planet looks just like the motion of an object on a spring.

a) Use Kepler's Third Law of planetary motion to determine the "spring constant" for a planet in circular orbit around a star with period T.

b) When the planet is at the extremes of its motion observed edge-on, the analogous "spring" is extended to its largest displacement. Using the "spring" analogy, determine the orbital velocity of the planet.

••14.77 An object in simple harmonic motion is *isochronous,* meaning that the period of its oscillations is independent of their amplitude. (Contrary to a common assertion, the operation of a pendulum clock is not based on this principle. A pendulum clock operates at fixed, finite amplitude. The gearing of the clock compensates for the anharmonicity of the pendulum.) Consider an oscillator of mass m in one-dimensional motion, with a restoring force $F(x) = -cx^3$, where x is the displacement from equilibrium and c is a constant with appropriate units. The motion of this oscillator is periodic but not isochronous.

a) Write an expression for the period of the undamped oscillations of this oscillator. If your expression involves an integral, it should be a definite integral. You do not need to evaluate the expression.

b) Using the expression of part (a), determine the dependence of the period of oscillation on the amplitude.

c) Generalize the results of parts (a) and (b) to an oscillator of mass m in one-dimensional motion with a restoring force corresponding to the potential energy $U(x) = \gamma\,|x|\alpha/\alpha$, where α is any positive value and γ is a constant.

MULTI-VERSION EXERCISES

14.78 A block of mass 1.605 kg is attached to a horizontal spring with spring constant 14.55 N/m and rests on a frictionless surface at the equilibrium position of the spring. The block is then pulled 12.09 cm from the equilibrium position and released. What is the distance of the block from the equilibrium position after $2.834 \cdot 10^{-1}$ s?

14.79 A block of mass 1.833 kg is attached to a horizontal spring with spring constant 14.97 N/m and rests on a frictionless surface at the equilibrium position of the spring. The block is then pulled 13.37 cm from the equilibrium position and released. At what time is the block located 4.990 cm from the equilibrium position?

14.80 A block of mass 1.061 kg is attached to a horizontal spring with spring constant 15.39 N/m and rests on a frictionless surface at the equilibrium position of the spring. The block is then pulled from the equilibrium position and released. After $3.900 \cdot 10^{-1}$ s, the block is located 1.25 cm from the equilibrium position. How far away from that position was the block pulled?

14.81 A pendulum consisting of a small sphere of mass 1.145 kg and a string of length 71.57 cm is suspended from a ceiling. Its motion is restricted by a peg that is sticking out of the wall 40.95 cm directly below the pivot point. What is the period of oscillation?

14.82 A pendulum consisting of a small sphere of mass 1.261 kg and a string of length 72.39 cm is suspended from a ceiling. Its motion is restricted by a peg that is sticking out of the wall directly below the pivot point. The period of oscillation is 1.404 s. How far below the ceiling is the restricting peg?

14.83 A vertical spring with spring constant 23.31 N/m is hanging from a ceiling. A small object with a mass of 1.375 kg is attached to

the lower end of the spring, and the spring stretches to its equilibrium length. The object is then pulled down a distance of 18.51 cm and released. What is the speed of the object when it is 1.849 cm from the equilibrium position?

14.84 A vertical spring with spring constant 23.51 N/m is hanging from a ceiling. A small object is attached to the lower end of the spring, and the spring stretches to its equilibrium length. The object is then pulled down a distance of 19.79 cm and released. The speed of the object a distance 7.417 cm from the equilibrium point is 0.7286 m/s. What is the mass of the object?

14.85 A vertical spring with spring constant 23.73 N/m is hanging from a ceiling. A small object with mass 1.103 kg is attached to the lower end of the spring, and the spring stretches to its equilibrium length. The object is then pulled down and released. The speed of the object when it is 4.985 cm from the equilibrium position is 0.4585 m/s. How far down was the object pulled?

When most people hear the word *waves,* the first thing they think of is ocean waves. Everybody has seen pictures of surfers riding enormous ocean waves in Hawaii or Australia (Figure 15.1) or of the towering waves created by a fierce storm on the open sea. These walls of water are certainly waves, and so are gentle breakers that wash onto a beach. However, waves are far more widespread than disturbances in water. Light and sound are both waves, and wave motion is involved in earthquakes and tsunamis as well as radio and television broadcasts. In fact, later in this book, we' ll see that the smallest, most fundamental particles of matter share many properties with waves. In a sense, we are all made of waves as much as particles.

FIGURE 15.1 Surfer riding a huge wave in Australia.

Paul kennedy/Alamy Stock Photo

In this chapter, we examine the properties and behavior of waves, building directly on Chapter 14's coverage of oscillations. We'll return to the subject of wave motion when we study light and when we consider quantum mechanics and atomic structure. Whole areas of physics are devoted to wave studies; for example, optics is the science of light waves and acoustics is the study of sound waves (see Chapter 16). Waves are also of fundamental importance in astronomy and in electronics. The concepts in this chapter are just the first steps toward understanding a large part of the physical world of waves around us.

WHAT WE WILL LEARN

- Waves are disturbances (or excitations) that propagate through space or some medium as a function of time. A wave can be understood as a series of individual oscillators coupled to their nearest neighbors.
- Waves can be either longitudinal or transverse.
- The wave equation governs the general motion of waves.
- Waves transport energy across distances; however, even though a wave is propagated by vibrating atoms in a medium, it does not generally transport matter with it.
- The superposition principle states a key property of waves: Two waveforms can be added to form another one.
- Waves can interfere with each other constructively or destructively. Under certain conditions, interference patterns form and can be analyzed.
- A standing wave can be formed by superposition of two traveling waves.
- Boundary conditions on strings determine the possible wavelengths and frequencies of standing waves.

15.1 Wave Motion

If you throw a stone in a still pond, it creates circular ripples that travel along the surface of the water, radially outward (Figure 15.2). If an object is floating on the surface of the pond (a stick, a leaf, or a rubber duck), you can observe that the object moves up and down as the ripples move outward underneath it but does not move noticeably outward with the waves.

FIGURE 15.2
Circular ripples on the surface of water.

Don Farrall/Getty Images

If you tie a rope to a wall, hold one end and stretch the rope out, and then rapidly move your arm up and down, this motion will create a wave crest that travels down the rope, as illustrated in Figure 15.3. Again this wave moves, but the material that the wave travels through (the rope) moves up and down but otherwise remains in place.

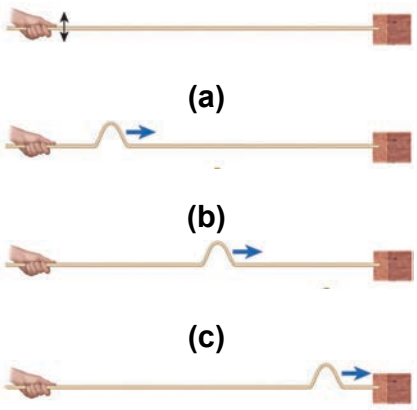

FIGURE 15.3 A rope held by a hand at one end and attached firmly to a wall at the other end. (a) The end of the rope is moved up and down by moving the hand. In (b), (c), and (d), a wave travels along the rope toward the wall.

These two examples illustrate a major characteristic of waves: A **wave** is an excitation that propagates through space or some medium as a function of time but does not generally transport matter along with it. In this fundamental way, wave motion is completely different from the motion we have studied so far. Electromagnetic and gravitational waves do not need a medium in which to propagate; they can move through empty space. Other waves do propagate in a medium; for example, sound waves can travel through a gas (air) or a liquid (water) or a solid (steel rails), but not through a vacuum.

Many other examples of waves surround us in everyday life, most of them with oscillations that are too small for us to observe. Light is an electromagnetic wave, as are the radio waves that FM and AM radios receive and the waves that carry TV signals into our houses—either through coaxial cables or through the air via broadcasts from antenna towers or geostationary satellites. We'll focus on electromagnetic waves in Chapter 31 (after we have studied electricity and magnetism in Chapters 21 through 30).

In this chapter, we study the motion of waves through media. Mechanical vibrations fall in this category, as do sound waves,

earthquake waves, and water waves. Since sound is such an important part of human communication, Chapter 16 is devoted exclusively to it.

Page 470

The stadium wave—called simply “the wave”—is a part of most major sports events: Spectators stand up and raise their arms as soon as they see their neighbor doing it, and then they sit down again. Thus, the wave travels around the stadium, but each spectator stays in place. How fast does this wave travel? Suppose that each person has a time delay comparable to his or her reaction time, 0.1 s, before imitating the adjacent spectator and getting up from the seat. Typically, seats are approximately 0.6 m (2 ft) wide. This means that the wave travels 0.6 m in 0.1 s. From simple kinematics, we know that this corresponds to a velocity of $v = \Delta x/\Delta t = (0.6\ \mathrm{m})/(0.1\ \mathrm{s}) = 6\ \mathrm{m/s}$. Since a typical football stadium is an oval with a circumference of approximately 400 m, we can estimate that it takes about 1 min for “the wave” to make it around the stadium once. This rather crude estimate is approximately right, within a factor of 2. Empirically, we find that “the wave” moves with a speed of approximately $12\ \mathrm{m/s}$. The reason for this higher speed is that people anticipate the arrival of the wave and jump up when they see the person two or three seats ahead of them jump up.

15.2 Coupled Oscillators

Let's begin our quantitative discussion of waves by examining a series of coupled oscillators—for example, a string of identical massive objects coupled by identical springs. One physical realization is shown in Figure 15.4, where a series of identical metal rods is held in place by a central horizontal bar. The rods can pivot freely about their centers and are connected to their nearest neighbors by identical springs. When the first rod is pushed, this excitation is transmitted from each rod to its neighbor, and the pulse generated in this way travels down the row of rods. Each rod is an oscillator and moves back and forth in the plane of the page. This setup represents a longitudinal coupling between the oscillators, in the sense that the direction of motion and the direction of coupling to the nearest neighbors are the same.

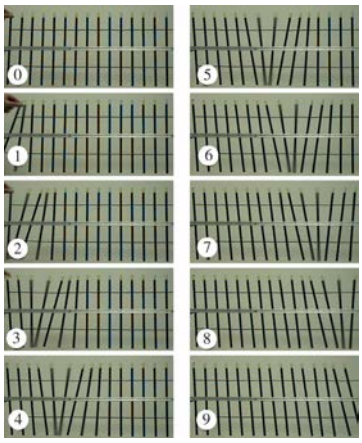

FIGURE 15.4 Series of identical rods coupled to their nearest neighbors by springs. The numbers on the frames indicate the time sequence. Each pair of frames is separated by a time interval of 0.133 s.

W. Bauer and G. D. Westfall

A physical realization of a transverse coupling is shown in Figure 15.5. In part (a) of the figure, all rods are attached to a tension strip in their horizontal equilibrium position; in part (b), rod i is deflected from the horizontal by an angle θ_i. A deflection of this kind has two effects: First, the tension strip provides a restoring force that tries to pull rod i back to the equilibrium position. Second, since the tension strip is now twisted on both sides of rod i, the deflection of that rod at an angle θ_i creates a force that acts to deflect rods $i-1$ and $i+1$ toward θ_i. If those rods are allowed to move freely, they will be deflected in that direction, and each rod in turn will generate a force acting on its two nearest neighbors.

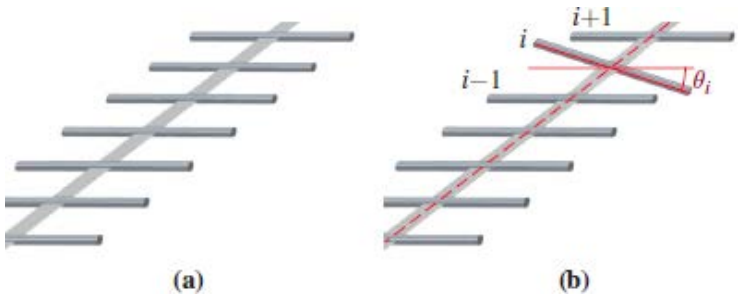

FIGURE 15.5 Parallel rods supported by a tension strip as a model for transversely coupled oscillators: (a) initial position, all rods parallel; (b) rod *i* is deflected by an angle θ_i.

Figure 15.6 shows a side view of the arrangement of parallel rods in Figure 15.5. Each circle represents the end of a rod, and the motion of this circle can be characterized by a coordinate y_i. Then y_i is related to the deflection angle, θ_i, via $y_i = \frac{1}{2} l \sin\theta_i$, where l is the length of the rod. The line connecting the circles represents the edge of the tension strip. In Figure 15.6a, all rods are in equilibrium, which implies that all deflections are zero. In Figure 15.6b, rod i is experiencing a deflection, the same as is depicted in Figure 15.5b. The force acting on rod i due to the tension in the strip is a type of spring force given by $F_i = -2ky_i$, where the effective spring constant is determined from the properties of the tension strip. Finally, in Figure 15.6c, all rods are allowed to move. The net force acting on rod i is then the sum of the forces exerted on it by rods $i+1$ and $i-1$, as mediated by the tension strip connecting the rods. These forces depend on the difference between the y-coordinates at the beginning and the end of the section of tension strip that connects the three rods:

$$F_+ = -k(y_i - y_{i+1})$$

and

$$F_- = -k(y_i - y_{i-1}).$$

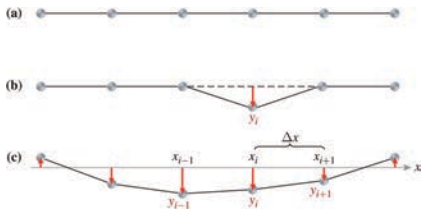

FIGURE 15.6 Side views of coupled rods of Figure 15.5: (a) equilibrium position; (b) one rod is deflected; (c) all rods are allowed to move and become deflected.

Thus, the net force acting on rod i is the sum of these two forces:

$$F_i = F_+ + F_- = -k(y_i - y_{i+1}) - k(y_i - y_{i-1}) = k(y_{i+1} - 2y_i + y$$

From Newton's Second Law, $F = ma$, we then find the acceleration, a_i of rod i:

$$ma_i = k(y_{i+1} - 2y_i + y_{i-1}). \qquad \textbf{(15.1)}$$

With initial conditions for the position and velocity of each oscillator, we could solve the resulting set of equations on a computer. However, we can actually derive a wave equation using equation 15.1, and we'll do so in Section 15.4.

Transverse and Longitudinal Waves

We need to emphasize an essential difference between the two systems of coupled oscillators shown in Figure 15.4 and Figure 15.5. In the first case, the oscillators are allowed to move only in the direction of their nearest neighbors, whereas in the second case, the oscillators are restricted to moving in a direction perpendicular to the direction of their nearest neighbors (Figure 15.7). In general, a wave that propagates along the direction in which the oscillators move is called a **longitudinal wave.** In Chapter 16, we'll see that sound waves are prototypical longitudinal waves. A wave that moves in a direction perpendicular to the direction in which the individual oscillators move is called a **transverse wave.** Light waves are transverse waves, as we will discuss in Chapter 31 on electromagnetic waves.

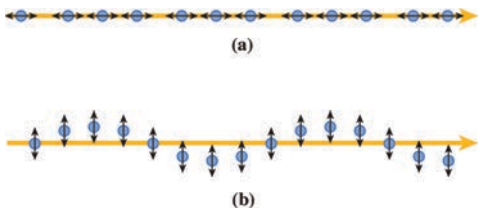

FIGURE 15.7
Representations of (a) longitudinal wave and (b) transverse wave propagating horizontally to the right. The long yellow arrows indicate the direction of wave propagation. The blue circles represent the individual oscillators, and the black double-headed arrows show the direction of their oscillations.

Seismic waves created by earthquakes exist as longitudinal (or compression) waves and as transverse waves. These waves can travel along the surface of the Earth as well as through the Earth and be detected far from the epicenter of the earthquake. The study of seismic waves has revealed detailed information about the composition of the interior of the Earth, as we'll see in Example 15.2.

15.3 Mathematical Description of Waves

So far, we have examined single wave pulses, such as the stadium wave and the wave that results from pushing once on a chain of coupled oscillators. A much more common class of wave phenomena involves a periodic excitation—in particular, a sinusoidal excitation. In the chain of oscillators of Figure 15.4 or Figure 15.5, a continuous wave can be generated by moving the first rod back and forth periodically. This sinusoidal oscillation also travels down the chain of oscillators, just like a single wave pulse.

Period, Wavelength, and Velocity

Figure 15.8a shows the result of a sinusoidal excitation as a function of both time and the horizontal coordinate, in the limit where a very large number of coupled oscillators are very close to each other—that is, in the continuum limit. First, let's examine this wave along the time axis for $x = 0$. This projection is shown in Figure 15.8b, which is a plot of the sinusoidal oscillation of the first oscillator in the chain:

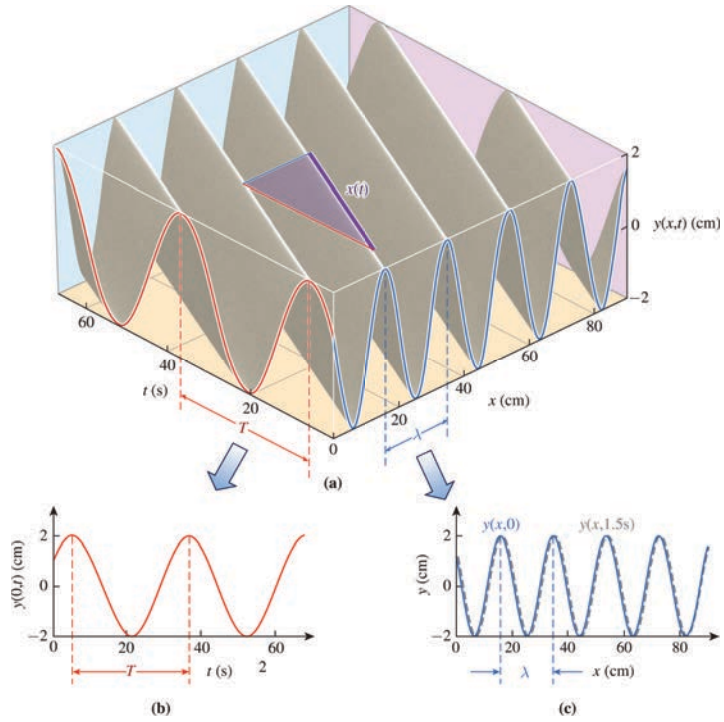

FIGURE 15.8 Sinusoidal wave: (a) the wave as a function of space and time coordinates; (b) dependence of the wave on time at position $x = 0$; (c) dependence of the wave on position at time $t = 0$ (blue curve) and at a later time $t = 1.5$ s (gray dashed curve).

$$y(x = 0, t) = A \sin(\omega t + \theta_0) = A \sin(2\pi f t + \theta_0), \quad \textbf{(15.2)}$$

where ω is the angular frequency (or angular velocity), f is the frequency, A is the amplitude of the oscillation, and θ_0 gives the phase shift. (The values used in Figure 15.8 are $A = 2.0$ cm, $\omega = 0.2$ s^{-1}, and $\theta_0 = 0.5$.) As for all oscillators, the period T is defined as the time

interval between two successive maxima and is related to the frequency by

$$T = \frac{1}{f}.$$

Figure 15.8c shows that for any given time, t, the dependence on the horizontal coordinate, x, of the oscillations is also sinusoidal. This dependence is shown for $t = 0$ (blue curve) and $t = 1.5\,\text{s}$ (gray dashed curve). The distance in space between two consecutive maxima is defined as the **wavelength,** λ.

Concept Check 15.1

The sinusoidal wave shown in Figure 15.8 is

a) traveling to the right (toward larger values of x).

b) traveling to the left (toward smaller values of x).

c) traveling neither to the right nor to the left.

d) Since this is just a snapshot of a wave, the direction of motion cannot be inferred.

As you can see in Figure 15.8a, diagonal lines of equal height describe the wave motion in the xt-plane. What is most important to realize about the wave motion depicted in Figure 15.8 and wave motion in general is that during one period, any given point on the wave advances by one wavelength.

Figure 15.9 presents the light purple triangle shown on the top surface of the wave in Figure 15.8a in the xt-plane to further illustrate the relationship among the wave velocity, the period, and the wavelength. Now you can see that the speed of propagation of the wave is in general given by

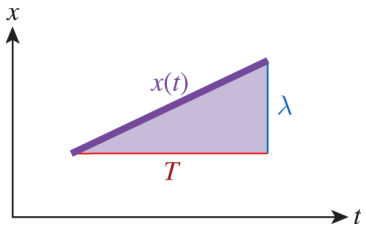

FIGURE 15.9 View of the *xt*-plane of Figure 15.8a showing that the slope of the line $x(t)$ is equal to the wave velocity defined by the ratio of the wavelength divided by the period, $v = \lambda/T$.

$$v = \frac{\Delta x}{\Delta t} = \frac{\lambda}{T},$$

or, using the relationship between period and frequency, $T = 1/f$, by

$$v = \lambda f. \tag{15.3}$$

This relationship among wavelength, frequency, and velocity holds for all types of waves and is one of the most important results in this chapter.

Sinusoidal Waveform, Wave Number, and Phase

How do we obtain a mathematical description of a sinusoidal wave as a function of space and time? We start with the motion of the oscillator at $x = 0$ (see equation 15.2), and realize that it takes a time $t = x/v$ for the excitation to move a distance x. Thus, we can simply replace t in equation 15.2 by $t - x/v$ to find the displacement $y(x,t)$ away from the equilibrium position as a function of space and time:

Page 473

Self-Test Opportunity 15.1

You are sitting in a boat in the middle of Lake Michigan. The water waves hitting the boat are traveling at $3.0\,\mathrm{m/s}$ and the crests are 7.5 m apart. What is the frequency with which the wave crests strike the boat?

$$y(x,t) = A\sin\left(\omega\left(t - \frac{x}{v}\right) + \theta_0\right).$$

We can then use equation 15.3 for the wave velocity, $v = \lambda f$, and obtain

$$\begin{aligned} y(x,t) &= A\sin\left(2\pi f\left(t - \frac{x}{v}\right) + \theta_0\right) \\ &= A\sin\left(2\pi f t - \frac{2\pi f x}{\lambda f} + \theta_0\right) \\ &= A\sin\left(\frac{2\pi}{T}t - \frac{2\pi}{\lambda}x + \theta_0\right). \end{aligned}$$

Similar to $\omega = 2\pi/T$, the expression for the **wave number,** κ, is

$$\kappa = \frac{2\pi}{\lambda}. \qquad \textbf{(15.4)}$$

Substituting ω and κ into the above expression for $y(x,t)$ then yields the descriptive function we want:

$$y(x,t) = A\sin(\omega t - \kappa x + \theta_0). \qquad \textbf{(15.5)}$$

A sinusoidal waveform of this kind is almost universally applicable when there is only one spatial dimension in which the wave can propagate. Later in this chapter, we'll generalize this waveform to more than one spatial coordinate.

We can also start with a given sinusoidal waveform at some point in space and ask where this waveform will be at a later time. From this perspective, we can write the expression for the waveform as a function of space and time as

$$y(x,t) = A\sin(\kappa x - \omega t + \phi_0). \qquad \textbf{(15.6)}$$

Equations 15.5 and 15.6 are equivalent to each other, because $\sin(-x) = -\sin(x) = \sin(\pi + x)$. The phase shift, ϕ_0, in equation 15.6 is related to the phase angle, θ_0, in equation 15.5 via $\phi_0 = \pi - \theta_0$. We'll use equation 15.6, which is the more common form, from here on.

The argument of the sine function in equation 15.6 is called the wave's **phase, $\boldsymbol{\phi}$**:

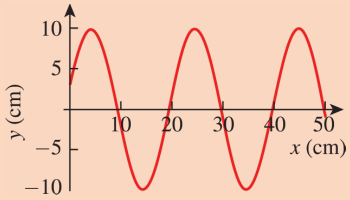
$$\phi = \kappa x - \omega t + \phi_0. \qquad \textbf{(15.7)}$$

In considering more than one wave simultaneously, the relationship of the phases of the waves plays an essential role in the analysis. Later in this chapter, we'll return to this point.

Finally, using $\kappa = 2\pi/\lambda$ and $\omega = 2\pi/T$, we can rewrite the equation for the velocity of the wave front (15.3) in terms of the wave number and the angular frequency:

Self-Test Opportunity 15.2

The figure shows a plot at $t = 0$ of a traveling wave of the form $y(x, t) = A\sin(\kappa x - \omega t + \phi_0)$. Determine the amplitude, A, the wave number, κ, and the phase shift, ϕ_0, of the wave.



$$v = \frac{\omega}{\kappa}. \qquad \textbf{(15.8)}$$

The angular frequency, ω, counts the number of oscillations in each time interval of 2π s: $\omega = 2\pi/T$, where T is the period. Similarly, the wave number, κ, counts the number of wavelengths, λ, that fit into a distance of 2π m: $\kappa = 2\pi/\lambda$. For example, $\kappa = 0.33\ \text{cm}^{-1}$ in the plot of Figure 15.8.

SOLVED PROBLEM 15.1 Traveling Wave

PROBLEM

A wave on a string is given by the function

$$y(x,t) = (0.00200\ \text{m})\sin\left[\left(78.8\ \text{m}^{-1}\right)x + \left(346\ \text{s}^{-1}\right)t\right].$$

What is the wavelength of this wave? What is its period? What is its velocity?

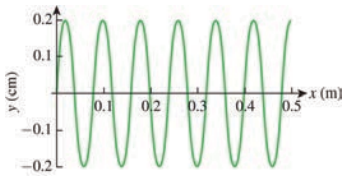
SOLUTION

THINK

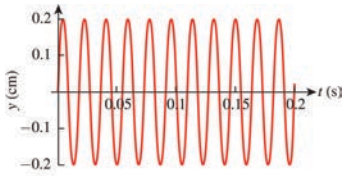
From the given wave function, we can identify the wave number and the angular frequency, from which we can extract the wavelength and period. We can then calculate the velocity of the traveling wave from the ratio of the angular frequency to the wave number.

SKETCH

Figure 15.10 shows plots of the wave function at $t = 0$ (part a) and at $x = 0$ (part b).



(a)



(b)

FIGURE 15.10 (a) The wave function at $t = 0$. (b) The wave function as a function of time at $x = 0$.

RESEARCH

Looking at the wave function given in the problem statement, $y(x,t) = (0.00200\,\text{m})\sin\left[\left(78.8\,\text{m}^{-1}\right)x + \left(346\,\text{s}^{-1}\right)t\right]$, and comparing it with the solution to the wave equation for a wave traveling in the negative x-direction (see equation 15.6),

$$y(x,t) = A\sin\left(\kappa x + \omega t + \phi_0\right),$$

we see that $\kappa = 78.8\,\text{m}^{-1}$ and $\omega = 346\,\text{s}^{-1}$.

SIMPLIFY

We can obtain the wavelength from the wave number,

$$\lambda = \frac{2\pi}{\kappa},$$

and the period from the angular frequency,

$$T = \frac{2\pi}{\omega}.$$

We can calculate the velocity of the wave from

$$v = \frac{\omega}{\kappa}.$$

CALCULATE

Putting in the numerical values, we get the wavelength and the period:

$$\lambda = \frac{2\pi}{78.8\,\text{m}^{-1}} = 0.079736\,\text{m}$$

and

$$T = \frac{2\pi}{346\,\text{s}^{-1}} = 0.018159\,\text{s}.$$

We now calculate the velocity of the traveling wave:

$$v = \frac{346\,\text{s}^{-1}}{78.8\,\text{m}^{-1}} = 4.39086\,\text{m/s}.$$

ROUND

We report our results to three significant figures:

$$\lambda = 0.0797\,\text{m}$$
$$T = 0.0182\,\text{s}$$
$$v = 4.39\,\text{m/s}.$$

DOUBLE-CHECK

To double-check our result for the wavelength, we look at Figure 15.10a. We can see that the wavelength (the distance required to complete one oscillation) is approximately 0.08 m, in agreement with our result. Looking at Figure 15.10b, we can see that the period (the time required to complete one oscillation) is approximately 0.018 s, also in agreement with our result.

Concept Check 15.2

The sinusoidal wave in Solved Problem 15.1 is traveling in the negative *x*-direction. Which of the following waves is traveling in the positive *x*-direction?

a) $y(x, t) = (-0.002\ \text{m})\sin\left[\left(78.8\,\text{m}^{-1}\right)x + \left(346\,\text{s}^{-1}\right)t\right]$

b) $y(x, t) = (0.002\ \text{m})\sin\left[\left(78.8\,\text{m}^{-1}\right)x + \left(346\,\text{s}^{-1}\right)t - 1\right]$

c) $y(x, t) = (0.00200\ \text{m})\sin\left[\left(-78.8\,\text{m}^{-1}\right)x + \left(346\,\text{s}^{-1}\right)t\right]$

d) None of the above.

e) All of the above.

15.4 Derivation of the Wave Equation

In this section, we derive a general equation of motion for waves, called simply the **wave equation:**

$$\frac{\partial^2}{\partial t^2} y(x,t) - v^2 \frac{\partial^2}{\partial x^2} y(x,t) = 0, \qquad \textbf{(15.9)}$$

where $y(x,t)$ is the displacement from the equilibrium position as a function of a single space coordinate, x, and a time coordinate, t, and v is the speed of propagation of the wave. This wave equation describes all undamped wave motion in one dimension.

DERIVATION 15.1 Wave Equation

Figure 15.11 reproduces Figure 15.6c. The x-axis, pointing in the conventional horizontal direction and to the right, is (as usual) perpendicular to the y-axis, along which the motion of each individual oscillator occurs. The horizontal distance between neighboring oscillators is Δx. The displacements of the oscillators, given by $y(x,t)$, are then functions of time and of position along the x-axis, with $y_i = y(x_i,t)$. The acceleration is defined as the second derivative of the displacement, $y(x,t)$, with respect to time. Since the displacement depends on more than one variable in this case (time as well as the horizontal coordinate), we need to use a partial derivative to express this relationship:

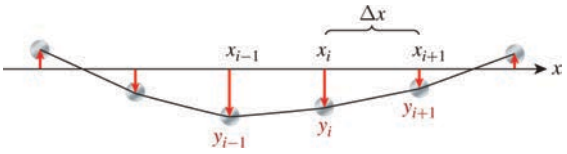


FIGURE 15.11 Side views of coupled rods where all rods are allowed to deflect.

$$a = \frac{\partial^2}{\partial t^2} y(x,t). \qquad \text{(i)}$$

If we go back to the original definition of the derivative as the limit of the ratio of differences, we can approximate a partial derivative with respect to the x-coordinate as

$$\frac{\partial}{\partial x} y(x,t) = \frac{\Delta y}{\Delta x} = \frac{y_{i+1} - y_i}{\Delta x}.$$

We can then approximate the second derivative as

$$\frac{\partial^2}{\partial x^2} y(x,t) = \frac{\Delta\left(\frac{\Delta y}{\Delta x}\right)}{\Delta x} = \frac{\frac{(y_{i+1} - y_i)}{\Delta x} - \frac{(y_i - y_{i-1})}{\Delta x}}{\Delta x} = \frac{y_i}{}$$

Both the right-hand side of this equation and the right-hand side of equation 15.1 contain $y_{i+1} - 2y_i + y_{i-1}$. Thus, we can combine these two equations:

$$ma_i = k(\Delta x)^2 \frac{\partial^2}{\partial x^2} y(x,t).$$

Substituting the second partial derivative of position with respect to time from equation (i) for the acceleration, we find

$$m\left[\frac{\partial^2}{\partial t^2} y(x,t)\right] = k\left(\Delta x^2\right) \frac{\partial^2}{\partial x^2} y(x,t).$$

Finally, we divide by the mass of the oscillator and obtain

$$\frac{\partial^2}{\partial t^2} y(x,t) - \frac{k}{m}(\Delta x)^2 \frac{\partial^2}{\partial x^2} y(x,t) = 0. \qquad \text{(ii)}$$

Page 476

This equation relating the second partial derivatives with respect to time and position is a form of the wave equation. The term $\frac{k}{m}(\Delta x)^2$ in equation (ii) is a constant determined by the specific parameters of the coupled oscillator being studied. We can define a constant $a^2 = \frac{k}{m}(\Delta x)^2$ with units $(\mathrm{m/s})^2$ so that equation (ii) becomes the wave equation

$$\frac{\partial^2}{\partial t^2} y(x,t) - a^2 \frac{\partial^2}{\partial x^2} y(x,t) = 0,$$

where a^2 is a constant to be determined.

The factor $\frac{k}{m}(\Delta x)^2$ can be factored into two components, $k(\Delta x)$ and $1/(m/(\Delta x))$. In the limit where the oscillators get very close to one

another, the first factor remains constant because as a spring is shortened, its spring constant increases. The second term is the inverse of the linear mass density, which is the same for any small section as it is for the overall system. Thus, the solution to the wave equation 15.9 provides the exact solution to the difference equation 15.1. Equation 15.9 is of general importance, and its applicability far exceeds the problem of coupled oscillators. The basic form given in equation 15.9 holds for the propagation of sound waves, light waves, or waves on a string. The difference in physical systems exhibiting wave motion manifests itself only in the way v, the speed of propagation of the wave, is calculated.

In mathematical terms, equation 15.9 is a partial differential equation. As you may know, some semester-long courses are entirely devoted to partial differential equations, and you will encounter many more partial differential equations if you major in the physical sciences or engineering.

Solutions of the Wave Equation

In Section 15.3, we developed equation 15.6, describing a sinusoidal waveform. Let's see if this is a solution of the general wave equation found in Derivation 15.1. To do this, we have to take the partial derivatives of equation 15.6 with respect to the x-coordinate and with respect to time:

$$\frac{\partial}{\partial t}y(x,t) = \frac{\partial}{\partial t}(A\sin(\kappa x - \omega t + \phi_0)) = -A\omega\cos(\kappa x - \omega t + \phi$$
$$\frac{\partial^2}{\partial t^2}y(x,t) = \frac{\partial}{\partial t}(-A\omega\cos(\kappa x - \omega t + \phi_0)) = -A\omega^2\sin(\kappa x - \omega t$$
$$\frac{\partial}{\partial x}y(x,t) = \frac{\partial}{\partial x}(A\sin(\kappa x - \omega t + \phi_0)) = A\kappa\cos(\kappa x - \omega t + \phi$$
$$\frac{\partial}{\partial x^2}y(x,t) = \frac{\partial}{\partial x}(A\kappa\cos(\kappa x - \omega t + \phi_0)) = -A\kappa^2\sin(\kappa x - \omega t +$$

Inserting these partial derivatives into the result from Derivation 15.1, we find

$$\begin{aligned}\frac{\partial^2}{\partial t^2}y(x,t) - a^2\frac{\partial^2}{\partial x^2}y(x,t) &= \\ \left[-A\omega^2\sin(\kappa x - \omega t + \phi_0)\right] - v^2\left[-A\kappa^2\sin(\kappa x - \omega t + \phi_0)\right] &= \\ -A\sin(\kappa x - \omega t + \phi_0)\left(\omega^2 - a^2\kappa^2\right) &=\end{aligned}$$

Thus we see that the function given by equation 15.6 is a solution of the wave equation derived in Derivation 15.1 provided that $\omega^2 - a^2\kappa^2 = 0$, or equivalently $a^2 = \omega^2/\kappa^2$. From equation 15.8 we know that $v = w/k$ so equation 15.6 is a solution to the wave equation with $a^2 = v^2$, corresponding to the general wave equation stated in equation 15.9.

Is there a larger class of solutions that includes the one we have already found? Yes, any arbitrary, continuously differentiable function Y with an argument containing the same linear combination of x and t as in equation 15.6, $\kappa x - \omega t$, is a solution to the wave equation. The

constants ω, k, and ϕ_0 can have arbitrary values. However, the convention generally followed is that the angular frequency and the wave number are both positive numbers. Thus, there are two general solutions to the wave equation:

$$Y(\kappa x - \omega t + \phi_0) \text{ for a wave moving in the positive } x-\text{direct}$$

and

$$Y(\kappa x + \omega t + \phi_0) \text{ for a wave moving in the negative } x-\text{direct}$$

This result is perhaps more obvious if we write these functions in terms of arguments that involve the wave speed, $v = \omega/\kappa$. We then see that $Y(x - vt + \phi_0/\kappa)$ is a solution for an arbitrary waveform moving in the positive *x*-direction and $Y(x + vt + \phi_0/\kappa)$ is a solution for a waveform moving in the negative *x*-direction.

As previously stated, the functional form of Y does not matter at all. We can see this by looking at the chain rule for differentiation, $df(g(x))/dx = (df/dg)(dg/dx)$. The partial derivatives in space and time contain the common factor df/dg, which cancels out in the same way that the sine function factored out in equation 15.10. Thus, the derivatives of the function $g = \kappa x \pm \omega t + \phi_0$ always lead to the same condition, $\omega^2 - v^2\kappa^2 = 0$, as applied to the solution for the sinusoidal waveform.

Waves on a String

String instruments form a large class of musical instruments. Guitars (Figure 15.12), cellos, violins, mandolins, harps, and others fall into this category. These instruments produce musical sounds when vibrations are induced on their strings.

FIGURE 15.12 (a) Typical electric guitar used by a rock band. (b) World's smallest guitar, produced in 2004 in the Cornell NanoScale Science and Technology Facility. It is smaller than the guitar in part (a) by a factor of 10^5 and has a length of $10\ \mu\text{m}$, approximately $\frac{1}{10}$ of the width of a human hair.

a: Ingram Publishing/Alamy Stock Photo; **b:** Image courtesy of Cornell University

Suppose a string has a mass M and a length L. In order to find the wave speed, v, on this string, we can think of it as composed of many small individual segments of length Δx and mass m, where

$$m = \frac{M\Delta x}{L} = \mu \Delta x.$$

Here the linear mass density, μ of the string is its mass per unit length (assumed to be constant):

$$\mu = \frac{M}{L}.$$

We can then treat the motion of a wave on a string as that of coupled oscillators. The restoring force is provided by the string tension force, F. The motion of a wave on a string is described by the wave equation with a wave velocity given by

$$v = \sqrt{\frac{F}{\mu}}. \qquad \textbf{(15.13)}$$

If you are curious about the origin of equation 15.13, you can work through Conceptual Question 15.21.

What does equation 15.13 imply? There are two immediate consequences. First, increasing the linear mass density of the string (that is, using a heavier string) reduces the wave velocity on the string. Second, increasing the string tension (for example, by tightening the tuning knobs at the top of the electric guitar shown in Figure 15.12) increases the wave velocity. If you play a string instrument, you know that tightening the tension increases the pitch of the sound produced by a string. We'll return to the relationship of tension to sound later in this chapter.

EXAMPLE 15.1 Elevator Cable

An elevator repairman (mass = 73 kg) sits on top of an elevator cabin of mass 655 kg inside a shaft in a skyscraper. A 61-m-long steel cable of mass 38 kg suspends the cabin. The man sends a signal to his colleague at the top of the elevator shaft by tapping the cable with his hammer.

PROBLEM

How long will it take for the wave pulse generated by the hammer to travel up the cable?

SOLUTION

The cable is under tension from the combined weight of the elevator cabin and the repairman:

$$F = mg = (73\ \text{kg} + 655\ \text{kg})\left(9.81\ \text{m/s}^2\right) = 7142\text{N}.$$

The linear mass density of the steel cable is

$$\mu = \frac{M}{L} = \frac{38\ \text{kg}}{61\ \text{m}} = 0.623\ \text{kg/m}.$$

Therefore, according to equation 15.13, the wave speed on this cable is

$$v = \sqrt{\frac{F}{\mu}} = 107\ \text{m/s}.$$

To travel up the 61-m-long cable, the pulse needs a time of

$$t = \frac{L}{v} = \frac{61\ \text{m}}{107\ \text{m/s}} = 0.57\ \text{s}.$$

DISCUSSION

This solution implies that the string tension is the same everywhere in the cable. Is this true? Not quite! We cannot really neglect the weight of the cable itself in determining the tension. The speed we

calculated is correct for the lowest point of the cable, where it attaches to the cabin. However, the tension at the upper end of the cable also has to include the complete weight of the cable. There the tension is

$$F = mg = (73\ \text{kg} + 655\ \text{kg} + 38\ \text{kg})\left(9.81\ \text{m/s}^2\right) = 7514\ \text{N},$$

which yields a wave speed of 110 m/s, about 3% greater than what we calculated. If we had to take this effect into account, we would have to calculate how the wave speed depends on the height and then perform the proper integration. However, since the maximum correction is 3%, we can assume that the average correction is about 1.5%, use an average wave speed of 108.5 m/s, and obtain a signal propagation time of 0.56 s. Thus, taking the mass of the cable into account changes the result by only 0.01 s.

Reflection of Waves

What happens when a wave traveling on a string encounters a boundary? The end of a string tied to a support on the wall can be considered a boundary. In Figure 15.3, a wave was initiated on a rope by moving one end of the rope up and down. The wave then traveled along the rope. When the wave reaches the end of the rope that is tied to a fixed support on the wall, the wave reflects as shown in Figure 15.13. Because the end of the rope is fixed, the reflected wave is inverted and returns in the opposite direction with a negative height. The amplitude of the wave at the fixed end point is zero.

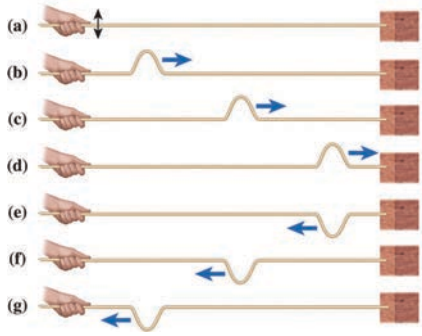

FIGURE 15.13 A rope held by a hand at one end and attached firmly to a wall at the other end. (a) The end of the rope is moved up and down. In (b), (c), and (d), a wave travels along the rope toward the right. In (e), (f), and (g), the wave travels along the rope toward the left after reflecting from the fixed end point at the wall.

If the end of the rope is attached via a frictionless movable connection, such as the one shown in Figure 15.14, the wave is reflected with no change in phase, and the returning wave has a positive amplitude. The maximum amplitude of the wave at the movable end point is twice the initial amplitude of the wave.

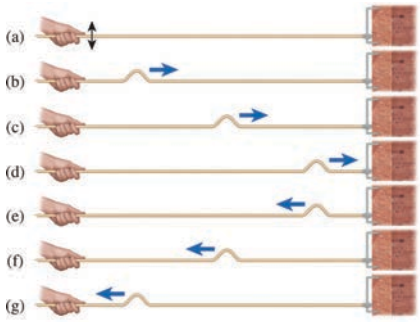

FIGURE 15.14 A rope held by a hand at one end and attached with a frictionless movable connection to a wall at the other end. (a) The end of the rope is moved up and down. In (b), (c), and (d), a wave travels along the rope toward the right. In (e), (f), and (g), the wave travels along the rope toward the left after reflecting from the movable end point.

In Chapter 34, we'll see that a light wave can be reflected at a boundary between two optical media with or without a phase change, depending on the properties of the two media.

15.5 Waves in Two- and Three-Dimensional Spaces

So far, we have only described one-dimensional waves, those moving on a string and on a linear chain of coupled oscillators. However, waves on the surface of water, like those in Figure 15.2, spread in a two-dimensional space—the plane of the water surface. A light bulb and a loudspeaker also emit waves, and these waves spread in three dimensions. Thus, a more complete mathematical description of wave motion is needed. A completely general treatment exceeds the scope of this text, but we can examine two special cases that cover most of the important wave phenomena that occur in nature.

Spherical Waves

If you examine Figure 15.2 and Figure 15.15, you see waves generated from one point and spreading as concentric circles. The mathematical idealization of waves emitted from point sources describes the waves as moving outward in concentric circles in two spatial dimensions or in concentric spheres in three spatial dimensions. Sinusoidal waveforms that spread in this way are described mathematically by

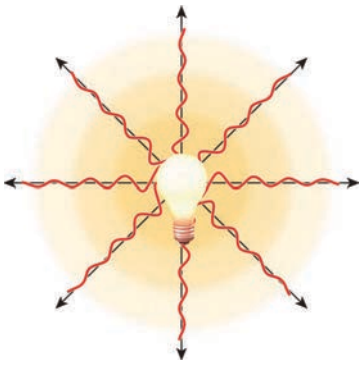

FIGURE 15.15
Waves spreading radially outward from a point source (a light bulb, in this case). The inner and outer surfaces of each concentric colored band are 1 wavelength apart.

$$\psi\left(\vec{r}, t\right) = A(r)\sin(\kappa r - \omega t + \phi_0). \qquad \textbf{(15.14)}$$

Here $\vec{r}$ is the position vector (in two or three dimensions), and $r = \left|\vec{r}\right|$ is its absolute value. Note that for the multidimensional case, we no longer use the letter y to represent the wave displacement but instead use the Greek letter Ψ (psi). This is necessary because multidimensional wave motion can depend on the y-coordinate as well as on the x-coordinate.

You can convince yourself that equation 15.14 describes waveforms in concentric circles (in two dimensions) or spheres (in three

dimensions) if you remember that the circumference of a circle or surface of a sphere has a constant distance to the origin and thus r has a constant value. A constant value of r at some time t implies a constant phase, $\phi = \kappa r - \omega t + \phi_0$. Since all of the points on a given circle or on the surface of a given sphere have the same phase, they have the same state of oscillation. Therefore, equation 15.14 indeed describes circular or spherical waves.

A waveform described by equation 15.14 does not have a constant amplitude, A, but one that depends on the radial distance to the origin of the wave (Figure 15.16). When we talk about energy transport by waves in Section 15.6, it will become clear that radial dependence of the amplitude is necessary for two- and three-dimensional waves and that the amplitude has to be a steadily decreasing function of the distance from the source. We'll use energy conservation to find out exactly how the amplitude varies with distance, but for now we'll use $A(r) = C/r$ (where C is a constant) for a three-dimensional spherical wave. For such a wave, equation 15.14 becomes

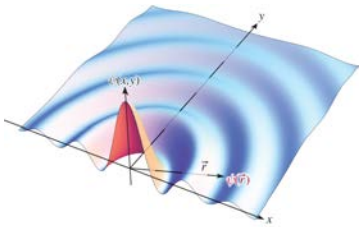

FIGURE 15.16 A spherical wave as a function of two spatial coordinates.

$$\psi\left(\overrightarrow{r}, t\right) = \frac{C}{r}\sin(\kappa r - \omega t + \phi_0). \qquad \textbf{(15.15)}$$

Plane Waves

Spherical waves originating from a point source can be approximated as plane waves at points that are very far away from the source. As shown in Figure 15.17, **plane waves** are waves for which the surfaces of constant phase are planes. For example, the light coming from the Sun is in the form of plane waves when it hits the Earth. Why can we use the plane-wave approximation? If we calculate the curvature of a sphere as a function of its radius and let that radius approach infinity, the curvature approaches zero. This means that any surface segment of this sphere locally looks like a plane. For example, the Earth is basically a sphere, but it is so large that locally the surface looks like a plane to us.

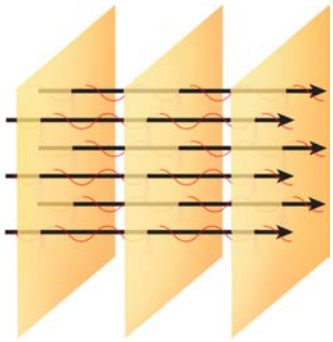

FIGURE 15.17 Plane waves. Each parallel plane represents a surface of constant phase. Adjacent planes are two wavelengths apart.

For a mathematical description of a plane wave, we can use the same functional form as for a one-dimensional wave:

$$\psi\left(\overrightarrow{r}, t\right) = A\sin(\kappa x - \omega t + \phi_0), \qquad \textbf{(15.16)}$$

where the x-axis is locally defined as the axis perpendicular to the plane of the wave. You may wonder why equation 15.16 again includes a constant amplitude. The answer is that very far away from the origin, ψ/r varies very slowly as a function of r, so using a constant amplitude gives the same degree of approximation as approximating the curvature

of a sphere as zero. For a perfectly flat planar wave, the amplitude is indeed constant.

Surface Waves

On December 26, 2004, an earthquake of magnitude 9.0 under the Indian Ocean off the coast of Sumatra triggered a *tsunami* (a Japanese word meaning "harbor wave"). This tsunami caused incredible destruction in the Aceh province of Indonesia and then raced across the Indian Ocean with the speed of a jetliner and caused many casualties in India and Sri Lanka. A computer simulation of the propagation of the tsunami is shown in Figure 15.18. What is the physical basis of the motion of a tsunami?

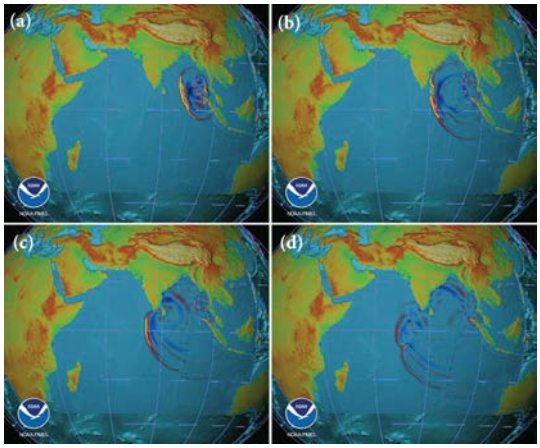

FIGURE 15.18 A computer simulation of the propagation of the tsunami near Sumatra that occurred on December 26, 2004. The four frames cover a time period of several hours.

NOAA

When an underwater earthquake occurs, the seafloor is often locally displaced and shifted upward as two plates of the Earth's crust move over each other. Thus, the water in the ocean is displaced, causing a pressure wave. This is one of the rare instances of a wave that carries matter (in this case, water) along with it; water does crash on the shore. However, the water reaching shore did not originate at the site of the earthquake, so no long-distance transportation of water takes place in a tsunami. We'll consider pressure waves in more detail in Chapter 16. For now, you only need to know that the pressure waves in the ocean have very long wavelengths, up to 100 km or even more. Since this wavelength is much larger than the typical depth of the ocean, which is approximately 4 km, the pressure waves resulting from earthquakes

cannot spread spherically, but only as surface waves. For these surface waves, the local wave speed is not constant, but depends on the depth of the ocean:

$$v_{\text{surface}} = \sqrt{gd}, \tag{15.17}$$

where $g = 9.81\ \text{m/s}^2$ is the acceleration due to gravity and d is the depth of the ocean, in meters. For a depth of 4000 m, this results in a wave speed of 200 m/s, or approximately 450 mph, as fast as a jetliner. However, when the leading edge of a tsunami reaches the shallow coastal waters, the wave speed decreases according to equation 15.17. This causes a pileup, as water farther out in the ocean is still traveling at a higher speed and catches up with the water that forms the leading edge of the tsunami. Thus, a tsunami wave crest has a height on the order of only a foot in the open ocean and can pass unnoticed under ships, while near shore it creates a wall of water up to 100 ft high that sweeps away everything in its path.

Seismic Waves

Earthquakes also generate waves that travel through the Earth. Two kinds of seismic waves generated by earthquakes are compression waves and transverse waves. Seismic compression waves are often called *P* (or *primary*) *waves,* and seismic transverse waves are often termed *S* (or *secondary*) *waves.* P waves can travel in solids and liquids, but S waves can travel only in solids. Liquids such as molten iron cannot sustain S waves.

The Earth has a variable composition as a function of distance from the center, as shown in Figure 15.19a. At the center of the Earth is an inner core composed mainly of solid iron and nickel. Next comes the outer core, which is composed mostly of molten iron. The inner and outer mantles are composed of lighter elements and exist in a solid, plastic state. The crust is hard and brittle. Most of the mass of the Earth is concentrated in the mantle.

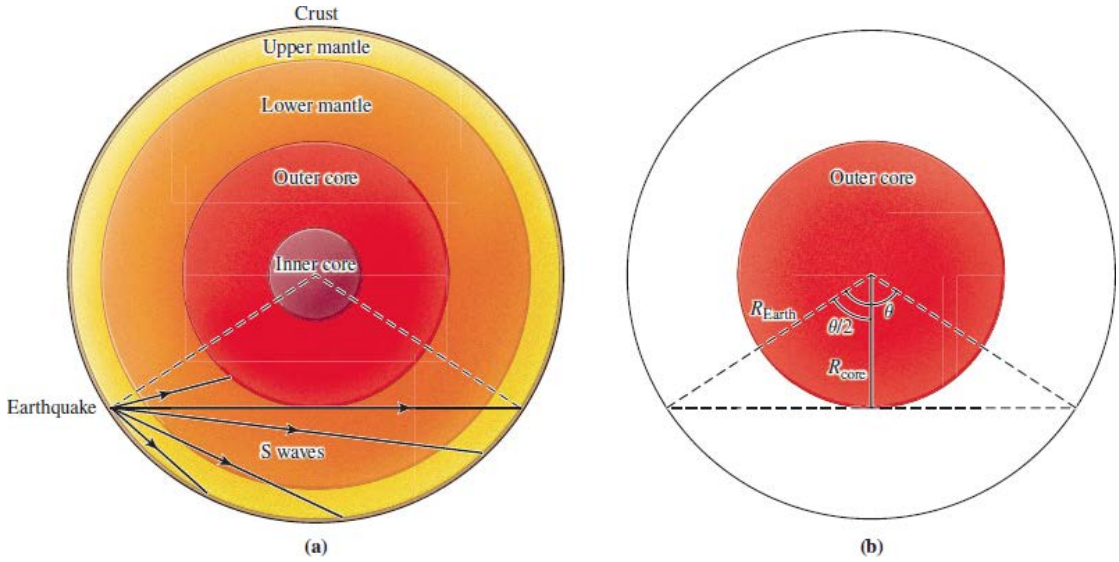

FIGURE 15.19 (a) The composition of the interior of the Earth. An earthquake takes place, creating S waves. The S waves can travel in the crust, the upper mantle, and the lower mantle but cannot travel in the molten outer core. (b) No S waves are observed at points around the Earth at angles greater than θ from the earthquake because the S waves cannot transit the molten outer core.

Seismic waves travel from the epicenter of the earthquake through the Earth and can be detected on the surface far away. Seismic compression (P) waves can traverse the entire volume of the Earth, while seismic transverse (S) waves cannot penetrate the molten core.

Thus, the core limits the extent of observation for S waves, as illustrated in Figure 15.19.

EXAMPLE 15.2 Measuring the Size of the Earth's Molten Core

Scientists have observed that the maximum angle around the surface of the Earth where S waves from an earthquake are observed is $\theta = 150^\circ$ (see Figure 15.19b). This effect is due to the fact that S waves cannot travel in the Earth's outer core because molten iron cannot support shear forces. The radius of the Earth is 6370 km.

PROBLEM

What is the radius of the molten core of the Earth?

SOLUTION

Looking at Figure 15.19b, we see that we can relate the radius of the molten core, R_{core}, the radius of the Earth, R_{Earth}, and the maximum angle of observation of S waves at the surface of the Earth:

$$\cos\left(\frac{\theta}{2}\right) = \frac{R_{\text{core}}}{R_{\text{Earth}}}.$$

We can then solve for the radius of the molten core:

$$R_{\text{core}} = R_{\text{Earth}} \cos\left(\frac{\theta}{2}\right) = (6370\ \text{km}) \cos\left(\frac{105^\circ}{2}\right) = 3880\ \text{km}$$

Note that this result is only approximate. Seismic transverse waves do not travel in exactly straight lines because of variations in density as a function of depth in the Earth. However, the calculated result is reasonably close to the measured value, $R_{\text{core}} = 3480$ km, which has been obtained by combining several different methods.

Earthquakes are not the only source of seismic waves. Such waves can also be generated through the underground use of explosives such as dynamite or TNT or even nuclear bombs. Thus, the monitoring of seismic waves is used to verify nuclear test bans and nonproliferation of nuclear weapons. Other means of generating seismic waves are thumper-trucks (which lift a large mass approximately 3 m off the ground and drop it), air guns, plasma sound sources, and hydraulic or electromechanical shakers. Why would anyone want to generate seismic waves? The waves can be used similar to the way S waves were used in Example 15.2 to look for underground deposits of different density. This basic technique of reflection seismology is widely utilized in oil and gas exploration and is thus of great current research interest.

15.6 Energy, Power, and Intensity of Waves

Section 15.1 pointed out that waves do not generally transport matter. However, they do transport energy, and in this section, we will determine how much.

Energy of a Wave

In Chapter 14, we saw that the energy of a mass oscillating on a spring is proportional to the spring constant and to the square of the oscillation amplitude: $E = \frac{1}{2}kA^2$. The energy of a wave is described by

$$E = \tfrac{1}{2}m\omega^2[A(r)]^2, \qquad \textbf{(15.18)}$$

where the amplitude of the wave has a radial dependence, as explained in Section 15.5. We see that the energy of a wave is proportional to the square of the amplitude and the square of the frequency. You can understand the derivation of equation 15.18 by working through Conceptual Question 15.22.

If the wave moves through an elastic medium, the mass, *m,* that appears in equation 15.18 can be expressed as $m = \rho V$, where ρ is the density and V is the volume through which the wave passes. This volume is the product of the cross-sectional area, $A_\perp$ (the area perpendicular to the velocity vector of the wave), that the wave passes through and the distance that the wave travels in time *t,* or $l = vt$. (*Note:* The symbol $A_\perp$ indicates the area, whereas the symbol *A,* without the subscript $\perp$, is used for the wave amplitude!) Thus, we find for the energy in this case

$$E = \tfrac{1}{2}\rho V\omega^2[A(r)]^2 = \tfrac{1}{2}\rho A_\perp l\omega^2[A(r)]^2 = \tfrac{1}{2}\rho A_\perp vt\omega^2[A(r)]^2.$$

If the wave is a spherical wave radiating outward from a point source and if no energy is lost to damping, we can determine the radial dependence of the amplitude from equation 15.19. In such a case, the energy for a given time *t* is a constant at a fixed value of *r,* as are the equilibrium density of the medium, the angular frequency, and the wave velocity. Equation 15.19 then yields the condition $A_\perp[A(r)]^2 = \text{constant}$. For a spherical wave in three dimensions, the area through which the wave passes is the surface of a sphere, as shown

in Figure 15.15. Thus, in this case, $A_{\perp} = 4\pi r^2$, and we obtain $r^2[A(r)]^2 = \text{constant} \Rightarrow A(r) \propto 1/r$. This is exactly the result for the radial dependence of the amplitude that was used in equation 15.15.

If the wave is spreading strictly in a two-dimensional space, as is true of surface waves on water, then the cross-sectional area is proportional to the circumference of a circle and is thus proportional to r, not r^2. In this case, we obtain for the radial dependence of the wave amplitude $r[A(r)]^2 = \text{constant} \Rightarrow A(r) \propto 1/\sqrt{r}$.

Power and Intensity of a Wave

In Chapter 5, we saw that the average power is the rate of energy transfer per time. With the energy contained in a wave as given by equation 15.19, we then have

$$\overline{P} = \frac{E}{t} = \tfrac{1}{2}\rho A_{\perp} v \omega^2 [A(r)]^2. \qquad \textbf{(15.20)}$$

Since all quantities on the right-hand side of equation 15.20 are independent of time, the power radiated by a wave is constant in time. Note that this equation applies to both transverse and longitudinal waves.

The intensity, *I,* of a wave is defined as the power radiated per unit cross-sectional area:

$$I = \frac{\overline{P}}{A_{\perp}}.$$

Substituting for $\overline{P}$ from equation 15.20 into this definition leads to

$$I = \tfrac{1}{2}\rho v \omega^2 [A(r)]^2. \qquad \textbf{(15.21)}$$

As you can see from this result, the intensity depends on the square of the amplitude, and so the radial dependence of the intensity is due to the dependence of the amplitude on the radial distance from the point of propagation. For a spherical wave in three dimensions, $A(r) \propto 1/r$, and thus

$$I \propto \frac{1}{r^2}.$$

Thus, for two points that are at distances of r_1 and r_2 from the point of propagation of a spherical wave, the intensities $I_1 = I(r_1)$ and $I_2 = I(r_2)$ measured at these two locations are related via

$$\frac{I_1}{I_2} = \left(\frac{r_2}{r_1}\right)^2, \tag{15.22}$$

as shown in Figure 15.20.

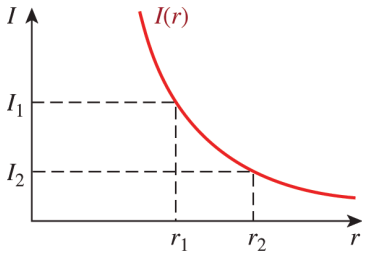

FIGURE 15.20
Inverse square law for the intensities of a spherical wave at two different distances from the source.

Figure 15.21 illustrates the dependence of the intensity of a wave on the distance from the source. If the intensity of a wave at a distance r is I, then the intensity of the wave at a distance of $2r$ is $I/4$. You can see why this relationship is true in Figure 15.21 because the same amount of power is passing through an area four times the size of $A_\perp$. Similarly, at a distance of $3r$, the intensity is $I/9$ because the same amount of power is passing through nine times the area.

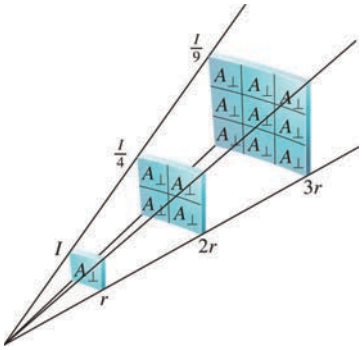

FIGURE 15.21 The intensity of a wave at a distance r is I. At a distance of $2r$, the intensity is $I/4$. At a distance of $3r$, the intensity is $I/9$.

Self-Test Opportunity 15.3

The intensity of electromagnetic waves from the Sun at the Earth is approximately $1400\ \mathrm{W/m^2}$. The distance of the Earth from the Sun is $149.6 \cdot 10^6$ km. How much power does the Sun generate?

Concept Check 15.3

The intensity of electromagnetic waves from the Sun at the Earth is $1400\ \mathrm{W/m^2}$. The distance from Mars to the Sun is approximately $\frac{3}{2}$ of the distance from Earth to the Sun. Therefore, the intensity of the Sun's electromagnetic waves at Mars is

a) the same as at Earth.

b) $\frac{3}{2}$ of that at Earth.

c) $\frac{9}{4}$ of that at Earth.

d) $\frac{2}{3}$ of that at Earth.

e) $\frac{4}{9}$ of that at Earth.

SOLVED PROBLEM 15.2 Power Transmitted by a Wave on a String

PROBLEM

The transverse displacement from equilibrium of a particular stretched string as a function of position and time is given by $y(x, y) = (0.130\,\text{m})\cos\left[\left(9.00\,\text{m}^{-1}\right)x + \left(72.0\,\text{s}^{-1}\right)t\right]$. The linear mass density of the string is 0.00677 kg/m. What is the average power transmitted by the string?

SOLUTION

THINK

We start with equation 15.20 for the average power transmitted by a wave. We can extract the amplitude, $A(r)$, the wave number, κ, and the angular frequency, ω, from the given function $y(x, t)$ by comparing it with the solution to the wave equation for a wave traveling in the negative x-direction (see equation 15.6). The product $\rho A_\perp$ is given by the linear mass density, μ.

SKETCH

Figure 15.22 identifies the relevant factors of the wave function.

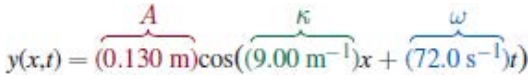

FIGURE 15.22 The wave function with the relevant factors identified.

RESEARCH

The power transmitted by a wave is given by equation 15.20:

$$\overline{P} = \tfrac{1}{2}\rho A_\perp v\omega^2[A(r)]^2.$$

For a wave moving on an elastic string, the product of the density, ρ, and the cross-sectional area, $A_\perp$, can be written as

$$\rho A_\perp = \frac{m}{V}A_\perp = \frac{m}{L\cdot A_\perp}A_\perp = \frac{m}{L} = \mu,$$

where $\mu = m/L$ is the linear mass density of the string. For a wave moving on an elastic string, $A(r)$ is constant, and so we can express the transmitted power as

$$\overline{P} = \tfrac{1}{2}\mu v\omega^2[A(r)]^2.$$

We can use equation 15.8 to obtain the speed of the wave:

$$v = \frac{\omega}{\kappa}.$$

SIMPLIFY

From the wave function specified in the problem statement, we see that $A(r) = 0.130\,\text{m}, \kappa = 9.00\,\text{m}^{-1}$, and $\omega = 72.0\,\text{s}^{-1}$. By convention, ω is a positive number, and the specified wave function represents a wave traveling in the negative x-direction. We can then calculate v:

$$v = \frac{\omega}{\kappa} = \frac{72.0\,\text{s}^{-1}}{9.00\,\text{m}^{-1}} = 8.00\,\text{m/s}\,.$$

CALCULATE

Putting the numerical values into equation 15.20, we get

$$\begin{aligned}\overline{P} &= \tfrac{1}{2}\mu v\omega^2[A(r)]^2 = \tfrac{1}{2}(0.00677\,\text{kg/m})(8.00\,\text{m/s})\left(72.0\,\text{s}^{-1}\right)^2 \\ &= 2.37247\,\text{W}.\end{aligned}$$

ROUND

We report our result to three significant figures:

$$\overline{P} = 2.37\,\text{W}.$$

DOUBLE-CHECK

To double-check our answer, let's assume that the energy of the wave corresponds to the energy of an object whose mass is equal to the mass of a one-wavelength-long section of string. This object is moving in the negative x-direction at the speed of the traveling

wave. The power is then the energy transmitted in one period. From the values for κ and ω extracted from the given wave function, we get the wavelength and the period:

$$\lambda = \frac{2\pi}{\kappa} = 0.698\,\text{m}.$$
$$T = \frac{2\pi}{\omega} = 0.0873\,\text{s}.$$

We can write the kinetic energy as

$$K = \tfrac{1}{2}(\mu\lambda)v^2 = 0.151\,\text{J}.$$

The power is then

$$P = \frac{K}{T} = \frac{0.151\,\text{J}}{0.0873\,\text{s}} = 1.73\,\text{W}.$$

This result is comparable to our result for the power transmitted along the string. Thus, our answer seems to be reasonable.

15.7 Superposition Principle and Interference

When two or more waves are simultaneously present at a point, the resultant displacement is simply the sum of the displacements of the component waves. This simple statement, called the **superposition principle**, is one of the most important in wave physics, but how do we know that it is true? Wave equations like equation 15.9 have a very important property: They are linear. What does this mean? If you find two different solutions, $y_1(x,t)$ and $y_2(x,t)$, to a linear differential equation, then any linear combination of those solutions, such as

$$y(x,t) = ay_1(x,t) + by_2(x,t), \qquad \textbf{(15.23)}$$

where a and b are arbitrary constants, is also a solution to the same linear differential equation. You can see this linear property in the differential equation, because it contains the function $y(x,t)$ to the first power only [there is no term containing $y(x,t)^2$ or $\sqrt{y(x,t)}$ or any other power of the function].

In physical terms, the linear property means that wave solutions can be added, subtracted, or combined in any other linear combination, and the result is again a wave solution. This physical property is the mathematical basis of the superposition principle:

Two or more wave solutions can be added, resulting in another wave solution.

$$y(x,t) = y_1(x,t) + y_2(x,t). \qquad \textbf{(15.24)}$$

Equation 15.24 is a special case of equation 15.23 with $a = b = 1$. Let's look at an example of the superposition of two wave pulses with different amplitudes and different velocities.

EXAMPLE 15.3 Superposition of Wave Pulses

Two wave pulses, $y_1(x,t) = A_1 e^{-(x-v_1 t)^2}$ and $y_2(x,t) = A_2 e^{-(x+v_2 t)^2}$, with $A_2 = 1.7A_1$ and $v_1 = 1.6v_2$, are at some distance from each other. Because of their mathematical form, these are called *Gaussian wave packets*. We assume that the two waves are of the same type, such as waves on a rope.

PROBLEM

What is the amplitude of the resulting wave at maximum overlap of the two pulses, and at what time does this occur?

SOLUTION

Both of these Gaussian wave packets are of the functional form $y(x,t) = Y(x \pm vt)$ and are therefore valid solutions of the one-dimensional wave equation 15.9. Thus, the superposition principle (equation 15.23) holds, and we can simply add the two wave functions to obtain the function for the resulting wave. The two Gaussian wave packets have maximum overlap when their centers are at the same position in coordinate space. The center of a Gaussian wave packet is at the location where the exponent has a value of zero. As you can see from the given functions, both wave packets will be centered at $x = 0$ at time $t = 0$, which is the answer to the question as to when the maximum overlap occurs. The amplitude at maximum overlap is simply $A = A_1 + A_2 = 2.7A_1$ (because $A_2 = 1.7A_1$, as specified in the problem statement).

DISCUSSION

It is instructive to look at plots illustrating these waves and their superposition. The two Gaussian wave packets start at time $t = -3$, in units of the width of a wave packet divided by the speed v_1, and propagate. Figure 15.23a is a three-dimensional plot of the wave function $y(x,t) = y_1(x,t) + y_2(x,t)$ as a function of coordinate x and time t. The velocity vectors $\vec{v_1}$ and $\vec{v_2}$ are shown. Figure 15.23b shows coordinate space plots of the waves at different points in time. The blue curve represents $y_1(x,t)$, the red curve represents

$y_2(x,t)$, and the black curve is their sum. At the middle point in time, the two wave packets achieve maximum overlap.

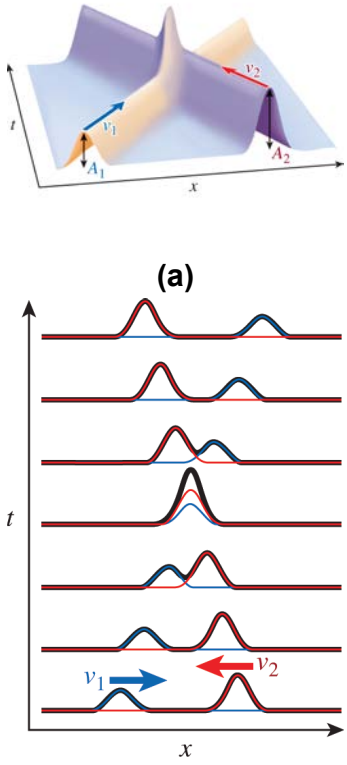

FIGURE 15.23 Superposition of two Gaussian wave packets: (a) three-dimensional representation; (b) coordinate space plots for different times.

What is essential to remember from the superposition principle is that waves can penetrate each other without changing their frequency, amplitude, speed, or direction. Modern communications technology is absolutely dependent on this fact. In any city, several TV and radio

stations broadcast their signals at different frequencies; there are also cell phone and satellite TV transmissions, as well as light waves and sound waves. All of these waves have to be able to penetrate each other without changing; otherwise, everyday communication would be impossible.

Interference of Waves

Interference is one consequence of the superposition principle. If waves pass through each other, their displacements simply add, according to equation 15.24. Interesting cases arise when the wavelengths and frequencies of the two waves are the same, or at least close to each other. Here we'll look at the case of two waves with identical wavelengths and frequencies. The case of waves whose frequencies are close to each other will be discussed in Chapter 16 on sound, when we discuss beats.

First, let's consider two one-dimensional waves with identical amplitude, A, wave number, κ, and angular frequency, ω. The phase shift ϕ_0 is set at zero for wave 1 but allowed to vary for wave 2. The sum of the waveforms is then

$$y(x,t) = A\sin(\kappa x - \omega t) + A\sin(\kappa x - \omega t + \phi_0). \quad \textbf{(15.25)}$$

For $\phi_0 = 0$, the two sine functions in equation 15.25 have identical arguments, so the sum is simply $y(x,t) = 2A\sin(\kappa x - \omega t)$. In this situation, the two waves add to the maximum extent possible, which is called **constructive interference.**

If we shift the argument of a sine or cosine function by π, we obtain the negative of that function: $\sin(\theta + \pi) = -\sin\theta$. For this reason, the two terms in equation 15.25 add up to exactly zero when $\phi_0 = \pi$. This situation is called **destructive interference.** The interference patterns for these two values of ϕ_0, along with three others, are shown in Figure 15.24 for $t = 0$.

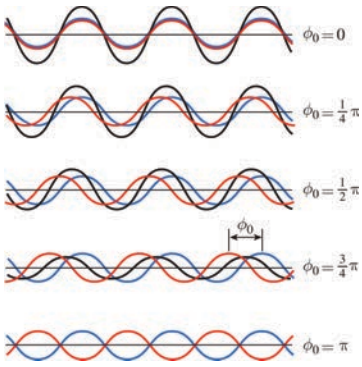

FIGURE 15.24
Interference of one-dimensional waves as a function of their relative phase shifts at $t = 0$. At later times, the patterns move rigidly to the right. Wave 1 is red, wave 2 is blue, and the sum of the two waves is black.

Interesting interference patterns are obtained with two identical circular waves whose sources are some distance from each other. Figure 15.25 shows the schematic interference pattern for two identical waves with $\kappa = 1\text{m}^{-1}$ and the same values of ω and A. One of the waves was shifted by Δx to the right and the other by $-\Delta x$ to the left. The figure shows different values of Δx, which should give you a good idea of how the interference pattern develops as a function of the separation of the centers of the waves. If you have ever dropped two stones at a time into a pond, you will recognize these interference patterns as similar to the surface ripples that resulted.

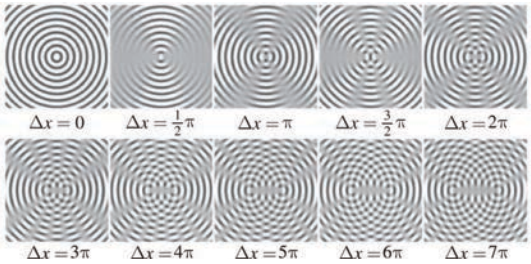

FIGURE 15.25 Schematic interference patterns of two identical two-dimensional periodic waves shifted a distance Δx to either side of the origin, where the unit of Δx is meters. White and black circles mark minima and maxima; gray indicates points where the sum of the waves equals zero.

15.8 Standing Waves and Resonance

A special type of superposition occurs for two traveling waves if they are identical except for opposite signs for ω : $y_1(x,t) = A\sin(\kappa x + \omega t), y_2(x,t) = A\sin(\kappa x - t)$. Let's first look at the mathematical result of this superposition (after which we'll gain physical insight):

$$\begin{aligned} y(x,t) &= y_1(x,t) + y_2(x,t) \\ &= A\sin(\kappa x + \omega t) + A\sin(\kappa x - \omega t) \Rightarrow \\ & y(x,t) = 2A\sin(\kappa x)\cos(\omega t). \end{aligned} \tag{15.26}$$

In the last step to obtain equation 15.26, we used the trigonometric addition formula, $\sin(\alpha \pm \beta) = \sin\alpha\cos\beta \pm \cos\alpha\sin\beta$. Thus, for the superposition of two traveling waves with the same amplitude, same wave number, and same speed but opposite direction of propagation, the dependence on the spatial coordinate and the dependence on the time separate (or factorize) into a function of just x times a function of just t. The result of this superposition is a wave that has **nodes** (where $y = 0$) and **antinodes** (where y can reach its maximum value) at particular points along the x-axis. Each antinode is located midway between neighboring nodes.

This superposition is much easier to visualize in graphical form. Figure 15.26a shows a wave given by $y_1(x,t) = A\sin(\kappa x + \omega t)$, and Figure 15.26b shows a wave given by $y_2(x,t) = A\sin(\kappa x - \omega t)$. Figure 15.26c shows the addition of the two waves. In all three plots, the waveform is shown as a function of the x-coordinate. Each plot also shows the wave at 10 different instants in time, with a time difference of $\pi/10$ between times as if viewing a time-lapse photograph. To compare the same instants of time in each plot, the curves are color-coded starting from red and progressing through orange to yellow. You can see

that the traveling waves move toward the left and the right, respectively, but the wave resulting from their superposition oscillates in place, with the nodes and the antinodes remaining at fixed locations on the x-axis. This interference wave is known as a **standing wave** and results from the factorization of the time dependence and the spatial dependence in equation 15.26. The two traveling waves are always out of phase at the nodes.

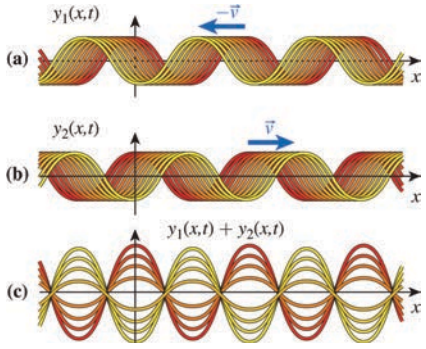

FIGURE 15.26 (a) and (b) Two traveling waves with velocity vectors in opposite directions. (c) Superposition of the two waves results in a standing wave.

The nodes of a standing wave always have zero amplitude. According to equation 15.18, the energy contained in a wave is proportional to the square of the amplitude. Thus, no energy is transported across a node by a standing wave. Wave energy gets trapped between the nodes of a standing wave and remains localized there. Also note that even though a standing wave is not moving, the relationship between wavelength, frequency, and wave speed, $v = \lambda f$, still holds. Here, v is the speed of the two traveling waves, which make up the standing wave.

Standing Waves on a String

The basis for the creation of musical sounds by string instruments is the generation of standing waves on strings that are put under tension. Section 15.4 discussed how the velocity of a wave on a string depends on the string tension and the linear mass density of the string (see equation 15.13). In this section, we discuss the basic physics of one-dimensional standing waves.

Let's start with a demonstration. Shown in Figure 15.27 is a string tied to an anchor on the left side and to a piston on the right. The piston oscillates up and down, in sinusoidal fashion, with a variable frequency, f. The up-and-down motion of the piston has only a very small amplitude, so we can consider the string to be fixed at both ends. The frequency of the piston's oscillation is varied, and at a certain frequency, f_0, the string develops a large-amplitude motion with a central antinode (Figure 15.27a). Clearly, this excitation of the string produces a standing wave. This is a resonant excitation of the string in the sense that the amplitude gets large only at a well-defined **resonance frequency.** If the frequency of the piston's motion is increased by 10%, as shown in Figure 15.27b, this resonant oscillation of the string vanishes. Lowering the piston's frequency by 10% has the same effect. Increasing the frequency to twice the value of f_0 results in another resonant excitation, one that has a single node in the center and antinodes at $\frac{1}{4}$ and $\frac{3}{4}$ of the length of the string (Figure 15.27c). Increasing the frequency to triple the value of f_0 results in a standing wave with two nodes and three antinodes (Figure 15.27d). The continuation of this series is clear: A frequency of nf_0 will result in a standing wave with n antinodes and $n - 1$ nodes (plus the two nodes at both ends of the string), which are equally spaced along the length of the string.

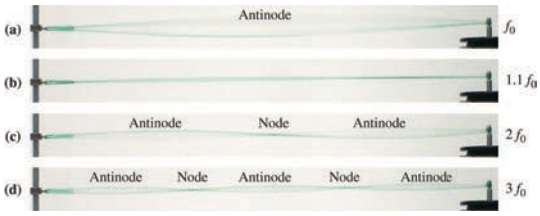

FIGURE 15.27 Generation of standing waves on a string.

W. Bauer and G. D. Westfall

Figure 15.28 shows that the condition for a standing wave is that an integer multiple, n, of half wavelengths fits exactly into the length of the string L. We give these special wavelengths the index n and write

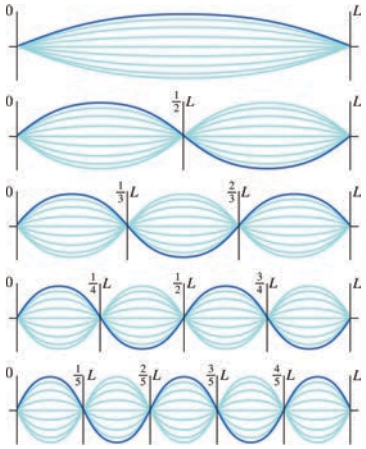

FIGURE 15.28
Lowest five standing-wave excitations of a string.

$$n\frac{\lambda_n}{2} = L, \quad n = 1, 2, 3, \ldots.$$

Solving for the wavelengths, we obtain

$$\lambda_n = \frac{2L}{n}, \quad n = 1, 2, 3 \ldots. \tag{15.27}$$

The index n on the wavelength (or frequency) indicates the **harmonic.** That is, $n = 1$ identifies the first harmonic (also called the *fundamental frequency*), $n = 2$ labels the second harmonic, $n = 3$ the third, and so on.

As mentioned before, $v = \lambda f$ still holds for a standing wave. Using this relationship, we can find the resonance frequencies of a string from equation 15.27:

$$f_n = \frac{v}{\lambda_n} = n\frac{v}{2L}, \quad n = 1, 2, 3, \ldots.$$

Finally, using equation 15.13 for the wave velocity on a string with linear mass density μ under tension F, $v = \sqrt{F/\mu}$, we have

$$f_n = \frac{v}{\lambda_n} = n\frac{\sqrt{F}}{2L\sqrt{\mu}} = n\sqrt{\frac{F}{4L^2\mu}}. \qquad \textbf{(15.28)}$$

Equation 15.28 reveals several interesting facts about the construction of string instruments. First, the longer the string, the lower the resonance frequencies. This is the basic reason why a cello, which produces lower notes, is longer than a violin. Second, the resonance frequencies are proportional to the square root of the tension on the string. If an instrument's frequency is too low (it sounds "flat"), you need to increase the tension. Third, the higher the linear mass density, μ, of the string, the lower the frequency. "Fatter" strings produce bass notes. Fourth, the second harmonic is twice as high as the fundamental frequency, the third is three times as high, and so on. When we discuss sound in Chapter 16, we'll see that this fact is the basis of the definition of the octave. For now, you can see that you can produce the second harmonic on the same string that is used for the first harmonic by putting a finger on the exact middle of the string and thus forcing a node to be located there.

Concept Check 15.4

A string of a given length is clamped at both ends and given a certain tension. Which of the following statements about a standing wave on this string is true?

a) The higher the frequency of a standing wave on the string, the closer together are the nodes.

b) Regardless of the frequency of the standing wave, the nodes are always the same distance apart.

c) For a standing wave on a string at a given tension, only one frequency is ever possible.

d) The lower the frequency of a standing wave on the string, the closer together are the nodes.

EXAMPLE 15.4 Tuning a Piano

A piano tuner's job is to make sure that all keys on the instrument produce the proper tones. On one piano, the string for the middle-A key is under a tension of 2900 N and has a mass of 0.006000 kg and a length of 0.6300 m.

PROBLEM

By what fraction does the tuner have to change the tension on this string in order to obtain the proper frequency of 440.0 Hz?

SOLUTION

First, we calculate the fundamental frequency (or first harmonic), using $n = 1$ in equation 15.28 and the given tension, length, and mass:

$$f_1 = \sqrt{\frac{2900\ \text{N}}{4(0.6300\ \text{m})(0.006000\ \text{kg})}} = 438\ \text{Hz}.$$

This frequency is off by 2 Hz, or too low by 0.5%, so the tension has to be increased. The proper tension can be found by solving equation 15.28 for F and then using the fundamental frequency of 440.0 Hz, the proper frequency for middle A:

$$f_n = n\sqrt{\frac{F}{4L^2(m/L)}} = n\sqrt{\frac{F}{4Lm}} \Rightarrow F = 4Lm\left(\frac{f_n}{n}\right)^2.$$

Inserting the numbers, we find

$$F = 4(0.6300\ \text{m})(0.006000\ \text{kg})(440.0\ \text{Hz})^2 = 2927\ \text{N}.$$

The tension needs to be increased by 27 N, which is 0.93% of 2900 N. The piano tuner needs to increase the tension on the string by 0.93% for it to produce the proper middle-A frequency.

DISCUSSION

We could also have found the required change in the tension by arguing in the following way: The frequency is proportional to the square root of the tension, and $\sqrt{1-x} \approx 1 - \frac{1}{2}x$ for small x. Since a 0.5% change in the frequency is needed, the tension has to be changed by twice that amount, or 1%.

By the way, a piano tuner can detect a frequency that is off by 2 Hz easily, by listening for beats, which we'll discuss in Chapter 16.

Concept Check 15.5

A guitar string is 0.750 m long and has a mass of 5.00 g. The string is tuned to E (660 Hz) when it vibrates at its fundamental frequency. How should the tension in the string be changed to tune it to A (440 Hz)?

a) increase the tension by a factor of $\frac{3}{2}$

b) increase the tension by a factor of $\left(\frac{3}{2}\right)^{1/2}$

c) decrease the tension to $\frac{2}{3}$ of its current value

d) decrease the tension to $\left(\frac{2}{3}\right)^{1/2}$

e) decrease the tension to $\left(\frac{2}{3}\right)^{2}$

Self-Test Opportunity 15.4

Researchers at the Cornell NanoScale Science and Technology Facility, where the guitar in Figure 15.12b was built, have also made an even smaller guitar string, from a single carbon nanotube only 1 to 4 nm in diameter. It is suspended over a trench of width $W = 1.5\ \mu\text{m}$. In their 2004 paper in *Nature,* the Cornell researchers reported a fundamental resonance frequency of the carbon nanotube at 55 MHz. What is the speed of a wave on this nanotube?

SOLVED PROBLEM 15.3 Standing Wave on a String

PROBLEM

A mechanical driver is used to set up a standing wave on an elastic string, as shown in Figure 15.29a. Tension is put on the string by running it over a frictionless pulley and hanging a metal block from it (Figure 15.29b). The length of the string from the top of the pulley to the driver is 1.25 m, and the linear mass density of the string is 5.00 g/m. The frequency of the driver is 45.0 Hz. What is the mass of the metal block?

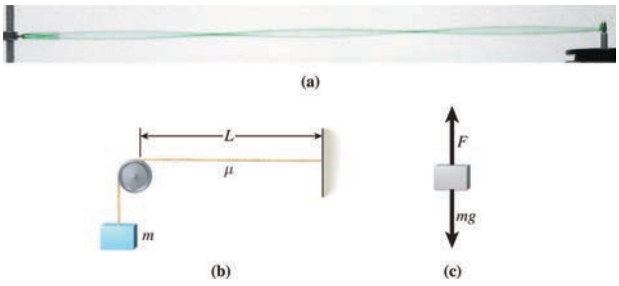

FIGURE 15.29 (a) A standing wave on an elastic string driven by a mechanical driver. (b) The string is put under tension by a hanging mass. (c) Free-body diagram for the hanging block.

a: W. Bauer and G. D. Westfall

SOLUTION

THINK

The weight of the metal block is equal to the tension placed on the elastic string. We can see from Figure 15.29a that the string is vibrating at its third harmonic because three antinodes are visible. We can thus use equation 15.28 to relate the tension on the string, the harmonic, the linear mass density of the string, and the frequency. Once we have determined the tension on the string, we can calculate the mass of the metal block.

SKETCH

Figure 15.29b shows the elastic string under tension due to a metal block hanging from it. The mechanical driver sets up a standing wave on the string. Here L is the length of the string from the pulley to the wave driver, μ is the linear mass density of the string, and m is the mass of the metal block. Figure 15.29c shows the free-body diagram of the hanging metal block, where F is the tension on the string and mg is the weight of the metal block.

RESEARCH

A standing wave with harmonic n and frequency f_n on an elastic string of length L and linear mass density μ satisfies equation 15.28:

$$f_n = n\sqrt{\frac{F}{4L^2\mu}}.$$

From the free-body diagram in Figure 15.29c, and the fact that the metal block does not move, we can write

$$F - mg = 0.$$

Therefore, the tension on the string is $F = mg$.

SIMPLIFY

We solve equation 15.28 for the tension on the string:

$$F = 4L^2\mu\frac{f_n^2}{n^2}.$$

Substituting mg for F and rearranging terms, we obtain

$$m = \frac{\mu}{g}\left(\frac{2Lf_n}{n}\right)^2.$$

CALCULATE

Putting in the numerical values, we get

$$m = \frac{\mu}{g}\left(\frac{2Lf_n}{n}\right)^2 = \frac{0.00500\ \text{kg/m}}{9.81\ \text{m/s}^2}\left(\frac{2(1.25\ \text{m})(45.0\ \text{Hz})}{3}\right)^2$$
$$= 0.716743\ \text{kg}.$$

ROUND

We report our result to three significant figures:

$$m = 0.717\ \text{kg}.$$

DOUBLE-CHECK

As a double-check of our result, we use the fact that a half-liter bottle of water has a mass of about 0.5 kg. Even a light string could support this mass without breaking. Thus, our answer seems reasonable.

Standing waves can also be created in two and three dimensions. While we will not treat these cases in any mathematical detail, it is interesting to see the wave patterns that can emerge. To visualize standing wave patterns on two-dimensional sheets, the sheets are driven with a tunable oscillator from below and salt grains are scattered evenly on top. The salt grains gather at the wave nodes, where they do not receive large kicks from the oscillator below. Figure 15.30 shows the result for a square plate driven at three different frequencies. You can see that the standing waves have nodal lines, which have different shapes at different frequencies. We won't discuss these nodal lines in quantitative detail, but it is important to realize that the higher the frequency, the closer the nodal lines are to each other. This is in complete analogy to the case of a one-dimensional standing wave on a string.

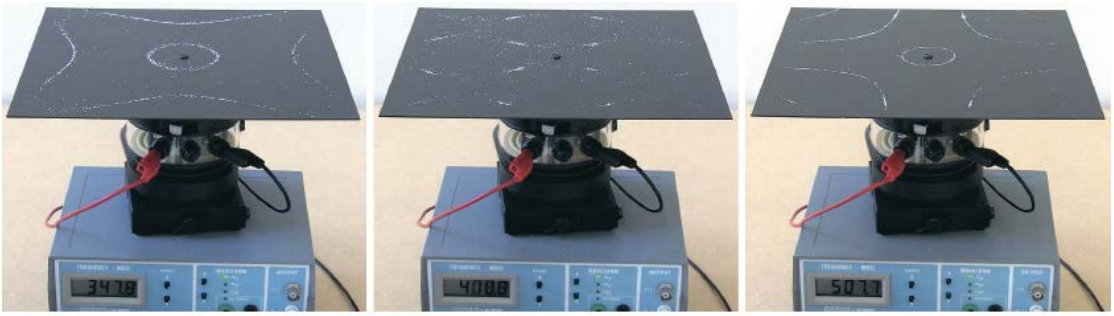

FIGURE 15.30 Standing-wave nodal patterns on a square plate driven at frequencies of (a) 348 Hz, (b) 409 Hz, and (c) 508 Hz.

W. Bauer and G. D. Westfall

Concept Check 15.6

The circular plate shown in the figure is driven at three different frequencies. From examining the three parts, rank the three frequencies from lowest to highest.

a) 1, 2, 3

b) 2, 3, 1

c) 3, 1, 2

d) 1, 3, 2

e) 2, 1, 3

15.9 Research on Waves

This chapter gives only a brief overview of wave phenomena. All physics majors and most engineering majors will take another complete course on waves that goes into more detail. Several other chapters in this book deal with waves. Chapter 16 is devoted to the longitudinal pressure waves called *sound waves*. Chapter 31 focuses on electromagnetic waves, Chapter 34 examines wave optics, and Chapter 36 explores a wave description of matter. This wave character of matter led directly to the development of quantum mechanics, the basis for most of modern physics, including nanoscience and nanotechnology.

Scientists and engineers continue to discover new aspects of wave physics, from fundamental concepts to applications. On the applied side, engineers are studying ways to guide microwaves through different geometries with the aid of finite element methods (which are computational methods that break a large object into a large number of small objects) and very time-intensive computer programs. If these geometries are not spatially symmetric—that is, if they are not exactly round or exactly rectangular—some surprising results can occur. For example, physicists can study quantum chaos with the aid of microwaves that are sent into a metal cavity in the shape of a stadium (a shape that has semicircles at both ends, connected by straight sections). Figure 15.31 shows such a stadium geometry, not for microwaves but for a physical system—a collection of individual iron atoms arranged on a copper surface by using a scanning tunneling microscope. The wave ripples in the interior of the stadium are standing electron matter waves.

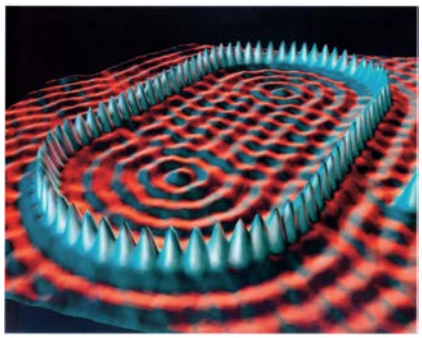

FIGURE 15.31 Iron atoms on a copper surface form a stadium-shaped cavity in which physicists can study electron matter waves.

On the most advanced level of investigation, particle theorists and mathematicians have come up with new classes of theories called *string theories*. The mathematics of string theories exceeds the scope of this book. However, it is interesting to note that string theorists obtain their physical insights from considering systems similar to those we have considered in this chapter—in particular, standing waves on a string. We'll touch on this subject again in Chapter 39 on particle physics.

Perhaps one of the most interesting experimental investigations into wave physics is the search for gravitational waves. Gravitational waves were predicted by Einstein's theory of general relativity (see Chapter 35) but are very weak and hard to detect unless generated by an extremely massive object. Astrophysicists have postulated that some astronomical

objects emit gravitational waves of such great intensity that they should be observable on Earth. Indirect evidence of the existence of such gravitational waves has come from the study of orbital frequencies of neutron star pairs, since the decrease of measured rotational energy in the pair can be explained by the radiation of gravitational waves. In 2015, scientists observed the first direct evidence for gravitational waves using LIGO (Laser Interferometer Gravitational-Wave Observatory). LIGO consists of two observatories, one in Hanford, Washington, and the other in Livingston, Louisiana, located 3002 km apart (see Figure 15.32). Each observatory has two tunnels, each 4 km long, arranged in an L shape. The observed gravity waves were emitted from a binary black hole merger. To detect gravitational waves, LIGO suspended several heavy, mirrored test masses placed at the ends of two perpendicular arms of the instrument. As gravitational waves passed through LIGO, they caused alternating stretching and compressing of space, which was out of phase for the two arms and was observable as minute movements of the mirrors. By bouncing laser light off the mirrors and recombining the beams, an interference pattern was detected producing the first measurements of gravitational waves. The results from LIGO are discussed in Chapter 35.

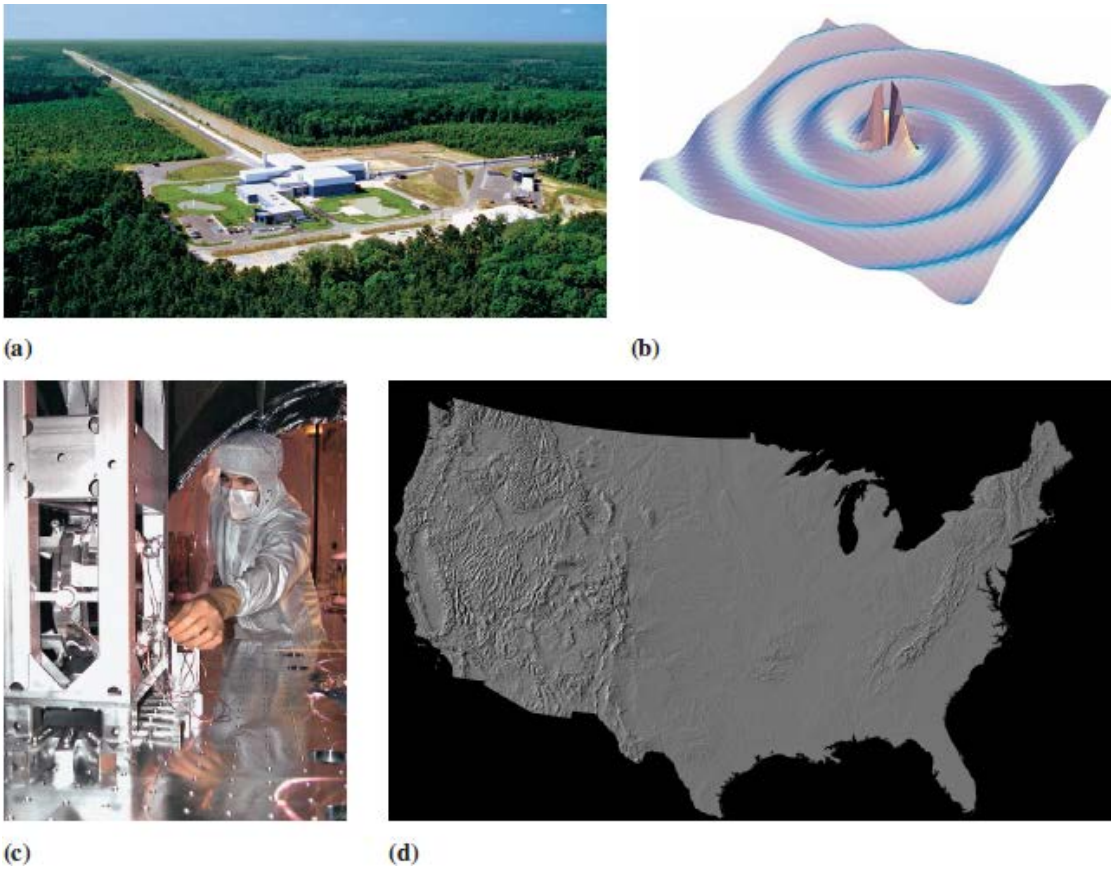

FIGURE 15.32 (a) Aerial view of the Livingston site of LIGO (Laser Interferometer Gravitational-Wave Observatory); (b) visualization of a gravitational wave; (c) a scientist adjusts the interferometer; (d) map of LIGO.

a, c: LIGO Laboratory, Supported by the National Science Foundation; **b:** LVK Collaboration; **d:** USGS

These experiments pushed the envelope of what was technically possible and measurable. For example, the expected movement of the test masses due to a gravitational wave is on the order of only 10^{-18}m, which is smaller than the diameter of a hydrogen atom by a factor of 100 million, or 10^{18}. Measuring a distance change that small was a huge technological achievement.

Plans also exist for a space-based gravitational wave observatory, named LISA (Laser Interferometer Space Antenna), which will consist of three spacecraft arranged in an equilateral triangle with side length $5 \cdot 10^6$ km. Scientists have recently used supercomputers to simulate

gravitational waves emitted from the collision of two massive black holes, as illustrated in Figure 15.33 in a calculation done by a group from NASA. Such waves might be intense enough to be detected on Earth.

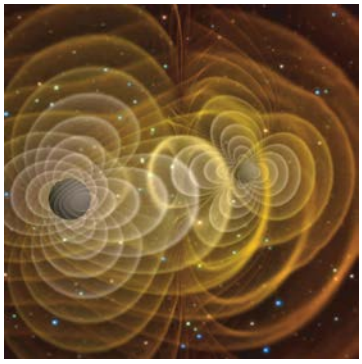

FIGURE 15.33
Supercomputer simulation of the collision of two massive black holes, creating gravitational waves that may be observable.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- The wave equation describes the displacement $y(x,t)$ from the equilibrium position for any wave motion: $\frac{\partial^2}{\partial t^2}y(x,t) - v^2\frac{\partial^2}{\partial x^2}y(x,t) = 0.$
- For any wave, v is the wave velocity, λ is the wavelength, and f is the frequency, and they are related by $v = \lambda f$.
- The wave number is defined as $\kappa = 2\pi/\lambda$, just as the angular frequency is related to the period by $\omega = 2\pi/T$.
- Any function of the form $Y(\kappa x - \omega t + \phi_0)$ or $Y(\kappa x + \omega t + \phi_0)$ is a solution to the wave equation. The first function describes a wave traveling in the positive x-direction, and the second function describes a wave traveling in the negative x-direction.
- The speed of a transverse wave on a string is $v = \sqrt{F/\mu}$, where $\mu = m/L$ is the linear mass density of the string and F is the string tension.
- A one-dimensional sinusoidal wave is given by $y(x,t) = A\sin(\kappa x - \omega t + \phi_0)$, where the argument of the sine function is the phase of the wave and A is the amplitude of the wave.
- A three-dimensional spherical wave is described by $\psi\left(\overrightarrow{r},t\right) = \frac{A}{r}\sin(\kappa r - \omega t + \phi_0)$, and a plane wave is described by $\psi\left(\overrightarrow{r},t\right) = A\sin(\kappa x - \omega t + \phi_0)$.
- The energy contained in a wave is $E = \frac{1}{2}\rho V\omega^2[A(r)]^2 = \frac{1}{2}\rho(A_\perp l)\omega^2[A(r)]^2 = \frac{1}{2}\rho(A_\perp vt)\omega^2[A(r)]^2$ where $A_\perp$ is the perpendicular cross-sectional area through which the wave passes.
- The power transmitted by a wave is $\overline{P} = \frac{E}{t} = \frac{1}{2}\rho A_\perp v\omega^2[A(r)]^2$, and its intensity is $I = \frac{1}{2}\rho v\omega^2[A(r)]^2$.

- For a spherical three-dimensional wave, the intensity is inversely proportional to the square of the distance to the source.
- The superposition principle holds for waves: Adding two solutions of the wave equation results in another valid solution.
- Waves can interfere in space and time, constructively or destructively, depending on their relative phases.
- Adding two traveling waves that are identical except for having velocity vectors that point in opposite directions yields a standing wave such as $y(x, t) = 2A\sin(\kappa x)\cos(\omega t)$, for which the dependence on space and time factorizes.
- The resonance frequencies (or harmonics) for waves on a string are given by $f_n = \dfrac{v}{\lambda_n} = n\dfrac{\sqrt{F}}{2L\sqrt{\mu}}$, for $n = 1, 2, 3, \ldots$. The index n indicates the harmonic (for example, $n = 4$ corresponds to the fourth harmonic).

ANSWERS TO SELF-TEST OPPORTUNITIES

15.1 $f = 0.40$ Hz.

15.2 $A = 10$ cm, $\kappa = 0.31$ cm^{-1}, $\phi_0 = 0.30$.

15.3 The surface area of a sphere with radius r is $4\pi r^2$, and the total power is $P = IA_\perp$. With $r = 1.5 \cdot 10^{11}$ m and $I = 1.4$ kW/m^2, we get $P = 3.9 \cdot 10^{26}$ W.

15.4 Lowest resonance frequency: $f_1 = \dfrac{v}{\lambda_1} = \dfrac{v}{2L}$

Wave speed: $v = 2Lf_1 = 2\left(1.5 \cdot 10^{-6}\text{ m}\right)\left(5.5 \cdot 10^{7}\text{ s}^{-1}\right) = 165$ m/s.

Page 494

PROBLEM-SOLVING GUIDELINES

1. If a wave fits the description of a one-dimensional traveling wave, you can write a mathematical equation describing it if you know the amplitude, *A,* of the motion and any two of these three quantities: velocity, *v,* wavelength, λ, and frequency, *f.* (Alternatively, you need to know two of the three quantities velocity, v, wave number, κ, and angular frequency, ω.)

2. If a wave is a one-dimensional standing wave on a string, its resonance frequencies are determined by the length, *L,* of the string and the speed, *v,* of the component waves. The speed of the wave, in turn, is determined by the tension, *F,* in the string and the linear mass density, μ, of the string.

MULTIPLE-CHOICE QUESTIONS

15.1 Fans at a local football stadium are so excited that their team is winning that they start "the wave" in celebration. Which of the following four statements is (are) true?

I. This wave is a traveling wave.

II. This wave is a transverse wave.

III. This wave is a longitudinal wave.

IV. This wave is a combination of a longitudinal wave and a transverse wave.

a) I and II

b) II only

c) III only

d) I and IV

e) I and III

15.2 You wish to decrease the speed of a wave traveling on a string to half its current value by changing the tension in the string. By what factor must you decrease the tension in the string?

a) 1

b) $\sqrt{2}$

c) 2

d) 4

e) none of the above

15.3 Suppose that the tension is doubled for a string on which a wave is propagated. How will the velocity of the wave change?

a) It will double.

b) It will quadruple.

c) It will be multiplied by $\sqrt{2}$.

d) It will be multiplied by $\frac{1}{2}$.

15.4 Which one of the following transverse waves has the greatest power?

a) a wave with velocity v, amplitude A, and frequency f

b) a wave with velocity v, amplitude $2A$, and frequency $f/2$

c) a wave with velocity $2v$, amplitude $A/2$, and frequency f

d) a wave with velocity $2v$, amplitude A, and frequency $f/2$

e) a wave with velocity $2v$, amplitude $A/2$, and frequency $2f$

15.5 The speed of light waves in air is greater than the speed of sound waves in air by *about* a factor of a million. Given a sound wave and a light wave of the same wavelength, both traveling through air, which statement about their frequencies is true?

a) The frequency of the sound wave will be about a million times greater than that of the light wave.

b) The frequency of the sound wave will be about a thousand times greater than that of the light wave.

c) The frequency of the light wave will be about a thousand times greater than that of the sound wave.

d) The frequency of the light wave will be about a million times greater than that of the sound wave.

e) There is insufficient information to determine the relationship between the two frequencies.

15.6 A string is made to oscillate, and a standing wave with three antinodes is created. If the tension in the string is increased by a factor of 4, the number of antinodes

a) increases.

b) remains the same.

c) decreases.

d) will equal the number of nodes.

15.7 The different colors of light we perceive are a result of the varying frequencies (and wavelengths) of the electromagnetic radiation. Infrared radiation has lower frequencies than does visible light, and ultraviolet radiation has higher frequencies than visible light does. The primary colors are red (R), yellow (Y), and blue (B). Order these colors by their wavelength, shortest to longest.

a) B, Y, R

b) B, R, Y

c) R, Y, B

d) R, B, Y

15.8 If transverse waves on a string travel with a velocity of 50 m/s when the string is under a tension of 20 N, what tension on the string is required for the waves to travel with a velocity of 30 m/s?

a) 7.2 N

b) 12 N

c) 33 N

d) 40 N

e) 45 N

f) 56 N

15.9 The intensity of electromagnetic waves from the Sun at the Earth is 1400 $\mathrm{W/m^2}$. How much power does the Sun generate? The distance from the Earth to the Sun is $149.6 \cdot 10^6$ km.

a) $1.21 \cdot 10^{20}$ W

b) $2.43 \cdot 10^{24}$ W

c) $3.94 \cdot 10^{26}$ W

d) $2.11 \cdot 10^{28}$ W

e) $9.11 \cdot 10^{30}$ W

15.10 A guitar string is 0.750 m long and has a mass of 5.00 g. The string is tuned to E (660 Hz) when it vibrates at its fundamental frequency. What is the required tension on the string?

a) $2.90 \cdot 10^3$ N

b) $4.84 \cdot 10^3$ N

c) $6.53 \cdot 10^3$ N

d) $8.11 \cdot 10^3$ N

e) $1.23 \cdot 10^4$ N

CONCEPTUAL QUESTIONS

15.11 You and a friend are holding the two ends of a Slinky stretched out between you. How would you move your end of the Slinky to create (a) transverse waves or (b) longitudinal waves?

15.12 A steel cable consists of two sections with different cross-sectional areas, A_1 and A_2. A sinusoidal traveling wave is sent down this cable from the thin end of the cable. What happens to the wave on encountering the A_1/A_2 boundary? How do the speed, frequency and wavelength of the wave change?

15.13 Noise results from the superposition of a very large number of sound waves of various frequencies (usually in a continuous spectrum), amplitudes, and phases. Can interference arise with noise produced by two sources?

15.14 The $1/R^2$ dependency for intensity can be thought of as being due to the fact that the same power is being spread out over the surface of a larger and larger sphere. What happens to the intensity of a sound wave inside an enclosed space, such as a long hallway?

15.15 If two traveling waves have the same wavelength, frequency, and amplitude and are added appropriately, the result is a standing wave. Is it possible to combine two standing waves in some way to give a traveling wave?

15.16 A Ping-Pong ball is floating in the middle of a lake and waves begin to propagate on the surface. Can you think of a situation in which the ball remains stationary? Can you think of a situation involving a single wave on the lake in which the ball remains stationary?

15.17 Why do circular water waves on the surface of a pond decrease in amplitude as they travel away from the source?

15.18 Consider a wave on a string, with amplitude A and wavelength λ, traveling in one direction. Find the relationship between the maximum speed of any portion of string, $v_{\max}$, and the wave speed, v.

15.19 Suppose a tightrope walker is standing in the middle of a rope a mile long. If one end of the rope is cut, how long will it be before the

tight-rope walker begins to fall? What would you have to know to answer this question?

15.20 Suppose a long line of cars waits at an intersection for the light to turn green. Once the light turns, the cars in the back cannot move right away, but have to wait until the cars ahead of them move. Explain this effect (called a *rarefaction* wave) in terms of the wave physics that we have studied in this chapter.

15.21 Derive the relationship for the speed of a wave on a string $v = \sqrt{F/\mu}$, where F is the tension force on the string and μ is the linear mass density of the string. Start with Derivation 15.1 and substitute the restoring force provided by the springs with a restoring force resulting from the tension of the string.

15.22 Derive the expression for the energy of a wave $E = \frac{1}{2} m \omega^2 A^2$, where m is the mass of the substance that is oscillating, ω is the angular velocity, and $A(r)$ is the amplitude. Start by expressing the kinetic energy and potential energy of the wave, and then add these to get the energy of the wave.

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Sections 15.1 through 15.3

15.23 One of the main things allowing humans to determine whether a sound is coming from the left or the right is the fact that the sound will reach one ear before the other. Given that the speed of sound in air is 343 m/s and that human ears are typically 20.0 cm apart, what is the maximum time resolution for human hearing that allows sounds coming from the left to be distinguished from sounds coming from the right? Why is it impossible for a diver to be able to tell from which direction the sound of a motorboat is coming? The speed of sound in water is $1.50 \cdot 10^3 \text{m/s}$.

15.24 Hiking in the mountains, you shout "hey," wait 2.00 s and shout again. What is the distance between the sound waves you cause? If you hear the first echo after 5.00 s, what is the distance between you and the point where your voice hit a mountain?

15.25 The displacement from equilibrium caused by a wave on a string is given by $y(x,t) = (-0.00200 \text{ m})\sin\left[\left(40.0 \text{ m}^{-1}\right)x - \left(800. \text{ s}^{-1}\right)t\right]$. For this wave, what are the (a) amplitude, (b) number of waves in 1.00 m, (c) number of complete cycles in 1.00 s, (d) wavelength, and (e) speed?

•**15.26** A traveling wave propagating on a string is described by the following equation:

$$y(x,t) = (5.00 \text{ mm})\sin\left(\left(157.08 \text{ m}^{-1}\right)x - \left(314.16 \text{ s}^{-1}\right)t + 0.7854\right.$$

a) Determine the minimum separation, Δx_{min}, between two points on the string that oscillate in perfect opposition of phases (move in opposite directions *at all times*).

b) Determine the minimum separation, Δx_{AB}, between two points A and B on the string, if point B oscillates with a phase difference of 0.7854 rad compared to point A.

c) Find the number of crests of the wave that pass through point A in a time interval $\Delta t = 10.0$ s and the number of troughs that pass through point B in the same interval.

d) At what point along its trajectory should a linear driver connected to one end of the string at $x = 0$ start its oscillation to generate this sinusoidal traveling wave on the string?

•• **15.27** Consider a linear array of n masses, each equal to m, connected by $n + 1$ springs, all massless and having spring constant k, with the outer ends of the first and last springs fixed. The masses can move without friction in the linear dimension of the array.

a) Write the equations of motion for the masses.

b) Configurations of motion for which all parts of a system oscillate with the same angular frequency are called *normal modes* of the system; the corresponding angular frequencies are the system's *normal-mode angular frequencies*. Find the normal-mode angular frequencies of this array. Note that there are n normal modes.

Section 15.4

15.28 Show that the function $D = A \ln(x + vt)$ is a solution of the wave equation (equation 15.9).

15.29 A wave travels along a string in the positive *x*-direction at 30.0 m/s. The frequency of the wave is 50.0 Hz. At $x = 0$ and $t = 0$, the wave velocity is 2.50 m/s and the vertical displacement is $y = 4.00$ mm. Write the function *y*(*x*,*t*) for the wave.

15.30 A wave on a string has a wave function given by $y(x,t) = (0.0200\text{ m})\sin\left[\left(6.35\text{ m}^{-1}\right)x + \left(2.63\text{ s}^{-1}\right)t\right]$.

a) What is the amplitude of the wave?

b) What is the period of the wave?

c) What is the wavelength of the wave?

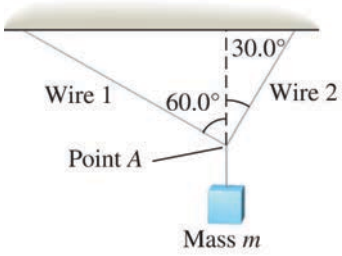
d) What is the speed of the wave?

e) In which direction does the wave travel?

•**15.31** A sinusoidal wave traveling in the positive *x*-direction has a wavelength of 12.0 cm, a frequency of 10.0 Hz, and an amplitude of 10.0 cm. The part of the wave that is at the origin at $t = 0$ has a vertical displacement of 5.00 cm. For this wave, determine the (a) wave number, (b) period, (c) angular frequency, (d) speed, (e) phase angle, and (f) equation of motion.

•**15.32** A mass *m* hangs on a string that is connected to the ceiling. You pluck the string just above the mass, and a wave pulse travels up to the ceiling, reflects off the ceiling, and travels back to the mass. Compare the round-trip time for this wave pulse to that of a similar wave pulse on the same string if the attached mass is increased to 3.00*m*. (Assume that the string does not stretch in either case and the contribution of the mass of the string to the tension is negligible.)

•**15.33** Point *A* in the figure is a distance *d* below the ceiling. Determine how much longer it will take for a wave pulse to travel from point *A* to the ceiling along wire 1 than along wire 2.

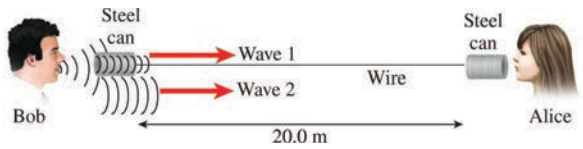


•15.34 A particular steel guitar string has a mass per unit length of 1.93 g/m.

a) If the tension on this string is 62.2 N, what is the wave speed on the string?

b) For the wave speed to be increased by 1.00%, how much should the tension be changed?

•15.35 Bob is talking to Alice using a tin can telephone, which consists of two steel cans connected by a 20.0-m-long taut steel wire (see the figure). The wire has a linear *mass* density of 6.13 m/s, and the tension on the wire is 25.0 N. The sound waves leave Bob's mouth, are collected by the can on the left, and then create vibrations in the wire, which travel to Alice's can and are transformed back into sound waves in air. Alice hears both the sound waves that have traveled through the wire (wave 1) and those that have traveled through the air (wave 2), bypassing the wire. Do these two kinds of waves reach her at the same time? If not, which wave arrives sooner and by how much? The speed of sound in air is 343 m/s. Assume that the waves on the string are transverse.



••15.36 A wire of uniform linear mass density hangs from the ceiling. It takes 1.00 s for a wave pulse to travel the length of the wire. How long is the wire?

••15.37

a) Starting from the general wave equation (equation 15.9), prove through direct derivation that the Gaussian wave packet described by the equation $y(x,t) = (5.00m)e^{-0.1(x-5t)^2}$ is indeed a traveling wave (that it satisfies the differential wave equation).

b) If x is specified in meters and t in seconds, determine the speed of this wave. On a single graph, plot this wave as a function of x at $t = 0$, $t = 1.00$ s, $t = 2.00$ s, and $t = 3.00$ s.

c) More generally, prove that any function $f(x,t)$ that depends on x and t through a combined variable $x \pm vt$ is a solution of the wave equation, irrespective of the specific form of the function f.

Section 15.5

•**15.38** Suppose the slope of a beach underneath an ocean is 12.0 cm of dropoff for every 1.00 m of horizontal distance. A wave is moving inland, slowing down as it enters shallower water. What is its acceleration when it is 10.0 m from the shoreline? (Take the direction toward the shoreline as the positive x-direction.)

•**15.39** An earthquake generates three kinds of waves: surface waves (L waves), which are the slowest and weakest; shear (S) waves, which are transverse waves and carry most of the energy; and pressure (P) waves, which are longitudinal waves and travel the fastest. The speed of P waves is approximately 7.0 km/s, and that of S waves is about 4.0 km/s. Animals seem to feel the P waves. If a dog senses the arrival of P waves and starts barking 30.0 s before an earthquake is felt by humans, approximately how far is the dog from the earthquake's epicenter?

Section 15.6

15.40 A string with a mass of 30.0 g and a length of 2.00 m is stretched under a tension of 70.0 N. How much power must be supplied to the string to generate a traveling wave that has a frequency of 50.0 Hz and an amplitude of 4.00 cm?

15.41 A string with a linear mass density of 0.100 kg/m is under a tension of 100. N. How much power must be supplied to the string to generate a sinusoidal wave of amplitude 2.00 cm and frequency 120. Hz?

•**15.42** A sinusoidal wave on a string is described by the equation $y = (0.100\ \text{m})\ \sin\ (0.750x - 40.0t)$, where x and y are in meters and t is in seconds. If the linear mass density of the string is 10.0 g/m, determine (a) the phase constant, (b) the phase of the wave at $x = 2.00$ cm and $t = 0.100$ s, (c) the speed of the wave, (d) the wavelength, (e) the frequency, and (f) the power transmitted by the wave.

Sections 15.7 and 15.8

15.43 In an acoustics experiment, a piano string with a mass of 5.00 g and a length of 70.0 cm is held under tension by running the string over a frictionless pulley and hanging a 250.-kg weight from it. The whole system is placed in an elevator.

a) What is the fundamental frequency of oscillation for the string when the elevator is at rest?

b) With what acceleration and in what direction (up or down) should the elevator move for the string to produce the proper frequency of 440. Hz, corresponding to middle A?

15.44 A string is 35.0 cm long and has a mass per unit length of $5.51 \cdot 10^{-4}$ kg/m. What tension must be applied to the string so that it vibrates at the fundamental frequency of 660. Hz?

15.45 A 2.00-m-long string of mass 10.0 g is clamped at both ends. The tension in the string is 150. N.

a) What is the speed of a wave on this string?

b) The string is plucked so that it oscillates. What is the wavelength and frequency of the resulting wave if it produces a standing wave with two antinodes?

•**15.46** Write the equation for a standing wave that has three antinodes of amplitude 2.00 cm on a 3.00-m-long string that is fixed at both ends and vibrates 15.0 times a second. The time $t = 0$ is chosen to be an instant when the string is flat. If a wave pulse were propagated along this string, how fast would it travel?

•**15.47** A 3.00-m-long string, fixed at both ends, has a mass of 6.00 g. If you want to set up a standing wave in this string having a frequency of 300. Hz and three antinodes, what tension should you put the string under?

•**15.48** A cowboy walks at a pace of about two steps per second, holding a glass of diameter 10.0 cm that contains milk. The milk sloshes higher and higher in the glass until it eventually starts to spill over the top. Determine the maximum speed of the waves in the milk.

•**15.49** Students in a lab produce standing waves on stretched strings connected to vibration generators. One such wave is described by the wave function
$y(x,t) = (2.00\text{ cm})\sin\left[\left(20.0\text{ m}^{-1}\right)x\right]\cos\left[\left(150.\text{ s}^{-1}\right)t\right]$, where y is

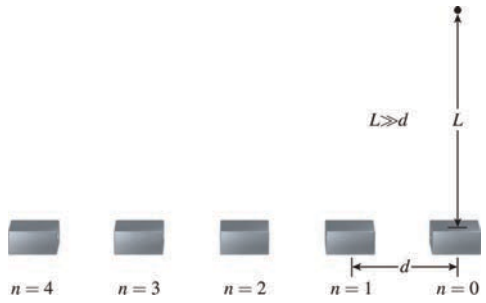
the transverse displacement of the string, x is the position along the string, and t is time. Rewrite this wave function in the form for a wave moving in the positive x-direction and a wave moving in the negative x-direction: $y(x,t) = f(x - vt) + g(x + vt)$; that is, find the functions f and g and the speed, v.

•15.50 An array of wave emitters, as shown in the figure, emits a wave of wavelength λ that is to be detected at a distance L directly above the rightmost emitter. The distance between adjacent wave emitters is d.

a) Show that when $L \gg d$, the wave from the nth emitter (counting from right to left with $n = 0$ being the rightmost emitter) has to travel an extra distance of $\Delta s = n^2 \left(d^2/2L\right)$.

b) If $\lambda = d^2/2L$, will the interference at the detector be constructive or destructive?

c) If $\lambda = d^2/2L = 10^{-3}$ m and $L = 1.00 \cdot 10^3$ m, what is d, the distance between adjacent emitters?



••15.51 A small ball floats in the center of a circular pool that has a radius of 5.00 m. Three wave generators are placed at the edge of the pool, separated by 120.°. The first wave generator operates at a frequency of 2.00 Hz. The second wave generator operates at a frequency of 3.00 Hz. The third wave generator operates at a frequency of 4.00 Hz. If the speed of each water wave is 5.00 m/s, and the amplitude of the waves is the same, sketch the height of the ball as a function of time from $t = 0$ to $t = 2.00$ s, assuming that the water surface is at zero height. Assume that all the wave generators impart a phase shift of zero. How would your answer change if one of the wave generators was moved to a different location at the edge of the pool?

••15.52 A string with linear mass density $\mu = 0.0250$ kg/m under a tension of $F = 250.$ N is oriented in the x-direction. Two transverse

waves of equal amplitude and with a phase angle of zero (at $t = 0$) but with different *angular* frequencies ($\omega = 3000.\ \text{rad/s}$ and $\omega/3 = 1000.\ \text{rad/s}$) are created in the string by an oscillator located at $x = 0$. The resulting waves, which travel in the positive *x*-direction, are reflected at a distant point where both waves have a node, so there is a similar pair of waves traveling in the negative *x*-direction. Find the values of *x* at which the first two nodes in the standing wave are produced by these four waves.

••**15.53** The equation for a standing wave on a string with mass density μ is $y(x, t) = 2A\ \cos\ (\omega t)\ \sin\ (\kappa x)$. Show that the average kinetic energy and potential energy over time for this wave per unit length of string are given by $K_{\text{ave}}(x) = \mu\,\omega^2 A^2 \sin^2 \kappa x$ and $U_{\text{ave}}(x) = F(\kappa A)^2\left(\cos^2 \kappa\, x\right)$.

Additional Exercises

15.54 A sinusoidal wave traveling on a string is moving in the positive x-direction. The wave has a wavelength of 4 m, a frequency of 50.0 Hz, and an amplitude of 3.00 cm. What is the wave function for this wave?

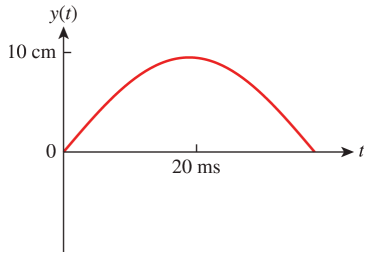
15.55 A guitar string with a mass of 10.0 g is 1.00 m long and attached to the guitar at two points separated by 65.0 cm.

a) What is the frequency of the first harmonic of this string when it is placed under a tension of 81.0 N?

b) If the guitar string is replaced by a heavier one that has a mass of 16.0 g and is 1.00 m long, what is the frequency of the replacement string's first harmonic?

15.56 Write the equation for a sinusoidal wave propagating in the negative x-direction with a speed of 120. m/s, if a particle in the medium in which the wave is moving is observed to swing back and forth through a 6.00-cm range in 4.00 s. Assume that $t = 0$ is taken to be the instant when the particle is at $y = 0$ and that the particle moves in the positive y-direction immediately after $t = 0$.

15.57 Shown in the figure is a plot of the displacement, y, due to a sinusoidal wave traveling along a string as a function of time, t. What are the (a) period, (b) maximum speed, and (c) maximum acceleration of this wave perpendicular to the direction in which it is traveling?



15.58 A50.0 -cm-long wire with a mass of 10.0 g is under a tension of 50.0 N. Both ends of the wire are held rigidly while it is plucked.

a) What is the speed of the waves on the wire?

b) What is the fundamental frequency of the standing wave?

c) What is the frequency of the third harmonic?

15.59 What is the wave speed along a brass wire with a radius of 0.500 mm stretched at a tension of 125 N? The density of brass is $8.60 \cdot 10^3\ \text{kg/m}^3$.

15.60 Two steel wires are stretched under the same tension. The first wire has a diameter of 0.500 mm, and the second wire has a diameter of 1.00 mm. If the speed of waves traveling along the first wire is 50.0 m/s, what is the speed of waves traveling along the second wire?

15.61 The middle-C key (key 40) on a piano corresponds to a fundamental frequency of about 262 Hz, and the soprano-C key (key 64) corresponds to a fundamental frequency of 1046.5 Hz. If the strings used for both keys are identical in density and length, determine the ratio of the tensions in the two strings.

15.62 A sinusoidal wave travels along a stretched string. A point along the string has a maximum velocity of 1.00 m/s and a maximum displacement of 2.00 cm. What is the maximum acceleration at that point?

•15.63 As shown in the figure, a sinusoidal wave travels to the right at a speed of v_1 along string 1, which has linear mass density μ_1. This wave has frequency f_1 and wavelength λ_1. Since string 1 is attached to string 2 (which has linear mass density $\mu_2 = 3\mu_1$), the first wave will excite a new wave in string 2, which will also move to the right. What is the frequency, f_2, of the wave produced in string 2? What is the speed, v_2, of the wave produced in string 2? What is the wavelength, λ_2, of the wave produced in string 2? Write all answers in terms of f_1, v_1, and λ_1.

•15.64 The tension in a 2.70 -m-long, 1.00 -cm-diameter steel cable $(\rho = 7800.\ \text{kg/m}^3)$ is 840. N. What is the fundamental frequency of vibration of the cable?

•15.65 A wave traveling on a string has the equation of motion $y(x,t) = 0.0200 \sin(5.00x - 8.00t)$, where x and y are in meters and t is in seconds.

a) Calculate the wavelength and the frequency of the wave.

b) Calculate its velocity.

c) If the linear mass density of the string is $\mu = 0.100$ kg/m, what is the tension on the string?

•15.66 Calvin sloshes back and forth in his bathtub, producing a standing wave. What is the frequency of such a wave if the bathtub is

150. cm long and 80.0 cm wide and contains water that is 38.0 cm deep?

•15.67 Consider a guitar string stretching 80.0 cm between its anchored ends. The string is tuned to play middle C, with a frequency of 261.6 Hz, when oscillating in its fundamental mode, that is, with one antinode between the ends. If the string is displaced 2.00 mm at its midpoint and released to produce this note, what are the wave speed, v, and the maximum speed, $v_{\max}$, of the midpoint of the string?

15.68 Two waves traveling in opposite directions along a string fixed at both ends create a standing wave described by $y(x,t) = 1.00 \cdot 10^{-2} \sin(25.0x) \cos(1200.t)$. The string has a linear mass density of 0.0100 kg/m, and the tension in the string is supplied by a mass hanging from one end. If the string vibrates in its third harmonic, calculate (a) the length of the string, (b) the velocity of the waves, and (c) the mass of the hanging mass.

15.69 A sinusoidal transverse wave of wavelength 20.0 cm and frequency 500. Hz travels along a string in the positive *z*-direction. The wave oscillations take place in the *xz*-plane and have an amplitude of 3.00 cm. At time $t = 0$, the displacement of the string at $x = 0$ is $z = 3.00$ cm.

a) A photo of the wave is taken at $t = 0$. Make a simple sketch (including axes) of the string at this time.

b) Determine the speed of the wave.

c) Determine the wave's wave number.

d) If the linear mass density of the string is 30.0 g/m, what is the tension in the string?

e) Determine the function $D(z,t)$ that describes the displacement x that is produced in the string by this wave.

••15.70 A heavy cable of total mass M and length $L = 5.00$ m has one end attached to a rigid support and the other end hanging free. A small transverse displacement is initiated at the bottom of the cable. How long does it take for the displacement to travel to the top of the cable?

MULTI-VERSION EXERCISES

15.71 A rubber band of mass 0.3491 g is stretched between two fingers, putting each side under a tension of 1.777 N. The overall stretched length of the band is 20.27 cm. One side of the band is plucked, setting up a vibration in 8.725 cm of the band's stretched length. What is the lowest-frequency vibration that can be set up on this part of the rubber band? Assume that the band stretches uniformly.

15.72 A rubber band of mass 0.4245 g is stretched between two fingers. The overall stretched length of the band is 20.91 cm. One side of the band is plucked, setting up a vibration in 8.117 cm of the band's stretched length. The lowest-frequency vibration that can be set up on this part of the rubber band is 184.2 Hz. What is the tension in each side of the rubber band? Assume that the band stretches uniformly.

15.73 A rubber band of mass 0.1701 g is stretched between two fingers, putting each side under a tension of 1.851 N. The overall stretched length of the band is 21.55 cm. One side of the band is plucked, setting up a vibration in the band's stretched length. The lowest-frequency vibration that can be set up on this part of the rubber band is 254.6 Hz. What is the length of the vibrating part of the band? Assume that the band stretches uniformly.

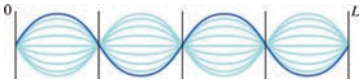
15.74 A satellite in a circular orbit around the Sun uses a square solar panel as a power source. The edges of the panel are 1.459 m long. The panel's efficiency is 16.57%. The satellite is $4.949 \cdot 10^7$ km from the Sun. How much power does the solar panel provide to the satellite? Assume that the total power output of the Sun is $3.937 \cdot 10^{26}$ W.

15.75 A satellite in a circular orbit around the Sun uses a square solar panel as a power source. The panel's efficiency is 16.87%. The satellite is $6.103 \cdot 10^7$ km from the Sun. The solar panel provides $5.215 \cdot 10^3$ W to the satellite. How long are the edges of the solar panel? Assume that the total power output of the Sun is $3.937 \cdot 10^{26}$ W.

15.76 A satellite in a circular orbit around the Sun uses a square solar panel as a power source. The edges of the panel are 2.375 m long. The

satellite is $7.257 \cdot 10^7$ km from the Sun. The solar panel provides $5.768 \cdot 10^3$ W to the satellite. What is the efficiency of the solar panel? Assume that the total power output of the Sun is $3.937 \cdot 10^{26}$ W.

15.77 Consider a string with a linear mass density of 0.2833 g/cm and a length of 116.7 cm, which is oscillating as shown in the figure. The tension on the string is 18.25 N. At what frequency is the string vibrating?



15.78 Consider a string with a linear mass density of 0.1291 g/cm and a length of 117.5 cm, which is oscillating as shown in the figure. The string is vibrating at a frequency of 93.63 Hz. What is the tension on the string?

15.79 Consider a string with a linear mass density of 0.1747 g/cm, which is oscillating as shown in the figure. The string is under a tension of 10.81 N and is vibrating at a frequency of 59.47 Hz. What is the length of the string?

Recognizing sounds is one of the most important ways in which we learn about the world around us. As we'll see in this chapter, human hearing is very sensitive and can distinguish a wide range of frequencies and degrees of loudness. However, although interpreting sound probably developed in animals from earliest times, as it warned of predators or provided help in hunting prey, sound has also been a powerful source of cultural ritual and entertainment for humans (Figure 16.1). Music has been part of human life for as long as society has existed.

FIGURE 16.1 U2 in the process of producing sound waves during their 2011 World Tour.

RG4 WENN Photos/Newscom

Sound is a type of wave, so this chapter's study of sound builds directly on the concepts about waves presented in Chapter 15. Some characteristics of sound waves also pertain to light waves and will be useful when we study those waves in later chapters. This chapter also examines sources of musical sounds and applications of sound in a wide range of other areas, from medicine to geography.

WHAT WE WILL LEARN

- Sound consists of longitudinal pressure waves and needs a medium in which to propagate.
- The speed of sound is usually higher in solids than in liquids and higher in liquids than in gases.
- The speed of sound in air depends on the temperature; it is approximately 343 m/s at normal atmospheric pressure and a temperature of $20^\circ\mathrm{C}$.
- The intensity of sound detectable by the human ear spans a large range and is usually expressed on a logarithmic scale in terms of decibels (dB).
- Sound waves from two or more sources can interfere in space and time, resulting in destructive or constructive interference.
- Interference of sound waves of slightly different frequencies results in oscillations in intensity known as beats. The beat frequency is the absolute value of the difference in the frequencies.
- The Doppler effect is the shift in the observed frequency of a sound due to the fact that the source moves (is approaching or receding) relative to the observer.
- If a sound source moves with a speed greater than that of sound, a shock wave, or Mach cone, develops.
- Standing resonant waves in open or closed pipes can be generated only at discrete wavelengths.

16.1 Longitudinal Pressure Waves

Sound is a pressure variation that propagates through some medium. In air, the pressure variation causes abnormal motion of air molecules in the direction of propagation; thus, a sound wave is longitudinal. When we hear a sound, our eardrums are set in vibration by the air next to them. If this air has a pressure variation that repeats with a certain frequency, the eardrums vibrate at this frequency.

Sound requires a medium for propagation. If the air is pumped out of a glass jar that contains a ringing bell, the sound ceases as the air is evacuated from the jar, even though the hammer clearly still hits the bell. Thus, sound waves originate from a source, or emitter, and need a medium to travel through. In spite of movie scenes that include a huge roar when a spaceship flies by or when a star or planet explodes, interstellar space is a silent place because it is a vacuum.

Figure 16.2 shows a continuous pressure wave composed of alternating variations of air pressure—a pressure excess (compression) followed by a pressure reduction (rarefaction). Plotting these variations along an x-axis for various times, as in Figure 16.2, allows us to deduce the wave speed.

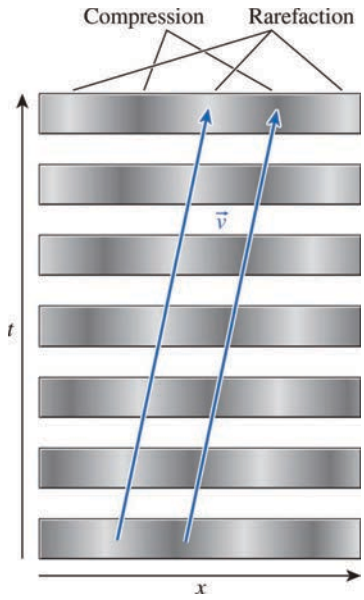

FIGURE 16.2
Propagation of a longitudinal pressure wave along an *x*-axis as a function of time.

Although sound has to propagate through a medium, that medium does not have to be air. When you are under water, you can still hear sounds, so you know that sound also propagates through liquids. In addition, you may have put your ear to a train track to obtain advance information on an approaching train (not recommended, by the way, because the train may be closer than you think). Thus, you know that sound propagates through solids. In fact, sound propagates faster and with less loss through metals than through air. If this were not so, putting your ear to the train track would be pointless.

Sound Velocity

When you watch fireworks on the Fourth of July, you see the explosions of the rockets before you hear the sounds (Figure 16.3). The reason is that the light emitted from the explosions reaches your eyes almost instantaneously, because the speed of light is approximately 300,000 km/s. However, the speed of sound is much slower, and so the sound waves from the explosions reach you some time after the light waves have already arrived.

FIGURE 16.3 You see fireworks before you hear their explosive sounds.

Smileus/Shutterstock

How fast does sound propagate—in other words, what is the speed of sound? For a wave on a string, we saw in Chapter 15 that the wave speed is $v = \sqrt{F/\mu}$, where F is the string tension (a force) and μ is the linear mass density of the string. From this equation, you can think of v as the square root of the ratio of the restoring force to the inertial response. If the wave propagates through a three-dimensional medium instead of a one-dimensional string, the inertial response originates from the density of the medium, ρ. Chapter 13 discussed the elasticity of solids and introduced the elastic modulus known as *Young's modulus*, Y. This modulus determines the fractional change in length of a thin rod as a function of the force per unit area applied to the rod. Analysis reveals that Young's modulus is the appropriate force term for a wave propagating along a thin solid rod; so we obtain

$$v = \sqrt{\frac{Y}{\rho}} \qquad \textbf{(16.1)}$$

for the speed of sound in a thin solid rod.

The speed of sound in fluids—both liquids and gases—is similarly related to the bulk modulus, *B,* defined in Chapter 13, as determining a material's volume change in response to external pressure. Thus, the speed of sound in a gas or liquid is given by

$$v = \sqrt{\frac{B}{\rho}}. \qquad \textbf{(16.2)}$$

Although these dimensional arguments show that the speed of sound is proportional to the square root of the modulus divided by the appropriate density, a more fundamental analysis, such as that in the following derivation, shows that the proportionality constants have a value of exactly 1 in equations 16.1 and 16.2.

DERIVATION 16.1 Speed of Sound

Suppose a fluid is contained in a cylinder, with a movable piston on one end (Figure 16.4). If this piston moves with speed v_p into the fluid, it will compress the fluid element in front of it. This fluid element, in turn, will move as a result of the pressure change; its leading edge will move with the speed of sound, v, which, by definition, is the speed of the pressure waves in the medium.

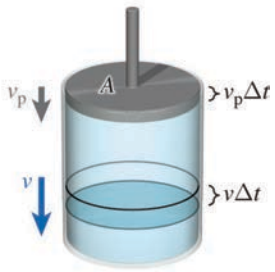

FIGURE 16.4 Piston compressing a fluid.

Pushing the piston into the fluid with a force, F, causes a pressure change, $p = F/A$ in the fluid (see Chapter 13), where A is the cross-sectional area of the cylinder and also of the piston. The force exerted on the fluid element of mass m causes an acceleration given by $\Delta v/\Delta t$:

$$F = m\frac{\Delta v}{\Delta t} = m\frac{v_p}{\Delta t} \Rightarrow p = \frac{F}{A} = \frac{m}{A}\frac{v_p}{\Delta t}.$$

Because the mass is the density of the fluid times its volume, $m = \rho V$, and the volume is that of the cylinder of base area A and length l, we can find the mass of the fluid element:

$$m = \rho V = \rho A l \Rightarrow p = \frac{m}{A}\frac{v_p}{\Delta t} = \frac{\rho A l}{A}\frac{v_p}{\Delta t} = \frac{\rho l v_p}{\Delta t}.$$

Since this fluid element responds to the compression by moving with speed v during the time interval Δt, the length of the fluid element that has experienced the pressure wave is $l = v\Delta t$, which finally yields the pressure difference:

$$p = \frac{\rho l v_{\mathrm{p}}}{\Delta t} = \frac{\rho (v\Delta t) v_{\mathrm{p}}}{\Delta t} = \rho v v_{\mathrm{p}}. \qquad \text{(i)}$$

From the definition of the bulk modulus (see Chapter 13), $p = B\Delta V/V$. We can combine this expression for the pressure and that obtained in equation (i):

$$p = \rho v v_{\mathrm{p}} = B\frac{\Delta V}{V}. \qquad \text{(ii)}$$

Again, the volume of the moving fluid, *V,* that has experienced the pressure wave is proportional to v since $V = Al = Av\Delta t$. In addition, the volume change in the fluid caused by pushing the piston into the cylinder is $\Delta V = Av_{\mathrm{p}}\Delta t$. Thus, the ratio $\Delta V/V$ is equivalent to v_{p}/v, the ratio of the piston's speed to the speed of sound. Inserting this result into equation (ii) yields

$$\rho v v_{\mathrm{p}} = B\frac{\Delta V}{V} = B\frac{v_{\mathrm{p}}}{v} \Rightarrow$$
$$\rho v^2 = B \Rightarrow$$
$$v = \sqrt{\frac{B}{\rho}}.$$

As you can see, the speed with which the piston is pushed into the fluid cancels out. Therefore, it does not matter what the speed of the excitation is; the sound always propagates with the same speed in the medium.

Equations 16.1 and 16.2 both state that the speed of sound in a given state of matter (gas, liquid, or solid) is inversely proportional to the square root of the density, which means that in two different gases, the speed of sound is higher in the one with the lower density. However, the values of Young's modulus for solids are much larger than the values of the bulk modulus for liquids, which are larger than those for gases. This difference is more important than the density dependence. From equations 16.1 and 16.2, it then follows that for the speeds of sound in solids, liquids, and gases, $v_{\text{solid}} > v_{\text{liquid}} > v_{\text{gas}}$. Representative values for the speed of sound in different materials under standard conditions of pressure (1 atm) and temperature $(20\,^{\circ}\text{C})$ are listed in Table 16.1.

Table 16.1 Speed of Sound in Some Common Substances

	Substance	Speed of Sound (m/s)
Gases	Krypton	220
	Carbon dioxide	260
	Air	343
	Helium	960
	Hydrogen	1280
Liquids	Methanol	1143
	Mercury	1451
	Water	1480
	Seawater	1520
Solids	Lead	1160
	Concrete	3200
	Hardwood	4000
	Steel	5800
	Aluminum	6400
	Diamond	12,000

Concept Check 16.1

You are in the middle of a concert hall that is 120.0 m deep. What is the time difference between the arrival of the sound directly from the orchestra at your position and the arrival of the sound reflected from the back of the concert hall?

a) 0.010 s

b) 0.056 s

c) 0.11 s

d) 0.35 s

e) 0.77 s

We are most interested in the speed of sound in air, because this is the most important medium for sound propagation in everyday life. At normal atmospheric pressure and 20° C, this speed of sound is

$$v_{\text{air}} = 343 \text{ m/s}. \tag{16.3}$$

Knowing the speed of sound in air explains the 5-second rule for thunderstorms: If 5 s or less pass between the instant you see a lightning strike (Figure 16.5) and the instant you hear the thunder, the lightning strike is 1 mi or less away. Since sound travels approximately 340 m/s, it travels 1700 m, or approximately 1 mi, in 5 s. The speed of light is approximately 1 million times greater than the speed of sound, so the visual perception of the lightning strike occurs with essentially no delay. Countries that use the metric system have a 3-second rule: A 3-s delay between lightning and thunder corresponds to 1 km of distance to the lightning strike (Figure 16.6).

FIGURE 16.5 The 5-second rule for lightning strikes is due to the difference in speed between light and sound.

View Stock/age fotostock

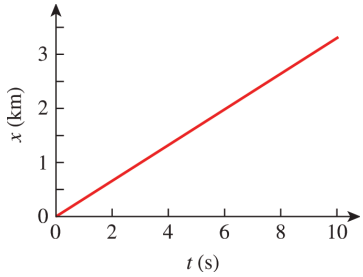

FIGURE 16.6 Distance x to the source (lightning strike) of the sound as a function of the time delay t in hearing the sound (thunder).

The speed of sound in air depends (weakly) on the air temperature, T. The following linear dependence is obtained experimentally:

$$v(T) = (331 + 0.6T/^\circ\mathrm{C})\ \mathrm{m/s}. \qquad \textbf{(16.4)}$$

EXAMPLE 16.1 Football Cheers

A student's apartment is located exactly 3.75 km from the football stadium. He is watching the game live on TV and sees the home team score a touchdown. According to his clock, 11.2 s pass after he hears the roar of the crowd on TV until he hears it again from outside.

PROBLEM

What is the temperature at game time?

SOLUTION

The TV signal moves with the speed of light and thus arrives at the student's TV at essentially the same instant as the action is happening in the stadium. Thus, the delay in the arrival of the roar at the student's apartment can be attributed entirely to the finite speed of sound. We find this speed of sound from the given data:

$$v = \frac{\Delta x}{\Delta t} = \frac{3750\,\text{m}}{11.2\,\text{s}} = 334.8\,\text{m/s}.$$

Using equation 16.4, we find the temperature at game time:

$$T = \frac{v(T) - 331}{0.6}\,^\circ\text{C} = \frac{334.8 - 331}{0.6}\,^\circ\text{C} = \frac{3.8}{0.6}\,^\circ\text{C} = 6.4^\circ$$

DISCUSSION

A word of caution is in order: Several uncertainties are inherent in this result. First, if we redid the calculation for a time delay of 11.1 s, we would find the temperature to be 11.4 °C, or 5 °C higher than what we found using 11.2 s as the delay. Second, if 0.1 s makes such a big difference in the determined temperature, we need to ask if the TV signal really gets to the student's apartment instantaneously. The answer is

no. If the student watches satellite TV, it takes about 0.2 s for the signal to make it up to the geostationary satellite and back down to the student's dish. In addition, short intentional delays are often inserted in TV broadcasts. Thus, our calculation is not very useful for practical purposes.

Sound Reflection

All waves, including sound waves, are at least partially reflected at the boundary between two different media. Sound waves are no exception. Sound waves that travel through air and then hit an object are partially reflected by the object. You can measure the distance to a distant large object by measuring the time between producing a short, loud sound and hearing that sound again after it has traveled to the object, reflected off the object, and returned to you. For example, if you were standing in Yosemite Valley and shouted in the direction of the flat face of Half Dome, 1.0 km away, the sound of your voice would carry across the valley, reflect off Half Dome, and return to you, making a round trip of 2.0 km. The speed of the sound of your voice is 343 m/s, so the time delay between shouting and hearing your reflected shout would be $t = (2000\,\text{m})/(343\,\text{m/s}) = 5.8\,\text{s}$, a time interval that you could easily measure with a wristwatch.

This principle is used in ultrasound imaging for medical diagnostic purposes. Ultrasound waves have a frequency much higher than a human can hear, between 2 and 18 mHz. The frequency is chosen to provide detailed images and to penetrate deeply into human tissue. When the ultrasound waves encounter a change in density of the tissue, some of them are reflected back. Measuring how much time the ultrasound waves take to travel from the emitter to the receiver and recording how much of the emission is reflected as well as the direction of the original waves allows an image to be formed. The average value of the speed of ultrasound waves used for imaging human tissue is 1540 m/s. The time for these ultrasound waves to travel 2.5 cm and return is $t = (0.050\,\text{m})/(1540\,\text{m/s}) = 32\,\mu s$, and the time to travel 10.0 cm and return is 130 μs Thus, the ultrasound device needs to be able to measure accurately times in the range from 30 to 130 μs. A typical image of a fetus produced by ultrasound imaging is shown in Figure 16.7.

FIGURE 16.7 An image of a fetus produced by the reflection of ultrasound waves.

Steve Allen/Stockbyte/Getty Images

Bats and dolphins navigate using sound reflection (Figure 16.8). They emit sound waves in a frequency range from 14,000 Hz to well over 100,000 Hz in a specific direction and determine information about their surroundings from the reflected sound. This process of echolocation allows bats to navigate in darkness.

The automotive industry is taking advantage of the same sound frequency range for navigation assistance, too. Ultrasonic sensors are used for parking-assist systems (Figure 16.9). Their advantages are that they are compact, reliable, and unaffected by light levels, atmospheric conditions, or the color of objects. Some of the manufacturers of self-driving cars also incorporate ultrasonic sensors into their sensor arrays to complement cameras and radar.

FIGURE 16.8 Bat flying in darkness, relying on echolocation for navigation.

W. Bauer and G. D. Westfall

16.2 Sound Intensity

In Chapter 15, the intensity of a wave was defined as the power per unit area. We saw that for spherical waves the intensity falls as the second power of the distance to the source, $I \propto r^{-2}$, giving the ratio

$$\frac{I(r_1)}{I(r_2)} = \left(\frac{r_2}{r_1}\right)^2. \tag{16.5}$$

This relationship also holds for sound waves. Since the intensity is the power per unit area, its physical units are watts per square meter $\left(\mathrm{W/m^2}\right)$.

Sound waves that can be detected by the human ear have a very large range of intensities, from whispers as low as $10^{-12}\ \mathrm{W/m^2}$ to the output of a jet engine or a rock band at close distance, which can reach $1\ \mathrm{W/m^2}$. The oscillations in pressure for even the loudest sounds, at the pain threshold of $10\ \mathrm{W/m^2}$, are on the order of only tens of micropascals (μPa). Normal atmospheric air pressure, by comparison, is 10^5 Pa. Thus, you can see that the air pressure varies by only 1 part in 10 billion, even for the loudest sounds. And the variation is several orders of magnitude less for the quietest sounds you can hear. This might give you a new appreciation for the capabilities of your ears.

Since human ears can register sounds over many orders of magnitude of intensity, a logarithmic scale is used to measure sound intensities. The unit of this scale is the bel (B), named for Alexander Graham Bell, but much more commonly used is the **decibel (dB)**: $1\ \mathrm{dB} = 0.1$ bel. bel. The Greek letter β symbolizes the sound level measured on this decibel scale and is defined as

$$\beta = 10 \log \frac{I}{I_0}. \tag{16.6}$$

Here $I_0 = 10^{-12}\ \text{W/m}^2$, which corresponds approximately to the minimum intensity that a human ear can hear. The notation "log" refers to the base-10 logarithm. (See Appendix A for a refresher on logarithms.) Thus, a sound intensity 1000 times the reference intensity, I_0, gives $\beta = 10 \log 1000\ \text{dB} = 10 \cdot 3\ \text{dB} = 30\ \text{dB}$. This sound level corresponds to a whisper not very far from your ear (Table 16.2).

Table 16.2 Levels of Sounds in Common Situations

Sound	Sound Level (dB)
Quietest sound heard	0
Background sound in library	30
Golf course	40–50
Street traffic	60–70
Train at railroad crossing	90
Dance club	110
Jackhammer	120
Jet taking off from aircraft carrier	130–150

Self-Test Opportunity 16.1

You hear a sound with level 80.0 dB, and you are located 10.0 m from the sound source. What is the power being emitted by the sound source?

Relative Intensity and Dynamic Range

The relative sound level, $\Delta\beta$, is the difference between two sound levels:

$$\begin{aligned}
\Delta\beta &= \beta_2 - \beta_1 \\
&= 10\log\frac{I_2}{I_0} - 10\log\frac{I_1}{I_0} \\
&= 10(\log I_2 - \log I_0) - 10(\log I_1 - \log I_0) \\
&= 10\log I_2 - 10\log I_1 \\
\Delta\beta &= 10\log\frac{I_2}{I_1}.
\end{aligned} \tag{16.7}$$

The *dynamic range* is a measure of the relative sound levels of the loudest and the quietest sounds produced by a source. The dynamic range of a compact disc is approximately 90 dB, whereas the range was about 70 dB for vinyl records. Manufacturers list the dynamic range for all high-end loudspeakers and headphones as well. In general, the higher the dynamic range, the better the sound quality. However, the price usually increases with the dynamic range.

SOLVED PROBLEM 16.1 Relative Sound Levels at a Rock Concert

Two friends attend a rock concert and bring along a sound meter. With this device, one of the friends measures a sound level of $\beta_1 = 105.0$ dB, whereas the other, who sits 4 rows (2.8 m) closer to the stage, measures $\beta_2 = 108.0$ dB.

PROBLEM

How far away are the two friends from the loudspeakers on stage?

SOLUTION

THINK

We express the intensities at the two seats using equation 16.5 and the relative sound levels at the two seats using equation 16.7. We can combine these two equations to obtain an expression for the relative sound levels at the two seats. Knowing the distance between the two seats, we can then calculate the distance of the seats to the loudspeakers on the stage.

SKETCH

Figure 16.10 shows the relative positions of the two friends.

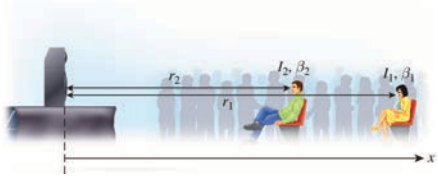

FIGURE 16.10 The relative distances, r_1 and r_2, of the two friends from the loudspeakers at a concert.

RESEARCH

The distance of the first friend from the loudspeakers is r_1, and the distance of the second friend from the loudspeakers is r_2. The intensity of the sound at r_1 is I_1, and the intensity of the sound at r_2 is I_2. The sound level at r_1 is β_1, and the sound level at r_2 is β_2. We can express the two intensities in terms of the two distances using equation 16.5:

$$\frac{I_1}{I_2} = \left(\frac{r_2}{r_1}\right)^2. \qquad \text{(i)}$$

We can then use equation 16.7 to relate the sound levels at r_1 and r_2 to the sound intensities:

$$\beta_2 - \beta_1 = 10 \log \frac{I_2}{I_1}. \qquad \text{(ii)}$$

Combining equations (i) and (ii), we get

$$\beta_2 - \beta_1 = \Delta\beta = 10 \log \left(\frac{r_1}{r_2}\right)^2 = 20 \log \left(\frac{r_1}{r_2}\right). \text{(iii)}$$

The relative sound level, $\Delta\beta$, is specified in the problem and we know that

$$r_2 = r_1 - 2.8 \text{ m}.$$

Thus, we can solve for the distance r_1 and then obtain r_2.

SIMPLIFY

Substituting the relationship between the two distances into equation (iii) gives us

$$\Delta\beta = 20\ \log\left(\frac{r_1}{r_1 - 2.8\,\text{m}}\right) \Rightarrow$$

$$10^{\Delta\beta/20} = \frac{r_1}{r_1 - 2.8\,\text{m}}$$

$$(r_1 - 2.8\,\text{m})10^{\Delta\beta/20} = r_1 10^{\Delta\beta/20} - (2.8\,\text{m})10^{\Delta\beta/20} = r_1 =$$

$$r_1 = \frac{(2.8\,\text{m})10^{\Delta\beta/20}}{10^{\Delta\beta/20} - 1}.$$

CALCULATE

Putting in the numerical values, we obtain the distance of the first friend from the loudspeakers:

$$r_1 = \frac{(2.8\,\text{m})10^{(108.0\,\text{dB}-105.0\,\text{dB})/20}}{10^{(108.0\,\text{dB}-105.0\,\text{dB})/20} - 1} = 9.58726\,\text{m}.$$

The distance of the second friend is

$$r_2 = (9.58726\,\text{m}) - (2.8\,\text{m}) = 6.78726\,\text{m}.$$

ROUND

We report our results to two significant figures:

$$r_1 = 9.6\,\text{m} \quad \text{and} \quad r_2 = 6.8\,\text{m}.$$

DOUBLE-CHECK

To double-check, we substitute our results for the distances back into equation (iii) to verify that we get the specified sound level difference:

$$\Delta\beta = (108.0\,\text{dB}) - (105.0\,\text{dB}) = 3.0\,\text{dB} = 20\log\left(\frac{9.6\,\text{m}}{6.8\,\text{m}}\right.$$

Therefore, our answer seems reasonable, or at least consistent with what was originally stated in the problem.

Concept Check 16.2

At an intersection, you pull up next to a car whose windows are closed. You know that the people in the car are listening to loud music, but you cannot figure out what the song is. All you can hear is the rhythmic thumping of the bass because the materials of which the car is made

a) attenuate the high frequencies more than the low ones.

b) attenuate the low frequencies more than the high ones.

c) amplify the low frequencies.

d) amplify the high frequencies.

Sound Attenuation

As sound travels through a medium, its intensity is reduced not only by the increasing distance from the source (the $1/r^2$ relationship discussed above) but also by scattering of the sound waves and absorption, which converts sound's energy into other forms of energy. This sound attenuation can be expressed as

$$I = I_0 e^{-\alpha x}, \tag{16.8}$$

where x is the path length and a is the absorption coefficient. The absorption coefficient is different for different materials and varies widely. Foams, for example, have very high absorption coefficients and are therefore used for sound insulation. The absorption coefficient also depends on the frequency of the sound; in general, it increases linearly with frequency.

Limits of Human Hearing

Our ears translate the pressure waves in air into what we perceive as sounds. The essential parts of the human ear are shown in a cutaway view in Figure 16.11. The ear canal opens to the outside and guides the sound waves to the eardrum, which vibrates when the sound waves hit it. Behind the eardrum is the inner ear, which is encased in some of the hardest bone in the human body. Inside the inner ear and connected to the eardrum are three small bones: hammer, anvil, and stirrup. The motions of the eardrum are transferred to the fluid-filled cochlea via these bones. In the cochlea, these motions are translated into nerve pulses, which are sent to the temporal lobe in the cerebral cortex.

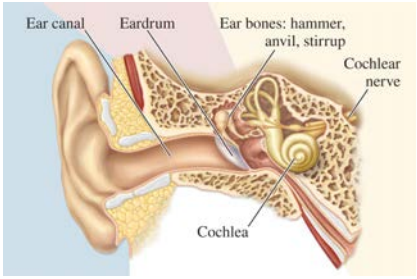

FIGURE 16.11 Parts of the human ear.

Human ears can detect sound waves with frequencies between approximately 20 Hz and 20,000 Hz. (Dogs, by the way, can detect even higher frequencies of sound.) As mentioned earlier, the threshold of human hearing was used as the anchor for the decibel scale. However, the ability of the human ear to detect sound depends strongly on the frequency of the sound, as well as the age of the human. Teenagers have no trouble hearing frequencies of 10,000 Hz, but most retirees cannot hear them at all. One example of such a high-pitched sound is the buzzing of cicadas in the summer, which many older people cannot hear anymore.

The sounds that we can hear best have frequencies around 1000 Hz. When you listen to music, the spectrum of sound typically extends over the entire range of human hearing. This occurs

because musical instruments produce a characteristic mixture of the base frequencies of the notes played and several overtones at higher frequencies. If you play music on a stereo system and turn down the volume, you reduce the sound intensity in all frequency ranges approximately uniformly. Depending on how far down you turn the volume, you can approach sound intensities in the very high and very low frequencies that are very close to or below your hearing threshold. As a result, the music sounds flat. In order to correct for this perceived narrowing of the spectrum of the sound, many stereo systems have a loudness switch, which artificially enhances the power output of the very low and very high frequencies relative to the rest of the spectrum, giving the music a fuller sound at low volume settings.

A sound level above 130 dB will cause pain, and sound levels above 150 dB can rupture an eardrum. In addition, long-term exposure to sound levels above 120 dB causes loss of sensitivity in the human ear. For this reason, it is advisable to avoid listening to very loud music for long periods of time. In addition, where loud noises are part of the work environment, for example, on the deck of an aircraft carrier (Figure 16.12), it is necessary to wear ear protection to avoid ear damage.

FIGURE 16.12 A Navy launch officer ducks under the wing of an F/A-18F being launched off the USS *John C. Stennis.* Ear protection is required in this environment of high-intensity sound.

EXAMPLE 16.2 Wavelength Range of Human Hearing

The range of frequencies for sounds that the human ear can detect corresponds to a range of wavelengths.

PROBLEM

What is the range of wavelengths for the sounds to which the human ear is sensitive?

SOLUTION

The range of frequencies the ear can detect is 20–20,000 Hz. At room temperature, the speed of sound is 343 m/s. Wavelength, speed, and frequency are related by

$$v = \lambda f \Rightarrow \lambda = \frac{v}{f}.$$

For the lowest detectable frequency, we then obtain

$$\lambda_{\text{max}} = \frac{v}{f_{\text{min}}} = \frac{343\ \text{m/s}}{20\ \text{Hz}} = 17\ \text{m}.$$

Since the highest detectable frequency is 1000 times the lowest, the shortest wavelength of audible sound is 0.001 times the value we just calculated: $\lambda_{\text{min}} = 0.017\ \text{m}$.

16.3 Sound Interference

Like all three-dimensional waves, sound waves from two or more sources can interfere in space and time. Let's first consider spatial interference of sound waves emitted by two **coherent sources**—that is, two sources that produce sound waves that have the same frequency and are in phase.

Figure 16.13 illustrates two loudspeakers emitting identical sinusoidal pressure fluctuations in phase. The circular arcs represent the maxima of the sound waves at some given instant in time. The horizontal line to the right of each speaker anchors a sine curve to show that an arc occurs wherever the sine has a maximum. The distance between neighboring arcs emanating from one source is exactly one wavelength, λ. You can clearly see that the arcs from the different loudspeakers intersect. Examples of such intersections are points A and C. If you count the maxima, you see that both A and C are exactly 8λ away from the lower loudspeaker, while A is 5λ away from the upper speaker and C is 6λ away. Thus, the path length difference, $\Delta r = r_2 - r_1$, is an integer multiple of the wavelength. This relationship is a general condition for constructive interference at a given spatial point:

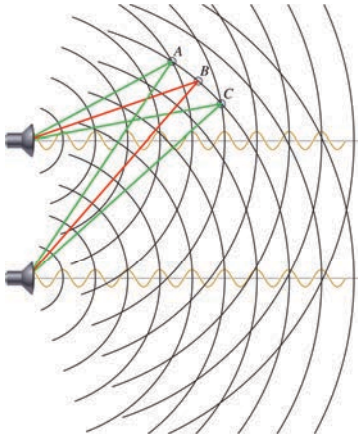

FIGURE 16.13
Interference of two identical sets of sinusoidal sound waves.

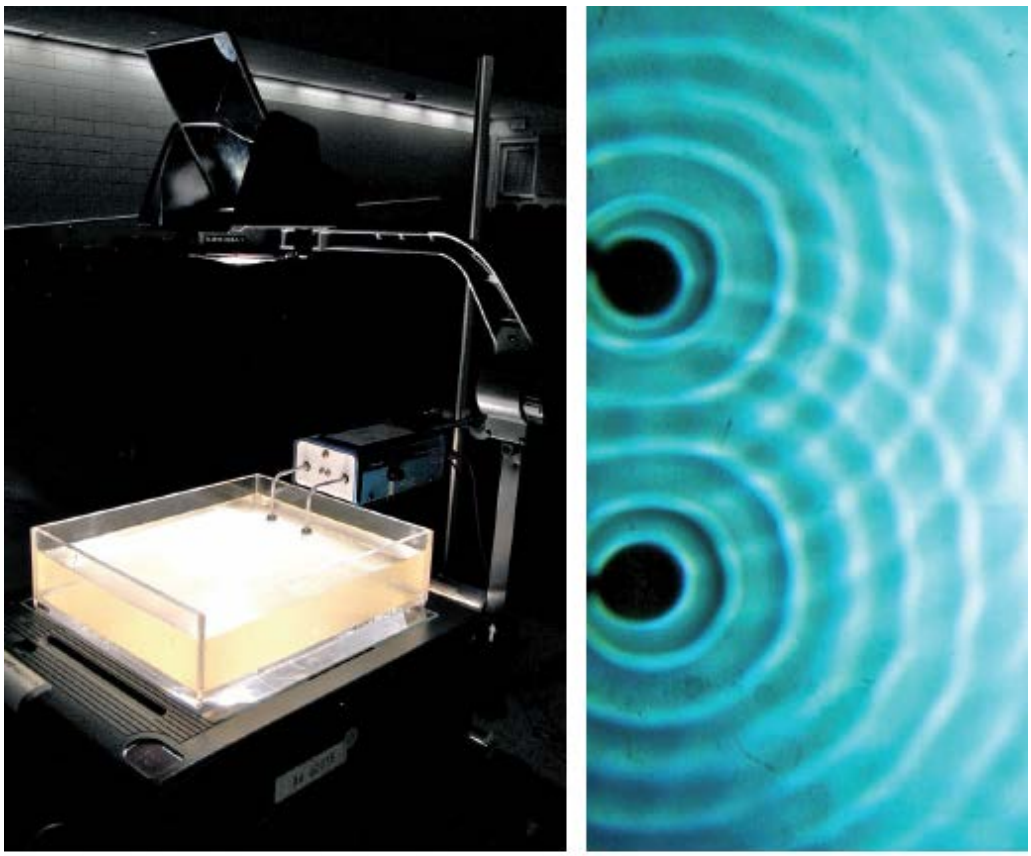
$$\Delta r = n\lambda, \text{ for all } n = 0, \pm 1, \pm 2, \pm 3, \ldots \text{ (constructive int}$$

Approximately halfway between points A and C in Figure 16.13 is point B. Just as for the other two points, the distance between B and the lower speaker is 8λ. However, this point is 5.5λ away from the upper speaker. As a result, at point B, the maximum of the sound wave from the lower speaker falls on a minimum of the sound wave from the upper speaker, and they cancel out. This means that destructive interference occurs at this point. You have probably already noticed that the path length difference is an odd number of half wavelengths. This is the general condition for destructive interference:

$$\Delta r = \left(n + \tfrac{1}{2}\right)\lambda, \text{ for all } n = 0, \pm 1, \pm 2, \pm 3, \ldots \text{ (destructi}$$

Wave interference can be visualized with the aid of a ripple tank, which is used in lecture demonstrations at many universities.

Figure 16.14a shows such a tank, which is a clear rectangular plastic container filled with water, sitting on top of an overhead projector. A motor drives two pegs, which move up and down synchronously and create surface waves on the water. The resulting wave pattern is projected onto a screen. Figure 16.14b is a projection image that shows the wave interference clearly. Notice the lines revealing where the two waves enhance each other (interfere constructively) and where they cancel each other out (interfere destructively).



(a) (b)

FIGURE 16.14 Setup for a lecture demonstration of wave phenomena. (a) The water-filled ripple tank, with a motor driving two pegs that generate surface waves on the water, sits on an overhead projector. (b) The projected image shows the interference of the water waves.

W. Bauer and G. D. Westfall

Why do we not detect the dead zones due to the lines of destructive interference in front of our stereo speakers when we listen to music at home? The answer is that these lines of interference depend on the wavelength and thus on the frequency. Sounds of different frequencies cancel each other out and add up maximally along different lines. Any note played by any instrument has a rich mixture of different frequencies; so, even if one particular frequency cancels, we can still hear all or most of the rest. Generally, we do not detect what is missing. In addition, all objects in a room scatter and reflect the sound emitted from stereo speakers to some degree, which makes detection of a dead zone even less likely. However, with pure sinusoidal tones, the existence of dead zones can be easily detected by ear. Nevertheless, spatial interference of sound waves does not play a huge role in daily life. In Chapter 34, where we discuss light waves, we will encounter many observable effects of wave interference.

Beats

It is also possible to have interference of two waves in time, which has much greater practical importance than interference in space does. To consider this effect, suppose an observer is located at some arbitrary point, x_0, in space, and two sound waves with slightly different frequencies and the same amplitude are emitted:

$$y_1(x_0,t) = A\sin(\kappa_1 x_0 + \omega_1 t + \phi_1) = A\sin\left(\omega_1 t + \widetilde{\phi}_1\right)$$
$$y_2(x_0,t) = A\sin(\kappa_2 x_0 + \omega_2 t + \phi_2) = A\sin\left(\omega_2 t + \widetilde{\phi}_2\right).$$

To obtain the right-hand side of each equation, we used the fact that the product of the wave number and the position is a constant for a given point in space and then just added that constant to the phase shift, which in this case is also a constant. We wrote these wave functions as one-dimensional waves, but the outcome is the same in three dimensions. For the next step, we simply set the two phase constants, $\widetilde{\phi}_1$ and $\widetilde{\phi}_2$, equal to zero, because they only cause a phase shift and have no other essential role. Therefore, the two time-dependent oscillations that form the starting waves are

$$y_1(x_0,t) = A\sin(\omega_1 t)$$
$$y_2(x_0,t) = A\sin(\omega_2 t).$$

If we do this experiment using two angular frequencies, ω_1 and ω_2, that are close to each other, we can hear a sound that oscillates in volume as a function of time. Why does this happen?

In order to answer this question, we add the two sine waves. To add two sine functions, we can use an addition theorem for trigonometric functions:

$$\sin\alpha + \sin\beta = 2\cos\left[\tfrac{1}{2}(\alpha-\beta)\right]\sin\left[\tfrac{1}{2}(\alpha+\beta)\right].$$

Thus, we obtain for the two sine waves

$$\begin{aligned} y(x_0,t) &= y_1(x_0,t) + y_2(x_0,t) \\ &= A\sin(\omega_1 t) + A\sin(\omega_2 t) \\ &= 2A\cos\left[\tfrac{1}{2}(\omega_1-\omega_2)t\right]\sin\left[\tfrac{1}{2}(\omega_1+\omega_2)t\right]. \end{aligned}$$

It is more common to write this result in terms of frequencies instead of angular speeds:

$$y(x_0,t) = 2A\cos\left[2\pi\tfrac{1}{2}(f_1-f_2)t\right]\,\sin\left[2\pi\tfrac{1}{2}(f_1+f_2)t\right]$$

The term $\frac{1}{2}(f_1+f_2)$ is simply the average of the two individual frequencies:

$$\overline{f} = \tfrac{1}{2}(f_1+f_2). \qquad \textbf{(16.12)}$$

The factor $2A\cos\left[2\pi\frac{1}{2}(f_1-f_2)t\right]$ in equation 16.11 can be thought of as a slowly varying amplitude of the rapidly varying function $\sin\left[2\pi\frac{1}{2}(f_1+f_2)t\right]$ when $|f_1-f_2|$ is small.

When the cosine term has a maximum or minimum value ($+1$ or -1), a **beat** occurs; $|f_1-f_2|$ is the beat frequency:

$$f_\mathrm{b} = |f_1-f_2|. \qquad \textbf{(16.13)}$$

Concept Check 16.3

If you detect a beat with two frequencies and then both frequencies are doubled, the resulting beat frequency will

a) stay the same.

b) double.

c) quadruple.

d) do any of the above.

e) do none of the above.

Two questions now arise: First, what happened to the factor $\frac{1}{2}$ in the cosine function of equation 16.11, and second, why is the beat frequency defined in terms of an absolute value? Use of the absolute value ensures that the beat frequency is positive, independent of which of the two frequencies is larger. For the cosine function, use of the absolute value does not matter at all, because $\cos|\alpha| = \cos\alpha = \cos(-\alpha)$. For the answer to why there is no factor $\frac{1}{2}$, take a look at Figure 16.15: Part (a) plots two sinusoidal tones as a function of time; part (b) shows the addition of the two functions, with the dashed envelope given by $\pm 2A\cos\left[2\pi\frac{1}{2}(f_1 - f_2)t\right]$. You can see that the amplitude of the addition of the two functions reaches a maximum twice for a given complete oscillation of the cosine function. This is perhaps more apparent from Figure 16.15c, the plot of the square of the function (equation 16.11), which is proportional to the sound intensity. Thus, the beat frequency, the frequency at which the volume oscillates up and down, is properly defined as shown in equation 16.13, omitting the factor $\frac{1}{2}$.

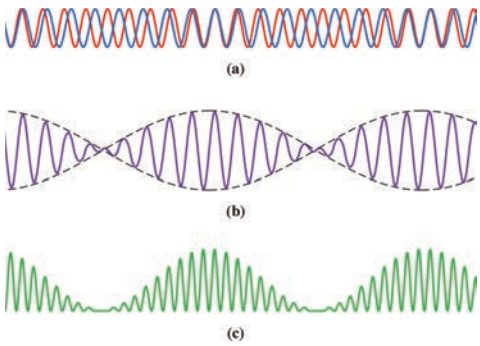


FIGURE 16.15 Beats of two sinusoidal tones. (a) The blue and red sine curves have frequencies that differ by 10%; (b) addition of the two curves; (c) square of the sum of the functions.

For example, striking two bars on a xylophone—one that emits at the proper frequency for middle A, 440 Hz, and another that emits at a frequency of 438 Hz—will produce two discernable volume oscillations per second. This is because the beat frequency is $f_\mathrm{b} = |440\,\mathrm{Hz} - 438\,\mathrm{Hz}| = 2\,\mathrm{Hz}$, and the period of oscillation of the volume is therefore $T_\mathrm{b} = 1/f_\mathrm{b} = \frac{1}{2}$ s.

SOLVED PROBLEM 16.2 Tuning a Violin

Beats are a very effective tool for tuning instruments. For example, when an orchestra gets ready to perform, one member, usually the first violin chair, plays a reference tone, and the other members tune their instruments relative to that sound by listening for beats. Let's see how this is done.

PROBLEM

A violin string produces 3.00 beats per second when sounded along with a standard tuning fork of frequency 440. Hz.

a) What is the frequency of the violin's sound?

b) What should be done to tune the violin string to the same frequency as the tuning fork?

SOLUTION

THINK

We know that two frequencies close to each other produce audible beats and that the beat frequency is the absolute value of the difference of these two frequencies. Thus, for part (a), we will obtain two values for the frequency of the violin's sound: one slightly above the tuning fork's reference frequency and one slightly below. For part (b), the obvious answer is that the tension in the string needs to be changed. In order to find out by how much, we need to apply concepts from Chapter 15, where we studied the relation between string tension and oscillation frequency.

SKETCH

Even though we recommend creating a sketch whenever possible, the present case is one of those few exceptions where a sketch does not add much.

RESEARCH

We have just seen that the beat frequency of two frequencies, f_1 and f_2, is given by $f_\text{b} = |f_1 - f_2|$. This means that either $f_\text{b} = f_1 - f_2$ or $f_\text{b} = f_2 - f_1$, where f_1 is the frequency produced by the tuning fork and f_2 that produced by the violin string. The two values of f_b are the two solutions for part (a).

For part (b), we use a result from Chapter 15: that the frequency of a standing wave on a string is proportional to the square root of the string tension force, $f \propto \sqrt{F}$, which we can write as $f = a\sqrt{F}$, where a is a constant. Taking the derivative of both sides of this equation we get

$$df = ad\left(\sqrt{F}\right) = a\frac{1}{2}\frac{dF}{\sqrt{F}} = \frac{a}{2}\frac{dF}{\sqrt{F}}.$$

Dividing both sides of this equation by f gives us

$$\frac{df}{f} = \frac{\left(\frac{a}{2}\frac{dF}{\sqrt{F}}\right)}{a\sqrt{F}} = \frac{1}{2}\frac{dF}{F}.$$

So the required relative change in the tension force, dF/F, is twice the relative change in the frequency, df/f. In order to calculate by what fraction to change the string tension, we note we need to change the violin frequency f_2 by f_b to get to the desired frequency f_1 So $df = f_\text{b}$, the relative frequency change is $df/f = f_\text{b}/f_1$.

SIMPLIFY

Part (a) has two solutions, $f_2 = f_1 - f_\text{b}$ and $f_2 = f_1 + f_\text{b}$. For part (b), we have

$$dF/F = 2(f_\text{b}/f_1).$$

CALCULATE

The two answers for part (a) are $f_2 = 440.\,\text{Hz} - 3.00\,\text{Hz} = 337.\,\text{Hz}$ and

$f_2 = 440.\,\text{Hz} + 3.00\,\text{Hz} = 443.\,\text{Hz}$.

For part (b) we find that our relative frequency change is $f_\text{b}/f_1 = 3.00/440.$ and therefore $dF/F = 2(3.00/440.) = 0.013636$.

ROUND

The two answers for part (a), $337.\,\text{Hz}$ and $443.\,\text{Hz}$, need no further rounding. Rounding our answer for part (b) to three significant figures, we see that the string tension force should be increased or decreased by a factor of $0.0136 = 1.36\%$.

DOUBLE-CHECK

Anytime you hear a beat, you know that the two frequencies that are producing it have to be close to each other. Both of our answers for part (a) are close to the reference frequency, and so they satisfy this minimum requirement. Only a small adjustment in the string tension should be needed, and our result for part (b) confirms this. But should the string tension be increased or decreased to tune the string to the reference frequency? This question cannot be answered with the information given in the problem statement. In practice, one simply tightens the string. If the beats are then less frequent, one is on the right track and needs to tighten the string further. If the beats become more frequent with tightening, this means that the original frequency was already above the reference frequency, and the string tension should be decreased instead.

Sound Diffraction

We can see an object only if the straight line between our eyes and the object is unobstructed. However, the situation is different for sound. We can hear somebody, for example, through an open doorway, even if we cannot see him or her. How is this possible? The reason is that the sound waves spread out spherically after they pass through the door opening and can reach any point in the room we are in. This effect is called *diffraction*. It is fairly easy to visualize diffraction using a ripple tank and projector. In the projected image in Figure 16.16, the white lines show the wave crests. You can see that the wavelength of the water surface wave (the distance between two neighboring crests) is comparable to the size of the opening between the two rectangular blocks (black) that were placed in the water. As we saw in Example 16.2, sound has wavelengths in the centimeter-to-meter range, making the ripple-tank demonstration a good analogy for what happens when sound passes through a door opening.

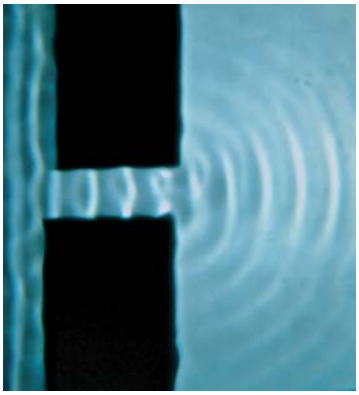

FIGURE 16.16
Ripple-tank projection image, in which a wave travels from left to right between two blocks and then spreads out spherically.

W. Bauer and G. D. Westfall

But light also consists of waves; so why don't we observe diffraction of light through doorways? The answer is that in order for pronounced diffraction effects to be observable, the wavelength has to be similar in size to or larger than the opening through which the wave propagates, and the wavelength range for light is very much smaller than a door opening. We will address the topic of light diffraction in much greater depth in Chapter 34.

Sound Localization

How do we know the direction from which a sound is coming? Since sound can undergo sizable diffraction, answering this question is not as easy as for light, for which we can simply point back to the source. Obviously, we have two ears, and if a sound's source is located on either our left or right side, the sound will travel different paths from the source to each ear. Our earlier discussion of the role of path differences in spatial sound interference may lead you to think that wave interference plays a role in sound localization. However, this is not the case.

One factor in sound localization is that the head "shadows" the ear that is farther away from the sound. This is the sound attenuation effect expressed by equation 16.8. Sound attenuation is frequency dependent, however, and plays the greatest role in localizing sounds in the higher frequency ranges. For frequencies below 800 Hz, the head causes very little attenuation, and the main clue used by the brain for sound localization is the interaural arrival-time difference, that is, the phase delay separating the arrivals of the sound at the two ears. For very low-frequency sounds, the wavelengths are large, on the order of several meters, which is much greater than the interaural distance. Localization of these sounds is very hard or even impossible. This is also the reason why your surround-sound system comes with only one subwoofer (which emits low-frequency sounds) but with at least four tweeters (which emit the high frequencies).

The field of psychoacoustics is devoted to topics like sound localization and has already made many breakthroughs, which, for example, leads to improvements in the design of concert halls and loudspeaker systems for touring rock bands, ensuring that there is not a bad seat in the concert venue.

Concept Check 16.4

Which of the following physical effects plays the smallest role in sound localization?

a) sound attenuation

b) interaural arrival-time difference

c) sound-intensity difference

d) phase difference

e) spatial interference

Active Noise Cancellation

We all know that noise can be muffled, or attenuated, and that some materials do this better than others. For example, if noise bothers you at night, you can use your pillow to cover your ears. Construction workers and other workers who have to spend extended periods in very loud environments wear ear-protecting headphones. Such ear protection reduces the amplitude of all sounds.

If you want to reduce background noise while listening to music, a technique to accomplish this is based on the principle of **active noise cancellation,** which relies on sound interference. An external sinusoidal sound wave arrives at the headphone and is recorded by a microphone (Figure 16.17). A processor inverts the phase of this sound wave and sends out the sound wave with the same frequency and amplitude, but opposite phase. The two sine waves add up (superposition principle), interfere destructively, and cancel out completely. At the same time, the speaker inside the headphones emits the music you want to hear, and the result is a listening experience that is free of background noise.

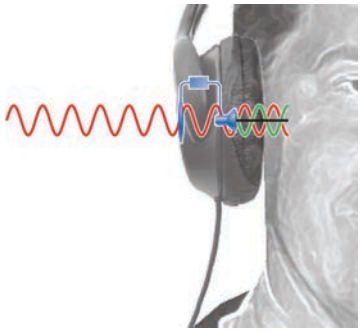

FIGURE 16.17
Active noise cancellation.

W. Bauer and G. D. Westfall

In practice, background noise never consists of a pure sinusoidal sound wave. Instead, many sounds of many different frequencies are mixed. In particular, the presence of high-frequency sounds constitutes a problem for active noise cancellation. However, this method works very well for periodic

low-frequency sounds, such as the engine noise from airliners. Another application is in some luxury automobiles, where active noise cancellation techniques reduce wind and tire noise.

16.4 Doppler Effect

We've all had the experience where a train approaching a railroad crossing sounds its warning horn and then, as it moves past our position, the sound pitch changes from a higher frequency to a lower one. This change in frequency is called the **Doppler effect.**

In order to gain a qualitative understanding of the Doppler effect, consider Figure 16.18. In part (a), the leftmost column, a stationary sound source emits spherical waves that travel outward. The time evolution of these radial waves is depicted at six equally spaced points in time, from top to bottom. The maxima of the five sine waves radiate outward as circles, color coded in each frame from yellow to red.

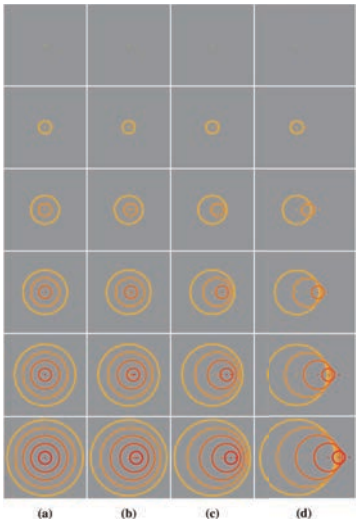

FIGURE 16.18 The Doppler effect for sound waves emitted at six equally spaced points in time: (a) stationary source; (b) source moving to the right; (c) source moving faster to the right; (d) source moving to the right faster than the speed of sound.

When the source moves, the same sound waves are emitted from different points in space. However, from each of these points, the maxima again travel outward as circles, as shown in parts (b) and (c) in Figure 16.18. The only difference between these two columns is the speed with which the source of the sound waves moves from left to right. In each case, you can see a "crowding" of the sound waves in front of the emitter, on the right side of it in this context. This crowding is greater with higher source velocity and is the entire key to understanding the Doppler effect. An observer located to the right of the source—that is to say, with the source moving toward him or her—experiences more wave fronts per unit time and thus hears a higher frequency. An observer located to the left of the moving source, with the source moving

away from him or her, experiences fewer wave fronts per unit time and thus hears a reduced frequency.

Quantitatively, the observed frequency, f_o, is given as

$$f_0 = f\left(\frac{v_{\text{sound}}}{v_{\text{sound}} \pm v_{\text{source}}}\right), \qquad \textbf{(16.14)}$$

where f is the frequency of the sound as emitted by the source, and v_{sound} and v_{source} are the speeds of the sound and of the source, respectively. The upper sign (+) applies when the source moves away from the observer, and the lower sign (–) applies when the source moves toward the observer.

The Doppler effect also occurs if the source is stationary and the observer moves. In this case, the observed frequency is given by

$$f_o = f\left(\frac{v_{\text{sound}} \mp v_{\text{observer}}}{v_{\text{sound}}}\right) = f\left(1 \mp \frac{v_{\text{observer}}}{v_{\text{sound}}}\right). \textbf{(16.15)}$$

The upper sign (–) applies when the observer moves away from the source, and the lower sign (+) applies when the observer moves toward the source.

In each case, moving source or moving observer, the observed frequency is lower than the source frequency when observer and source are moving away from each other and is higher than the source frequency when they are moving toward each other.

DERIVATION 16.2 Doppler Shift

Let's begin with an observer at rest and a sound source moving toward the observer. If the sound source is at rest and emits a sound with frequency f, then the wavelength is $\lambda = v_{\text{sounds}}/f$, which is also the distance between two successive wave crests. If the sound source moves toward the observer with speed v_{source}, then the distance between two successive crests as perceived by the observer is reduced to

$$\lambda_{\text{o}} = \frac{v_{\text{sound}} - v_{\text{source}}}{f}.$$

Page 513

Using the relationship between wavelength, frequency, and the (fixed!) speed of sound, $v_{\text{sound}} = \lambda f$, we find the frequency of the sound as detected by the observer:

$$f_{\text{o}} = \frac{v_{\text{sound}}}{\lambda_{\text{o}}} = f\left(\frac{v_{\text{sound}}}{v_{\text{sound}} - v_{\text{source}}}\right).$$

This result proves equation 16.14 with the minus sign in the denominator. The plus sign is obtained by reversing the sign of the source velocity vector.

You may want to try the derivation for the case in which the observer is moving as an exercise.

Concept Check 16.5

Consider the case of a stationary observer and a source moving with constant velocity (less than the speed of sound) and emitting a sound of frequency f. If the source moves toward the observer, equation 16.14 predicts a higher observed frequency, f_+. If the source moves away from the observer, a lower observed frequency, f_-, results. Let's call the difference between the higher frequency and the original frequency Δ_+ and the difference between the original frequency and the lower frequency Δ_- : $\Delta_+ = f_+ - f$ and $\Delta_- = f - f_-$. Which statement about the frequency differences is correct?

a) $\Delta_+ > \Delta_-$

b) $\Delta_+ = \Delta_-$

c) $\Delta_+ < \Delta_-$

d) It depends on the original frequency, f.

e) It depends on the source velocity, v.

Concept Check 16.6

Now consider the case of a stationary source emitting a sound of frequency f and an observer moving with constant velocity (less than the speed of sound). If the observer moves toward the source, equation 16.15 predicts a higher observed frequency, f_+. If the observer moves away from the source, a lower observed frequency, f_-, results. Let's call the difference between the higher frequency and the original frequency Δ_+ and the difference between the original frequency and the lower frequency Δ_- : $\Delta_+ = f_+ - f$ and $\Delta_- = f - f_-$. Which statement about the frequency differences is correct?

a) $\Delta_+ > \Delta_-$

b) $\Delta_+ = \Delta_-$

c) $\Delta_+ < \Delta_-$

d) It depends on the original frequency, f.

e) It depends on the source velocity, v.

Finally, what happens if both the source and the observer move? The answer is that the expressions for the Doppler effect for moving source and moving observer simply combine, and the observed frequency is given by

$$f_o = f\left(\frac{v_{\text{sound}} \mp v_{\text{observer}}}{v_{\text{sound}}}\right)\left(\frac{v_{\text{sound}}}{v_{\text{sound}} \mp v_{\text{source}}}\right) = f\left(\frac{v_{\text{soun}}}{v_{\text{sou}}}\right.$$

Here the upper signs in the numerator and the denominator apply when observer or source is moving away from the other, and the lower signs apply when observer or source is moving toward the

other. If the source and observer are moving in the same direction but with different speeds, the signs of the velocities must be chosen with respect to the fixed medium of the air.

Concept Check 16.7

Suppose a source emitting a sound with frequency f moves to the right (in the positive x-direction) with a speed of 30 m/s. An observer is located to the right of the source and also moves to the right (in the positive x-direction) with a speed of 50 m/s. The observed frequency, f_o. will be _____ the original frequency, f.

a) lower than

b) the same as

c) higher than

SOLVED PROBLEM 16.3 Doppler Shift of Reflected Ambulance Siren

PROBLEM

An ambulance has picked up an injured rock climber and is heading directly away from the canyon wall (where the climber was injured) at a speed of 31.3 m/s (70 mph). The ambulance's siren has a frequency of 400.0 Hz. After the ambulance turns off its siren, the injured rock climber can hear the reflected sound from the canyon wall for a few seconds. The speed of sound in air is $v_{\text{sound}} = 343\ \text{m/s}$. What is the frequency of the reflected sound from the ambulance's siren as heard by the injured rock climber in the ambulance?

SOLUTION

THINK

The ambulance can be considered to be a source moving with speed $v_{\text{ambulance}}$ and emitting a sound of frequency f. The frequency, f_1, of the siren at the fixed wall of the canyon can be calculated using the speed of sound, v_{sound}. The canyon wall reflects the sound of the siren back toward the moving ambulance. The climber in the ambulance can be thought of as a moving observer of the reflected sound of the siren. Combining the two Doppler shifts gives the frequency, f_2, of the reflected siren as heard on the moving ambulance.

SKETCH

Figure 16.19 shows the ambulance moving away from the canyon wall with speed $v_{\text{ambulance}}$ while emitting a sound from its siren of frequency f.

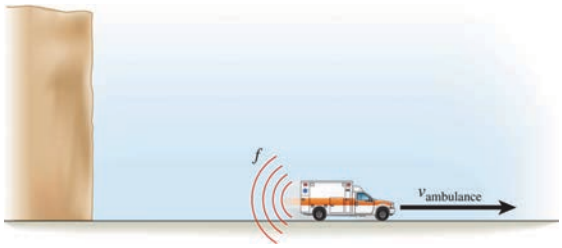

FIGURE 16.19 An ambulance moves away from a canyon wall with its siren operating.

RESEARCH

The frequency, f_1, of the sound heard by a stationary observer standing at the canyon wall resulting from the sound of frequency f emitted by the ambulance's siren moving with speed $v_{\text{ambulance}}$ is given by equation 16.14:

$$f_1 = f\left(\frac{v_{\text{sound}}}{v_{\text{sound}} + v_{\text{ambulance}}}\right), \qquad \text{(i)}$$

where the plus sign is applicable because the ambulance is moving away from the stationary observer. The sound is reflected from the canyon wall back toward the moving ambulance. Now the injured rock climber in the ambulance is a moving observer. We can calculate the frequency observed by the rock climber, f_2, using equation 16.15:

$$f_2 = f_1\left(1 - \frac{v_{\text{ambulance}}}{v_{\text{sound}}}\right), \qquad \text{(ii)}$$

where the minus sign is used because the observer is moving away from the source.

SIMPLIFY

We can combine equations (i) and (ii) to obtain

$$f_2 = f\left(\frac{v_{\text{sound}}}{v_{\text{sound}} + v_{\text{ambulance}}}\right)\left(1 - \frac{v_{\text{ambulance}}}{v_{\text{sound}}}\right).$$

You can see that this result is a special case of equation 16.16, where the speeds of observer and source are both the speed of the ambulance and both observer and source are moving away from each other.

CALCULATE

Putting in the numerical values, we get

$$f_2 = (400\ \text{Hz})\left(\frac{343\ \text{m/s}}{343\ \text{m/s} + 31.3\ \text{m/s}}\right)\left(1 - \frac{31.3\ \text{m/s}}{343\ \text{m/s}}\right)$$

ROUND

We report the result to three significant figures:

$$f_2 = 333\ \text{Hz}.$$

DOUBLE-CHECK

The frequency of the reflected sound observed by the injured rock climber is approximately 20% lower than the original frequency of the ambulance's siren. The speed of the ambulance is about 10% of the speed of sound. The two Doppler shifts, one for the sound emitted from the moving ambulance and one for the reflected sound observed in the moving ambulance, should each shift the frequency by approximately 10%. So the observed frequency seems reasonable.

Doppler Effect in Two- and Three-Dimensional Space

So far, our discussion of the Doppler effect has assumed that the source (or observer) moves with constant velocity on a straight line, which passes right through the location of the observer (or source). However, if you are waiting at a railroad crossing, for example, a train does not pass directly through your location but has a perpendicular distance of closest approach, b, as shown in Figure 16.20. In this situation, what you hear is not an instantaneous switch from the higher frequency of the approaching train to the lower frequency of the receding train that equation 16.14 implies, but instead a gradual and smooth change from the higher to the lower frequency.

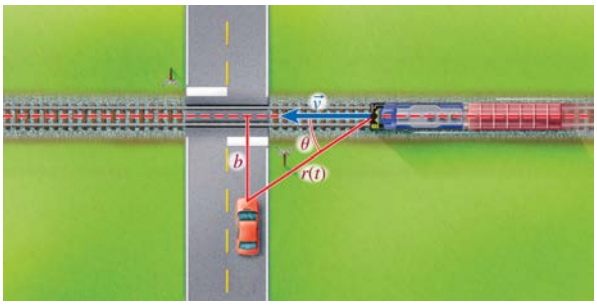

FIGURE 16.20 Doppler effect in a two-dimensional space—a car at a railroad crossing.

To obtain a quantitative expression of the Doppler effect for this case, we let $t = 0$ be the instant when the train is closest to the car, that is, as it crosses the road. For $t < 0$, the train is then moving toward the observer, and for $t > 0$, it is moving away from the observer. The origin of the spatial coordinate system is chosen as the location of the observer, the driver of the car. Then the distance of the train to the origin is given by $r(t) = \sqrt{b^2 + v^2t^2}$, where v is the (constant) speed of the train (see Figure 16.20). The angle θ between the train's velocity vector and the direction from which the sound is emitted relative to the car is given by

$$\cos\theta(t) = \frac{vt}{r(t)} = \frac{vt}{\sqrt{b^2 + v^2t^2}}.$$

The velocity of the sound source as observed in the car as a function of time is the projection of the train's velocity vector onto the radial direction:

$$v_{\text{source}}(t) = v\cos\theta(t) = \frac{v^2t}{\sqrt{b^2 + v^2t^2}}.$$

We can now substitute for v_{source} in equation 16.14 and obtain

$$f_{\text{o}}(t) = f\frac{v_{\text{sound}}}{v_{\text{sound}} \pm v_{\text{source}}(t)} = f\frac{v_{\text{sound}}}{v_{\text{sound}} + \dfrac{v^2t}{\sqrt{b^2 + v^2t^2}}}. \quad \textbf{(16}$$

In equation 16.17, the source velocity is negative for $t < 0$, corresponding to an approaching source, while the source velocity is positive for $t > 0$, corresponding to a receding source.

The formula of equation 16.17 may look complicated, but it is actually a smoothly varying function, as shown in Figure 16.21. Assume that the moving train emits a sound of frequency $f = 440$ Hz and that the sound's speed is 343 m/s. Figure 16.21a shows three plots of the frequency observed by a stationary observer in a car 10 m from the railroad crossing when a train moving at 20, 30, and 40 m/s passes through. Figure 16.21b shows plots of the frequencies observed by three stationary observers in cars parked at distances of 10, 40, and 70 m from the railroad crossing as a train passes at a speed of 40 m/s. These three curves converge toward the asymptotic frequencies of $f = 498$ Hz for the approaching train and $f = 394$ Hz for the receding train, which are the values predicted by equation 16.14. However, the closer the observer is to the railroad crossing, the more sudden the transition from the higher frequency to the lower one becomes.

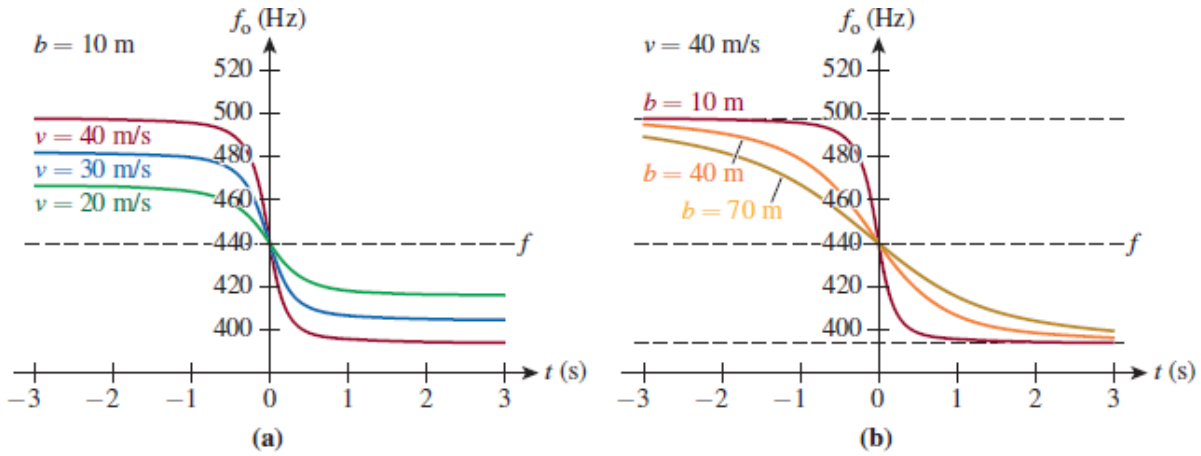

FIGURE 16.21 Time dependence of the frequency observed by a stationary observer: (a) source velocities of 20 m/s, 30 m/s, and 40 m/s and distance of closest approach of 10 m; (b) source velocity of 40 m/s and distances of closest approach of 10 m, 40 m, and 70 m.

Self-Test Opportunity 16.2

Show that the time derivative of the function determining the observed frequency (equation 16.17) at $t = 0$ is given by $\left.\frac{df_o}{dt}\right|_{t=0} = -\frac{fv^2}{bv_{\text{sound}}}$.

It is fairly easy to set up a demonstration of the Doppler effect. Just drive down a road at constant speed, continuously honking your horn, and have a friend videotape you. Then you can analyze the video clip with a frequency analyzer and see how the frequencies of the car horn change as you pass by the camera. In Figure 16.22, the car drove along a country highway with a speed of 26.5 m/s and passed by the camera at a closest distance of 14.0 km. The six dominant frequencies of the car's horn, given by $f = n(441\ \text{Hz})$, $n = 1, 2, \ldots, 6$, are clearly visible in this figure as the narrow red bands representing high decibel values, and you can see the frequency shift as the car passes by. The superimposed dashed gray lines are the results of the calculations using equation 16.17 with a distance of closest approach $b = 14.0$ m and

a source speed $v_{\text{source}} = 26.5\,\text{m/s}$. You can see that they are in complete agreement with the experimental measurements.

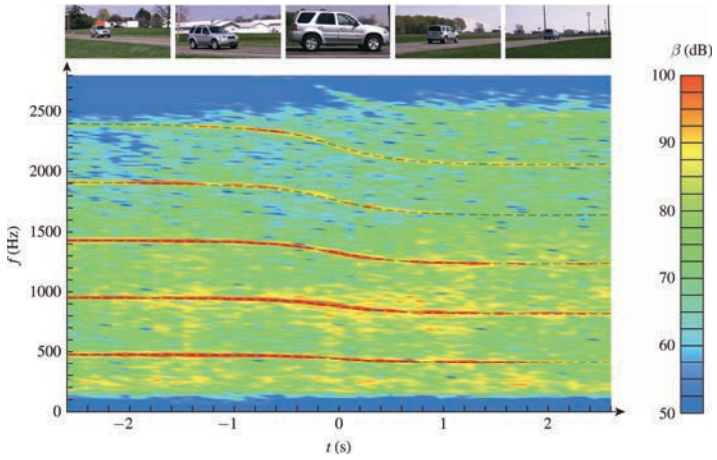

FIGURE 16.22 Demonstration of the Doppler effect.

W. Bauer and G. D. Westfall

Self-Test Opportunity 16.3

Derive a formula similar to equation 16.17 for an observer moving on a straight line and passing a stationary source at some nonzero distance of closest approach.

Applications of the Doppler Effect

In Section 16.1, we examined the application of ultrasound waves to the imaging of human tissues. The Doppler effect for ultrasound waves can be used to measure the speed of blood flowing in an artery, which can be an important diagnostic tool for cardiac disease. An example of the measurement of blood flow in the carotid artery is shown in Figure 16.23. This kind of measurement is implemented by transmitting ultrasound waves toward the flowing blood. The ultrasound waves reflect off the moving blood cells back toward the ultrasound device, where they are detected.

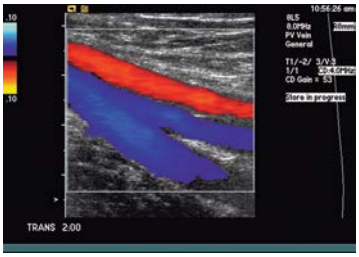

FIGURE 16.23
Doppler ultrasound image of blood flowing in the carotid artery. Red and blue indicate the speeds of the blood flow.

Courtesy Wake Radiology

EXAMPLE 16.3 Doppler Ultrasound Measurement of Blood Flow

PROBLEM

What is the typical frequency change for ultrasound waves reflecting off blood flowing in an artery?

SOLUTION

Ultrasound waves have a typical frequency of $f = 2.0\,\text{MHz}$. In an artery, blood flows with a speed of $v_{\text{blood}} = 1.0\,\text{m/s}$. The speed of ultrasound waves in human tissue is $v_{\text{sound}} = 1540\,\text{m/s}$. The blood cells can be thought of as moving observers for the ultrasound waves. Thus, if a blood cell is moving toward the source of the ultrasound, the frequency observed by the blood cell, f_1, is given by equation 16.15 with a plus sign

$$f_1 = f\left(1 + \frac{v_{\text{blood}}}{v_{\text{sound}}}\right). \qquad \text{(i)}$$

The reflected ultrasound waves with frequency f_1 constitute a moving source. The stationary Doppler ultrasound device will then observe reflected ultrasound waves with a frequency, f_2, given by equation 16.14 with a minus sign

$$f_2 = f_1\left(\frac{v_{\text{sound}}}{v_{\text{sound}} - v_{\text{blood}}}\right). \qquad \text{(ii)}$$

Thus, the frequency observed by the Doppler ultrasound device is obtained by combining equations (i) and (ii)

$$f_2 = f\left(1 + \frac{v_{\text{blood}}}{v_{\text{sound}}}\right)\left(\frac{v_{\text{sound}}}{v_{\text{sound}} - v_{\text{blood}}}\right).$$

Note that this equation is just a special case of equation 16.16, the expression for the Doppler effect with a moving source and a moving observer; here the speed of the observer and that of the source are both that of the blood cell. Putting in the numbers gives us

$$f_2 = (2.0\,\text{MHz})\left(1 + \frac{1.0\,\text{m/s}}{1540\,\text{m/s}}\right)\left(\frac{1540\,\text{m/s}}{1540\,\text{m/s} - 1.0\,\text{m/s}}\right.$$

The frequency difference, Δf, is then

$$\Delta f = f_2 - f = 2.6\,\text{kHz}.$$

This frequency change is the maximum observed when the blood is flowing as a result of a heart pulse. Between heart pulses, the blood slows down and almost stops. Combining the original ultrasound waves with frequency f and the reflected ultrasound waves with frequency f_2 yields a beat frequency, $f_{\text{beat}} = f_2 - f$, which varies from 2.6 kHz to zero as the heart pulses. These frequencies can be perceived by human ears, which means the beat frequency can simply be amplified and heard as a pulse monitor. This Doppler ultrasound effect is the basis of fetal heart probes.

Note that this example assumes that the blood is flowing directly toward the Doppler ultrasound device. In general, there is an angle between the direction of the transmitted ultrasound waves and the direction of the blood flow, which decreases the frequency change. Doppler ultrasound devices take this angle into account using information on the orientation of the artery.

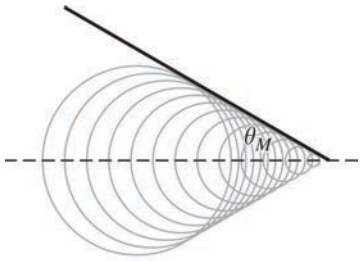
The Doppler radar that you hear about on TV weather reports uses the Doppler effect for electromagnetic waves. Moving

raindrops change the reflected radar waves to different frequencies and thus are detected by the Doppler radar. (However, the Doppler shift for electromagnetic waves such as radar waves is governed by a different formula than that used for sound. Electromagnetic waves will be discussed in Chapter 31.) Doppler radar is also used to detect rotation (and possible tornados) in thunderstorms by finding regions with motion both toward and away from the observer. Another common use of the Doppler effect is in the radar speed detectors employed by police around the world. And similar techniques are used by astronomers to measure red shifts of galaxies (more on this topic in Chapter 35 on relativity).

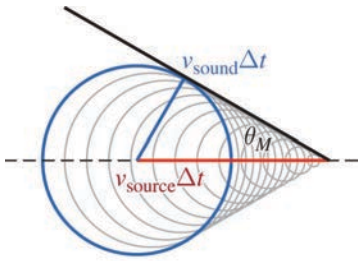
Mach Cone

We have yet to examine Figure 16.18d. In this column, the source speed exceeds the speed of sound. As you can see, in this case, the origin of a subsequent wave crest lies outside the circle formed by the previous wave crest.

Figure 16.24a shows the successive wave crests emitted by a source whose speed is greater than the speed of sound, called a **supersonic source.** You can see that all of these circles have a common tangent line that make an angle θ_{M}, called the **Mach angle,** with the direction of the velocity vector (in this case, the horizontal). This accumulation of wave fronts produces a large, abrupt, conical-shaped wave called a **shock wave,** or **Mach cone.** The Mach angle of the cone is given by



(a)



(b)

FIGURE 16.24 (a) The Mach cone, or shock wave. (b) Geometry for Derivation 16.3.

$$\theta_{\mathrm{M}} = \sin^{-1}\left(\frac{v_{\text{sound}}}{v_{\text{source}}}\right). \qquad \textbf{(16.18)}$$

This formula is valid only for source speeds that exceed the speed of sound, and in the limit where the source speed is equal to the speed of sound, θ_{M} approaches 90°. The greater the source speed, the smaller is the Mach angle.

Concept Check 16.8

The Mach angle

a) increases with increasing speed of the source, as long as that speed remains below the speed of sound.

b) decreases with increasing speed of the source, as long as that speed remains below the speed of sound.

c) is independent of the speed of the source.

d) increases with increasing speed of the source, as long as that speed remains above the speed of sound.

e) decreases with increasing speed of the source, as long as that speed remains above the speed of sound.

DERIVATION 16.3 Mach Angle

The derivation of equation 16.18 is quite straightforward if we examine Figure 16.24b, which shows the circle of a wave crest that was formed at some initial time, $t = 0$, but is now at a later time, Δt, The radius of this circle at time Δt is $v_{\text{sound}}\Delta t$ and is shown by the blue straight line. Note that the radius makes a 90° angle with the tangent line, indicated in black. However, during the same time, Δt, the source has moved a distance $v_{\text{source}}\Delta t$, which is indicated by the red line in the figure. The red, blue, and black lines in the figure form a right triangle. Then, by definition of the sine function, the sine of the Mach angle, θ_{M}, is

$$\sin\theta_{\text{M}} = \frac{v_{\text{sound}}\Delta t}{v_{\text{source}}\Delta t}.$$

Canceling out the common factor Δt and taking the inverse sine on both sides of this equation yields equation 16.18, as desired.

Interestingly, shock waves can be detected in all kinds of physical systems involving all kinds of waves. Motorboats can create shock waves relatively easily by moving across the water surface at high speeds. From these triangular bow waves, you can determine the speed of the surface waves on a lake, if you know the speed of the boat.

The speed of sound in atomic nuclei is approximately a third of the speed of light. Since particle accelerators can collide nuclei at speeds very close to the speed of light, shock waves should be created even in this environment. Some computer simulations have shown that this effect is present in collisions of atomic nuclei at very high energies, but definite experimental proof has been

difficult to obtain. Several nuclear physics laboratories around the world are actively investigating this phenomenon.

Finally, it would seem unlikely that shock waves involving light could be observed, since the speed of light in vacuum is the maximum speed possible in nature, and thus the source velocity cannot exceed the speed of light in vacuum. When the Russian physicist Pavel Cherenkov (also sometimes spelled Čerenkov) proposed in the 1960s that this effect did occur, it was dismissed as impossible. However, so-called *Cherenkov radiation* (Figure 16.25) can be emitted when a source such as a high-energy proton or electron moving at close to the speed of light enters a medium, like water, where the speed of light is significantly lower. Then the source does move faster than the speed of light in that medium, and a Mach cone can form. Modern particle detectors make use of this Cherenkov radiation; measuring the emission angle allows the velocity of the particle that emitted the radiation to be calculated.

NRC File Photo

EXAMPLE 16.4 The Concorde

The speed of a supersonic aircraft is often given as a Mach number, M. A speed of Mach $1 (M = 1)$ means that the aircraft is traveling at the speed of sound. A speed of Mach $2 (M = 2)$ means that the aircraft is traveling at twice the speed of sound. The Concorde supersonic airliner (Figure 16.26) cruised at 60,000 feet, where the speed of sound is 295 m/s (660 mph). The maximum cruise speed of the Concorde was Mach $2.04 (M = 2.04)$.

FIGURE 16.26
The supersonic Concorde jetliner taking off. Regular commercial service on the Concorde began in 1976 and ended in 2003.

Aviation Images Ltd/Alamy Stock Photo

PROBLEM

At this speed, what was the angle of the Mach cone produced by the Concorde?

SOLUTION

The angle of the Mach cone is given by equation 16.18:

$$\theta_{\mathrm{M}} = \sin^{-1}\left(\frac{v_{\text{sound}}}{v_{\text{source}}}\right).$$

The speed of the source in this case is that of the Concorde, which is traveling at a speed of

$$v_{\text{source}} = Mv_{\text{sound}} = 2.04v_{\text{sound}}.$$

Thus, we can write the Mach angle as

$$\theta_{\mathrm{M}} = \sin^{-1}\left(\frac{v_{\text{sound}}}{Mv_{\text{sound}}}\right) = \sin^{-1}\left(\frac{1}{M}\right).$$

For the Concorde, we then have

$$\theta_{\mathrm{M}} = \sin^{-1}\left(\frac{1}{2.04}\right) = 0.512\,\text{rad} = 29.4^{\circ}.$$

16.5 Resonance and Music

Basically all musical instruments rely on the excitation of resonances to generate sound waves of discrete, reproducible, and predetermined frequencies. No discussion of sound could possibly be complete without a discussion of musical tones.

Tones

Which frequencies correspond to which musical tones? The answer to this question is not simple and has changed over time. The current twelve-tone equal temperament scale dates back several centuries. The publication of Johann Sebastian Bach's work *Das wohltemperierte Klavier (The Well-Tempered Clavier)* in 1722, comprised of 24 compositions in each of the possible major and minor scales, represented a landmark in the development of the modern tonal scale. Let's review these accepted values.

The tones associated with the white keys of the piano are called A, B, C, D, E, F, and G. The C closest to the left end of the keyboard is designated C_1. The note below it, oddly enough, is B0. Thus, the sequence of tones for the white keys, from left to right, on a piano is A0, B0, C1, D1, E1, F1, G1, A1, B1, C2, D2,..., A7, B7, C8. The scale is anchored with middle A (A4) at precisely 440 Hz. The next higher A (A5) is an octave higher, which means that its frequency is exactly twice that of middle A, or 880 Hz.

Between these two A's are 11 halftones: A-sharp/B-flat, B, C, C-sharp/D-flat, D, D-sharp/E-flat, E, F, F-sharp/G-flat, G, and G-sharp/A-flat. Ever since the work of J. S. Bach, these 11 halftones divide the octave into exactly 12 equal intervals, all of which differ by the same factor, a factor that will give the number 2 when multiplied with itself 12 times. This factor is $2^{1/12} = 1.0595$. The frequencies of all the tones can be found through successive multiplication with this factor. For example, D (D5) is 5 steps up from middle A: $\left(1.0595^5\right)(440 \text{ Hz}) = 587.3 \text{ Hz}$. Frequencies of notes in other octaves are found by multiplication or division by a factor of 2. For example, the next higher D (D6) has a frequency of $2(587.3 \text{ Hz}) = 1174.7 \text{ Hz}$.

Human voices have classifications based on the average ranges shown in Table 16.3. Thus, basically all songs sung by humans exhibit a range of frequencies of one order of magnitude, between 100 and 1000 Hz. No human voice and practically no musical instrument generates a pure single-frequency tone. Instead, musical tones have a rich admixture of overtones that gives each instrument and each human voice its own characteristics. For string instruments, the hollow wooden body of the instrument,

which serves to amplify the sound of the strings, influences this admixture.

Table 16.3 Frequency Ranges for Classifications of Human Singers

Classification	Lowest Note	Highest Note
Bass	E2 (82 Hz)	G4 (392 Hz)
Baritone	A2 (110 Hz)	A4 (440 Hz)
Tenor	D3 (147 Hz)	B4 (494 Hz)
Alto	G3 (196 Hz)	F5 (698 Hz)
Soprano	C4 (262 Hz)	C6 (1047 Hz)

The touch-tone phones rely on sounds of preassigned frequencies. For each key that you press on the phone, two relatively pure tones are generated. Figure 16.27 shows the arrangement of these tones. Each key in a given row sets off the tone displayed to its right, and each key in a column triggers the tone displayed under it. If you press the 2 key, for example, the frequencies 697 Hz and 1336 Hz are produced. When someone dials a phone number, these frequencies are emitted and can be recorded. In Figure 16.28 we have used a spectrograph to analyze the sound emitted by an iPhone when one pushes each button on the phone keypad. As you can see, the frequencies emitted for each keypad button can be clearly identified.

FIGURE 16.27 The frequencies generated by the keys of a touch-tone phone.

Stockbyte/Getty Images

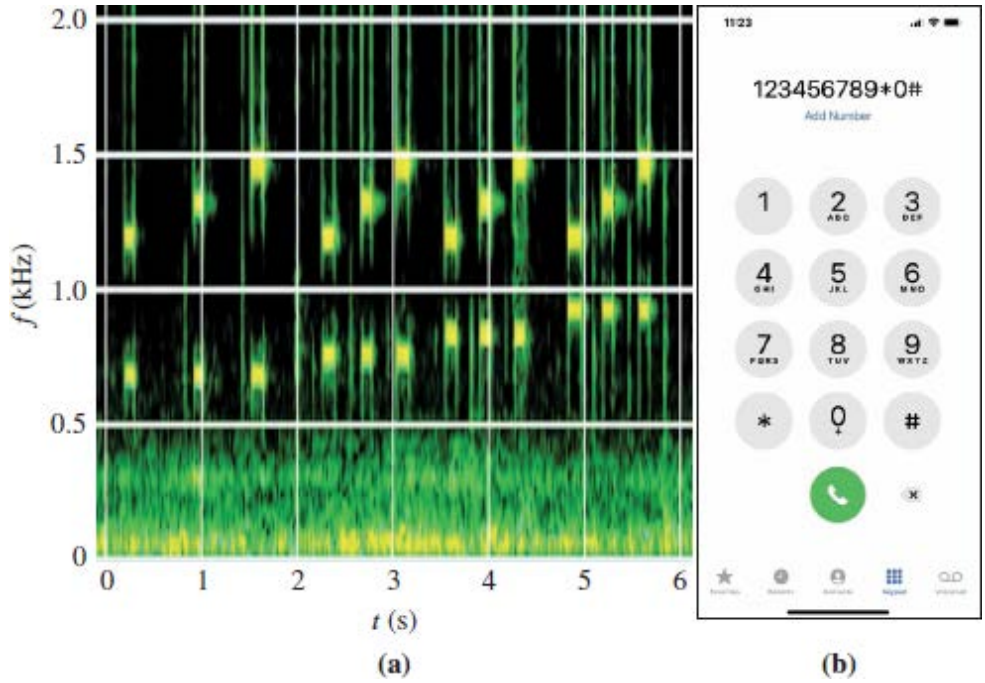

FIGURE 16.28 Frequencies emitted by pushing each button on the keypad of an iPhone: (a) frequency analysis with a spectrograph; (b) screen capture of the iPhone, showing the sequence of keys pushed.

Half-Open and Open Pipes

We discussed standing waves on strings in Chapter 15. These waves form the basis for the sounds produced by all string instruments. It is important to remember that standing waves can be excited on strings only at discrete resonance frequencies. Most percussion instruments, like drums, also work on the principle of exciting discrete resonances. However, the waveforms produced by these instruments are typically two-dimensional and are much more complicated than those produced on strings.

Wind instruments use half-open or open pipes to generate sounds. A *half-open pipe* is a pipe that is open at only one end and closed at the other end (such as a clarinet or trumpet); an open pipe is open on both ends (such as a flute). Figure 16.29a shows some of the possible standing waves in a half-open pipe. In the top pipe is the standing wave with the largest wavelength, for which the first antinode coincides with the length of the pipe. Since the distance between a node and the first antinode is a fourth of a wavelength, this resonance condition corresponds to $L = \frac{1}{4}\lambda$, where L is the length of the pipe. The middle and bottom pipes in Figure 16.29a have standing waves with smaller possible wavelengths, for which the second or third antinodes fall on the pipe opening, and $L = \frac{3}{4}\lambda$ and $L = \frac{5}{4}\lambda$, respectively. In general, the condition for a resonant standing wave in a half-open pipe is thus

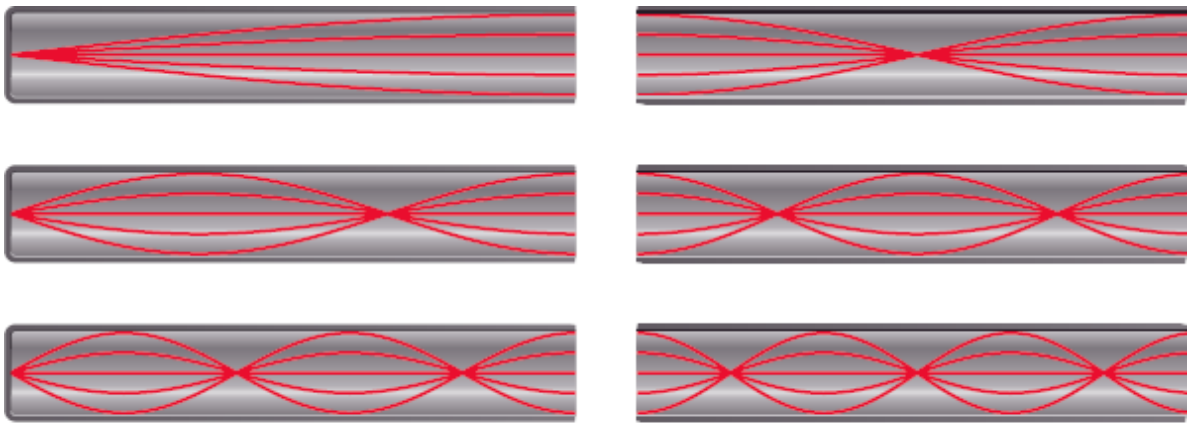

FIGURE 16.29 (a) Standing waves in a half-open pipe; (b) standing waves in an open pipe. The red lines represent the sound amplitude at various times.

$$L = \frac{2n-1}{4}\lambda, \text{ for } n = 1, 2, 3, \ldots$$

Solving this equation for the possible wavelengths results in

$$\lambda_n = \frac{4L}{2n-1}, \text{ for } n = 1, 2, 3, \ldots \qquad \textbf{(16.19)}$$

Using $v = \lambda f$, we obtain the possible frequencies:

$$f_n = (2n-1)\frac{v}{4L}, \text{ for } n = 1, 2, 3, \ldots, \qquad \textbf{(16.20)}$$

where n corresponds to the number of nodes.

Figure 16.29b displays the possible standing waves in an open pipe. In this case, there are antinodes at both ends of the pipe, and the condition for a resonant standing wave is

$$L = \frac{n}{2}\lambda, \quad n = 1, 2, 3, \ldots.$$

This relationship results in wavelengths and frequencies of

$$\lambda_n = \frac{2L}{n}, \quad n = 1, 2, 3, \ldots \tag{16.21}$$

$$f_n = n\frac{v}{2L}, \quad n = 1, 2, 3, \ldots \tag{16.22}$$

where again n is the number of nodes.

Concept Check 16.9

Which 4-digit number was dialed?

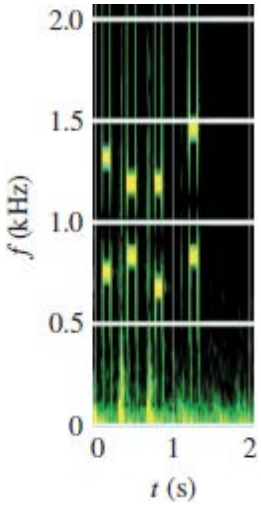
a) 5719

b) 6068

c) 3492

d) 1832

e) 2094



For both half-open and open pipes, the fundamental frequency (first harmonic) is obtained with $n = 1$. For a half-open pipe, the first overtone (or second harmonic, for which $n = 2$) is three times as high as the fundamental frequency. However, for an open pipe, the first overtone ($n = 2$) is twice as high as the fundamental frequency, or one octave higher.

EXAMPLE 16.5 A Pipe Organ

Church organs operate on the principle of creating standing waves in pipes. If you have ever been in an old cathedral, you have very likely seen an impressive collection of organ pipes (Figure 16.30).

FIGURE 16.30 Pipes of a church organ.

stockcam/iStock/Getty Images

PROBLEM

If you wanted to build an organ whose fundamental frequencies covered the frequency range of a piano, from A0 to C8, what range of lengths would you need to use for the pipes?

SOLUTION

The frequencies for A0 and C8 are $f_{\text{A0}} = 27.5\,\text{Hz}$ and $f_{\text{C8}} = 4186\,\text{Hz}$. According to equations 16.20 and 16.22, the fundamental frequencies for a half-open pipe and an open pipe are

$$f_{1,\text{half-open}} = \frac{v}{4L} \quad \text{and} \quad f_{1,\text{open}} = \frac{v}{2L}.$$

This means that the open pipes have to be twice as long as the corresponding half-open pipes for the same frequency. The lengths of the half-open pipes for the highest and lowest frequencies need to be

$$L_{\text{half-open,C8}} = \frac{v}{4f_{\text{C8}}} = \frac{343\,\text{m/s}}{16{,}744\,\text{Hz}} = 0.0205\,\text{m}.$$

$$L_{\text{half-open,A0}} = \frac{v}{4f_{\text{A0}}} = \frac{343\,\text{m/s}}{110\,\text{Hz}} = 3.118\,\text{m}.$$

COMMENT

Real organ pipes can indeed be as long as 10 ft. The part that produces the standing wave can be as short as 0.5 in; however, the base of a pipe is approximately 0.5 ft in length, so the shortest pipes typically observed in a church organ are at least that long.

SOLVED PROBLEM 16.4 Standing Wave in a Pipe

PROBLEM

A standing sound wave is set up in a pipe of length 0.410 m (Figure 16.31) containing air at normal pressure and temperature. What is the frequency of this sound?

FIGURE 16.31 A standing sound wave in a pipe.

SOLUTION

THINK

First, we recognize that the standing sound wave shown in Figure 16.31 corresponds to one in a pipe that is closed on the left end and open on the right end. Thus, we are dealing with a standing wave in a half-open pipe. Four nodes are visible. Combining these observations and knowing the speed of sound, we can calculate the frequency of the standing wave.

SKETCH

The standing wave with the pipe drawn in and the nodes marked is shown in Figure 16.32.

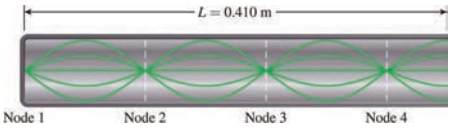


FIGURE 16.32 A standing sound wave with four nodes in a half-open pipe.

RESEARCH

The frequency of this standing wave in a half-open pipe is given by

$$f_n = (2n - 1)\frac{v}{4L}, \qquad \text{(i)}$$

where $n = 4$ is the number of nodes. The speed of sound in air is $v = 343\ \text{m/s}$, and the length of the pipe is $L = 0.410\ \text{m}$.

SIMPLIFY

For $n = 4$, we can write equation (i) for the frequency of the standing wave as

$$f_4 = [2(4) - 1]\frac{v}{4L} = \frac{7v}{4L}.$$

CALCULATE

Putting in the numerical values, we get

$$f = \frac{7(343\ \text{m/s})}{4(0.410\ \text{m})} = 1464.02\ \text{Hz}.$$

ROUND

We report our result to three significant figures:

$$f = 1460\ \text{Hz}.$$

DOUBLE-CHECK

This frequency is well within the range of human hearing and just above the range of frequencies produced by the human voice. Therefore, our answer seems reasonable.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- Sound is a longitudinal pressure wave that requires a medium in which to propagate.
- The speed of sound in air at normal pressure and temperature (1 atm, 20 °C) is 343 m/s.
- In general, the speed of sound in a solid is given by $v = \sqrt{Y/\rho}$, and that in a liquid or a gas is given by $v = \sqrt{B/\rho}$.
- A logarithmic scale is used to measure sound intensities. The unit of this scale is the decibel (dB). The sound level, β, in this decibel scale is defined as $\beta = 10 \log \frac{I}{I_0}$, where I is the intensity of the sound waves and $I_0 = 10^{-12}\ \mathrm{W/m^2}$, which corresponds approximately to the minimum intensity that a human ear can hear.
- Sound waves emitted by two coherent sources constructively interfere if the path length difference is $\Delta r = n\lambda$, for all $n = 0, \pm 1, \pm 2, \pm 3, \ldots$, and destructively interfere if the path length difference is $\Delta r = (n + \frac{1}{2})\lambda$, for all $n = 0, \pm 1, \pm 2, \pm 3, \ldots$.
- Two sine waves with equal amplitudes and slightly different frequencies produce beats with a beat frequency of $f_\mathrm{b} = |f_1 - f_2|$.
- As a result of the Doppler effect, the frequency of sound from a moving source as perceived by a stationary observer is $f_\mathrm{o} = f\left(\dfrac{v_\mathrm{sound}}{v_\mathrm{sound} \pm v_\mathrm{source}}\right)$, where f is the frequency of the sound as emitted by the source and v_sound and v_source are the speeds of sound and of the source, respectively. The upper sign (+) applies when the source moves away from the observer, and the lower sign (–) applies when the source moves toward the observer.

- The source of sound can be stationary while the observer moves. In this case, the observed frequency of the sound is given by $f_{\mathrm{o}} = f\left(\frac{v_{\mathrm{sound}} \mp v_{\mathrm{observer}}}{v_{\mathrm{sound}}}\right) = f\left(1 \mp \frac{v_{\mathrm{observer}}}{v_{\mathrm{sound}}}\right)$. Here the upper sign (–) applies when the observer moves away from the source, and the lower sign (+) applies when the observer moves toward the source.
- The Mach angle of the shock wave formed by a sound source moving at a supersonic speed is $\theta_{\mathrm{M}} = \sin^{-1}\left(\frac{v_{\mathrm{sound}}}{v_{\mathrm{source}}}\right)$.
- The relationship between the length of a half-open pipe and the wavelengths of possible standing waves inside it is $L = \frac{2n-1}{4}\lambda$, for $n = 1, 2, \ldots$; for open pipes, the relationship is $L = \frac{n}{2}\lambda$, for $n = 1, 2, \ldots$.

ANSWERS TO SELF-TEST OPPORTUNITIES

$$\beta = 10 \log \frac{I}{I_0} \Rightarrow I = I_0 \left(10^{\beta/10}\right)$$

16.1 $P = IA = I\left(4\pi r^2\right) = I_0 \left(10^{\beta/10}\right)\left(4\pi r^2\right)$

$$P = 4\pi\left(10^{-12}\ \mathrm{W/m^2}\right) 10^{(80\ \mathrm{dB})/10} (10.0\ \mathrm{m})^2 = 0.126\ \mathrm{W}.$$

$$f_o(t) = f \frac{v_{\text{sound}}}{v_{\text{sound}} + \dfrac{v^2 t}{\sqrt{b^2 + v^2 t^2}}}$$

16.2
$$\frac{df_o(t)}{dt} = -f v_{\text{sound}} \frac{\left(-\dfrac{t^2 v^4}{\left(b^2 + v^2 t^2\right)^{3/2}} + \dfrac{v^2}{\sqrt{b^2 + v^2 t^2}} \right)}{\left(v_{\text{sound}} + \dfrac{v^2 t}{\sqrt{b^2 + v^2 t^2}} \right)^2}$$

$$\left.\frac{df_o(t)}{dt}\right|_{t=0} = -f v_{\text{sound}} \frac{\left(\dfrac{v^2}{\sqrt{b^2}}\right)}{\left(v_{\text{sound}}\right)^2} = -f \frac{v^2}{b v_{\text{sound}}}.$$

$$v_{\text{observer}}(t) = \frac{v^2 t}{\sqrt{b^2 + v^2 t^2}}$$

16.3 $f_o(t) = f \dfrac{v_{\text{sound}} \mp v_{\text{observer}}(t)}{v_{\text{sound}}}$

$$f_o(t) = f \frac{v_{\text{sound}} - \dfrac{v^2 t}{\sqrt{b^2 + v^2 t^2}}}{v_{\text{sound}}}.$$

PROBLEM-SOLVING GUIDELINES

1. Be sure you're familiar with the properties of logarithms to solve problems involving the intensity of sound. In particular, remember that $\log(A/B) = \log A - \log B$ and that $\log x^n = n \log x$.

2. Situations involving the Doppler effect can be tricky. Sometimes you need to break the path of the sound wave into segments and treat each segment separately, depending on whether motion of the source or motion of the observer is occurring. Often a sketch is useful to identify which expression for the Doppler effect pertains to which part of the situation.

3. You don't need to memorize formulas for the overtone frequencies of open pipes or half-open pipes. Instead, remember that the closed end of a pipe is the location of a node and the open end of a pipe is the location of an antinode. Then you can reconstruct the standing waves from that point.

MULTIPLE-CHOICE QUESTIONS

16.1 You stand on the curb waiting to cross a street. Suddenly you hear the sound of a horn from a car approaching you at a constant speed. You hear a frequency of 80 Hz. After the car passes by, you hear a frequency of 72 Hz. At what speed was the car traveling?

a) 17 m/s

b) 18 m/s

c) 19 m/s

d) 20 m/s

16.2 A sound level of 50 decibels is

a) 2.5 times as intense as a sound of 20 decibels.

b) 6.25 times as intense as a sound of 20 decibels.

c) 10 times as intense as a sound of 20 decibels.

d) 100 times as intense as a sound of 20 decibels.

e) 1000 times as intense as a sound of 20 decibels.

16.3 A police car is moving in your direction, constantly accelerating, with its siren on. As it gets closer, the sound you hear will

a) stay at the same frequency.

b) drop in frequency.

c) increase in frequency.

d) More information is needed.

16.4 You are creating a sound wave by shaking a paddle in a liquid medium. How can you increase the speed of the resulting sound wave?

a) You shake the paddle harder to give the medium more kinetic energy.

b) You vibrate the paddle more rapidly to increase the frequency of the wave.

c) You create a resonance with a faster-moving wave in air.

d) All of these will work.

e) None of these will work.

f) Only (a) and (b) will work.

g) Only (a) and (c) will work.

h) Only (b) and (c) will work.

16.5 Standing on the sidewalk, you listen to the horn of a passing car. As the car passes, the frequency of the sound changes from high to low in a continuous manner; that is, there is no abrupt change in the perceived frequency. This occurs because

a) the pitch of the horn's sound changes continuously.

b) the intensity of the observed sound changes continuously.

c) you are not standing directly in the path of the moving car.

d) of all of the above reasons.

16.6 A sound meter placed 3 m from a speaker registers a sound level of 80 dB. If the volume on the speaker is then turned down so that the power is reduced by a factor of 25, what will the sound meter read?

a) 3.2 dB

b) 11 dB

c) 32 dB

d) 55 dB

e) 66 dB

16.7 What has the greatest effect on the speed of sound in air?

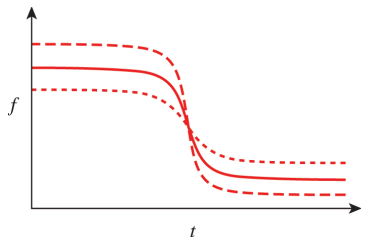
a) temperature of the air

b) frequency of the sound

c) wavelength of the sound

d) pressure of the atmosphere

16.8 A driver sits in her car at a railroad crossing. Three trains go by at different (constant) speeds, each emitting the same sound. Bored, the driver makes a recording of the sounds. Later, at home, she plots the frequencies as a function of time on her computer, resulting in the plots shown in the figure. Which of the three trains had the highest speed?



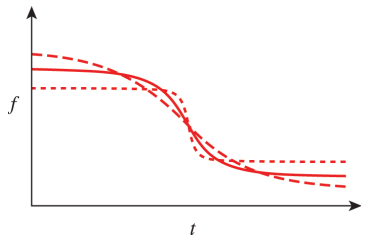
a) the one represented by the solid line

b) the one represented by the dashed line

c) the one represented by the dotted line

d) impossible to tell

16.9 Three physics faculty members sit in three different cars at a railroad crossing. Three trains go by at different (constant) speeds, each emitting the same sound. Each faculty member uses a cell phone to record the sound of a different train. On the next day, during a faculty meeting, they plot the frequencies as a function of time on a computer, resulting in the plots shown in the figure. Which of the three trains had the highest speed?



a) the one represented by the solid line

b) the one represented by the dashed line

c) the one represented by the dotted line

d) impossible to tell

16.10 In Question 16.9, which of the three faculty members was closest to the train tracks?

a) the one who recorded the sound represented by the solid line

b) the one who recorded the sound represented by the dashed line

c) the one who recorded the sound represented by the dotted line

d) impossible to tell

16.11 The beat frequency of two frequencies f_1 and f_2 is

a) the absolute value of the sum of the frequencies, $|f_1 + f_2|$.

b) the absolute value of the difference of the frequencies, $|f_1 - f_2|$.

c) the average of the two frequencies.

d) half of the sum of the two frequencies.

e) half of the absolute value of the difference of the two frequencies.

16.12 Suppose a source emitting a sound of frequency *f* moves toward the right (in the positive *x*-direction) with a speed of 30 m/s. An observer is located to the right of the source and also moves toward the right (in the positive *x*-direction) with a speed of 50 m/s. Which of the following is the correct expression for the frequency that the observer perceives, f_o?

a) $$f_\text{o} = f\left(\frac{v_\text{sound} - 50\,\text{m/s}}{v_\text{sound} - 30\,\text{m/s}}\right)$$

b) $$f_\text{o} = f\left(\frac{v_\text{sound} + 50\,\text{m/s}}{v_\text{sound} - 30\,\text{m/s}}\right)$$

c) $$f_\text{o} = f\left(\frac{v_\text{sound} - 50\,\text{m/s}}{v_\text{sound} + 30\,\text{m/s}}\right)$$

d) $$f_\text{o} = f\left(\frac{v_\text{sound} + 50\,\text{m/s}}{v_\text{sound} + 30\,\text{m/s}}\right)$$

16.13 Audible beats can be produced by two sine waves with frequencies f_1 and f_2, if

a) the two frequencies are close to each other.

b) f_1 is greater than f_2.

c) f_1 is smaller than f_2.

d) the two frequencies are identical.

16.14 If two loudspeakers at points *A* and *B* emit identical sine waves at the same frequency and constructive interference is observed at point *C*, then the

a) distance from *A* to *C* is the same as that from *B* to *C*.

b) points *A*, *B*, and *C* form an equilateral triangle.

c) difference between the distance from *A* to *C* and the distance from *B* to *C* is an integer multiple of the wavelength of the emitted waves.

d) difference between the distance from *A* to *C* and the distance from *B* to *C* is a half-integer multiple of the wavelength of the emitted waves.

CONCEPTUAL QUESTIONS

16.15 A (somewhat risky) way of telling if a train that cannot be seen or heard is approaching is by placing your ear on the rail. Explain why this works.

16.16 A classic demonstration of the physics of sound involves an alarm clock in a bell vacuum jar. The demonstration starts with air in the vacuum jar at normal atmospheric pressure and then the jar is evacuated to lower and lower pressures. Describe the expected outcome.

16.17 You are sitting near the back of a twin-engine commercial jet, which has the engines mounted on the fuselage near the tail. The nominal rotation speed for the turbofan in each engine is 5200 revolutions per minute, which is also the frequency of the dominant sound emitted by the engine. What audio clue would suggest that the engines are not perfectly synchronized and that the turbofan in one of them is rotating approximately 1% faster than that in the other? How would you measure this effect if you had only your wristwatch (could measure time intervals only in seconds)? To hear this effect, go to http://vnatsci.ltu.edu/s_schneider/physlets/main/beats.shtml. This simulation works best with integer natural frequencies, so round your frequencies to the ones place.

16.18 You determine the direction from which a sound is coming by subconsciously judging the difference in time it takes to reach the right and left ears. Sound directly in front (or back) of you arrives at both ears at the same time; sound from your left arrives at your left ear before your right ear. What happens to this ability to determine the location of a sound if you are underwater? Will sounds appear to be located more in front or more to the side of where they actually are?

16.19 On a windy day, a child standing outside a school hears the school bell. If the wind is blowing toward the child from the direction of the bell, will it alter the frequency, the wavelength, or the velocity of the sound heard by the child?

16.20 A police siren contains two frequencies, producing a wavering sound (beats). Explain how the siren sound changes as a police car approaches, passes, and moves away from a pedestrian.

16.21 The Moon has no atmosphere. Is it possible to generate sound waves on the Moon?

16.22 When two pure tones with similar frequencies combine to produce beats, the result is a train of wave packets. That is, the sinusoidal waves are partially localized into packets. Suppose two sinusoidal waves of equal amplitude A, traveling in the same direction, have wave numbers κ and $\kappa + \Delta\kappa$ and angular frequencies ω and $\omega + \Delta\omega$, respectively. Let Δx be the length of a wave packet, that is, the distance between two nodes of the envelope of the combined sine functions. What is the value of the product $\Delta x \Delta\kappa$?

16.23 As you walk down the street, a convertible drives by on the other side of the street. You hear the deep bass speakers in the car thumping out a groovy but annoyingly loud beat. Estimate the intensity of the sound you perceive, and then calculate the minimum intensity that the poor ears of the convertible's driver and passengers are subject to.

16.24 If you blow air across the mouth of an empty soda bottle, you hear a tone. Why is it that if you put some water in the bottle, the pitch of the tone increases?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 16.1

16.25 Standing on a sidewalk, you notice that you are halfway between a clock tower and a large building. When the clock strikes the hour, you hear an echo of the bell 0.500 s after hearing it directly from the tower. How far apart are the clock tower and the building?

16.26 Two farmers are standing on opposite sides of a very large empty field that is 510. m across. One farmer yells out some instructions, and 1.50 s pass until the sound reaches the other farmer. What is the temperature of the air?

16.27 The density of a sample of air is $1.205\ \text{kg/m}^3$, and the bulk modulus is $1.42 \cdot 10^5\ \text{N/m}^2$.

a) Find the speed of sound in the air sample.

b) Find the temperature of the air sample.

• **16.28** You drop a stone down a well that is 9.50 m deep. How long is it before you hear the splash? The speed of sound in air is 343 m/s.

16.29 Electromagnetic radiation (light) consists of waves. More than a century ago, scientists thought that light, like other waves, required a medium (called the *ether*) to support its transmission. Glass, having a typical mass density of $\rho = 2500\ \text{kg/m}^3$, also supports the transmission of light. What would the bulk modulus of glass have to be to support the transmission of light waves at a speed of $v = 2.0 \cdot 10^8\ \text{m/s}$? Compare this to the actual bulk modulus of window glass, which is $5.0 \cdot 10^{10}\ \text{N/m}^2$.

Section 16.2

16.30 Compare the intensity of sound at the pain level, 120 dB, with that at the whisper level, 20 dB.

16.31 The sound level in decibels is typically expressed as $\beta = 10 \log(I/I_0)$, but since sound is a pressure wave, the sound level can be expressed in terms of a pressure difference. Intensity depends on the amplitude squared, so the expression is $\beta = 20 \log(P/P_0)$, where P_0 is the smallest pressure difference noticeable by the ear: $P_0 = 2.00 \cdot 10^{-5}$ Pa. A loud rock concert has a sound level of 110. dB. Find the amplitude of the pressure wave generated by this concert.

16.32 At a state championship high school football game, the shout of a single person in the stands has an intensity level of about 50 dB at the center of the field. What would be the intensity level at the center of the field if all 10,000 fans at the game shouted from roughly the same distance away from that center point?

•**16.33** Two people are talking at a distance of 3.00 m from where you are, and you measure the sound intensity as $1.10 \cdot 10^{-7}$ W/m^2. Another student is 4.00 m away from the talkers. What sound intensity does the other student measure?

• **16.34** An excited child in a campground lets out a yell. Her parent, 1.20 m away, hears it as a 90.0-dB sound. A climber sits 850. m away from the child, on top of a nearby mountain. How loud does the yell sound to the climber?

• **16.35** While enjoyable, rock concerts can damage people's hearing. In the front row at a rock concert, 5.00 m from the speaker system, the sound intensity is 115.0 dB. How far back would you have to sit for the sound intensity to drop below the recommended safe level of 90.0 dB?

Section 16.3

16.36 Two sources, A and B, emit a sound of a certain wavelength. The sound emitted from both sources is detected at a point away from the sources. The sound from source A is a distance d from the observation point, whereas the sound from source B has to travel a distance of 3λ. What is the largest value of the wavelength, in terms of d, for the maximum sound intensity to be detected at the observation point? If $d = 10.0$ m and the speed of sound is 340. m/s, what is the frequency of the emitted sound?

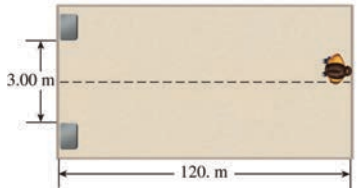
16.37 A college student is at a concert and really wants to hear the music, so she sits between two in-phase loudspeakers, which point toward each other and are 50.0 m apart. The speakers emit sound at a frequency of 490. Hz. At the midpoint between the speakers, there will be constructive interference, and the music will be at its loudest. At what distance closest to the midpoint along the line between the two speakers could she also sit to experience the loudest sound?

16.38 A string of a violin produces 2 beats per second when sounded along with a standard fork of frequency 400. Hz. The beat frequency increases when the string is tightened.

a) What was the frequency of the violin at first?

b) What should be done to tune the violin?

• **16.39** You are standing against a wall opposite two speakers that are separated by 3.00 m, as shown in the figure. The two speakers begin emitting a 1372-Hz tone in phase. Where along the far wall should you stand so that the sound from the speakers is as soft as possible? Be specific; how far away from a spot centered between the speakers will you be? The far wall is 120. m from the wall that has the speakers. (Assume that the walls are good absorbers, and therefore, the contribution of reflections to the perceived sound is negligible.)



• **16.40** You are playing a note that has a fundamental frequency of 400. Hz on a guitar string of length 50.0 cm. At the same time, your friend plays a fundamental note on an open organ pipe, and 4 beats per second are heard. The mass per unit length of the string is 2.00 g/m. Assume that the speed of sound is 343 m/s.

a) What are the possible frequencies of the open organ pipe?

b) When the guitar string is tightened, the beat frequency decreases. Find the original tension in the string.

c) What is the length of the organ pipe?

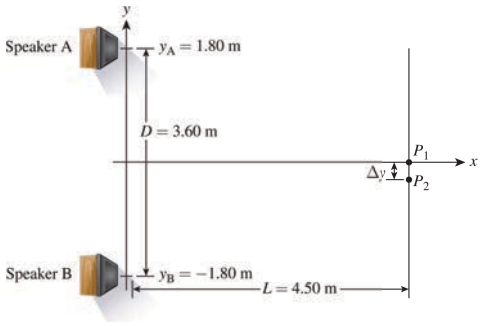
•**16.41** Two 100.0-W speakers, A and B, are separated by a distance $D = 3.60$ m. The speakers emit in-phase sound waves at a frequency $f = 10{,}000.0$ Hz. Point P_1 is located at $x_1 = 4.50$ m and $y_1 = 0$ m; point P_2 is located at $x_2 = 4.50$ m and $y_2 = -\Delta y$.

a) Neglecting speaker B, what is the intensity, $I_{A1}\left(\text{in W/m}^2\right)$, of the sound at point P_1 due to speaker A? Assume that the sound from the speaker is emitted uniformly in all directions.

b) What is this intensity in terms of decibels (sound level, β_{A1})?

c) When both speakers are turned on, there is a maximum in their combined intensities at P_1. As one moves toward P_2, this intensity reaches a single minimum and then becomes maximized again at P_2. How far is P_2 from P_1; that is, what is Δy? You may assume that $L \gg \Delta y$ and $D \gg \Delta y$, which will allow you to simplify the algebra by using

$$\sqrt{a \pm b} \approx a^{1/2} \pm \frac{b}{2a^{1/2}} \text{ when } a \gg b.$$



Section 16.4

16.42 A policeman with a very good ear and a good understanding of the Doppler effect stands on the shoulder of a freeway assisting a crew in a 40-mph work zone. He notices a car approaching that is honking its horn. As the car gets closer, the policeman hears the sound of the horn as a distinct B4 tone (494 Hz). The instant the car passes by, he hears the sound as a distinct A4 tone (440 Hz). He immediately jumps on his motorcycle, stops the car, and gives the motorist a speeding ticket. Explain his reasoning.

16.43 A meteorite hits the surface of the ocean at a speed of 8.80 km/s. What is the angle of the shock wave it produces (a) in the air just before hitting the ocean surface and (b) in the ocean just after entering? Assume that the speeds of sound in air and in water are 343 m/s and 1560 m/s, respectively.

16.44 A train whistle emits a sound at a frequency $f = 3000.$ Hz when stationary. You are standing near the tracks when the train goes by at a speed of $v = 30.0$ m/s. What is the magnitude of the change in the frequency ($|\Delta f|$) of the whistle as the train passes? (Assume that the speed of sound is $v = 343$ m/s.)

•16.45 You are driving along a highway at 30.0 m/s when you hear a siren. You look in the rearview mirror and see a police car approaching you from behind with a constant speed. The frequency of the siren that you hear is 1300. Hz. Right after the police car passes you, the frequency of the siren that you hear is 1280. Hz.

a) How fast was the police car moving?

b) You are so nervous after the police car passes you that you pull off the road and stop. Then you hear another siren, this time from an ambulance approaching from behind. The frequency of its siren that you hear is 1400. Hz. Once it passes, the frequency is 1200. Hz. What is the actual frequency of the ambulance's siren?

• 16.46 A bat flying toward a wall at a speed of 7.00 m/s emits an ultrasound wave with a frequency of 30.0 kHz. What frequency does the reflected wave have when it reaches the flying bat?

• **16.47** A plane flies at Mach 1.30, and its shock wave reaches a man on the ground 3.14 s after the plane passes directly overhead. Assume that the speed of sound is 343.0 m/s.

a) What is the Mach angle?

b) What is the altitude of the plane?

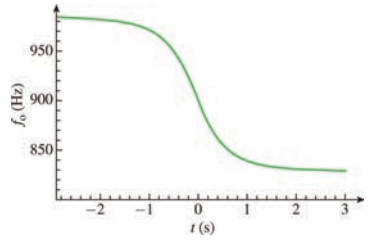
• **16.48** You are traveling in a car toward a hill at a speed of 40.0 mph. The car's horn emits sound waves of frequency 250. Hz, which move with a speed of 340. m/s.

a) Determine the frequency with which the waves strike the hill.

b) What is the frequency of the reflected sound waves you hear?

c) What is the beat frequency produced by the direct and the reflected sounds at your ears?

•**16.49** A car is parked at a railroad crossing. A train passes, and the driver of the car records the time dependence of the frequency of the sound emitted by the train, as shown in the figure.



a) What is the frequency heard by someone riding on the train?

b) How fast is the train moving?

c) How far away from the train tracks is the driver of the car?

$$\left(Hint: \left.\frac{df_o}{dt}\right|_{t=0} = -\frac{fv^2}{bv_{\text{sound}}}. \right)$$

••**16.50** Many towns have tornado sirens, large elevated sirens used to warn locals of imminent tornados. In one small town, a siren is elevated 100. m off the ground. A car is being driven at 100. km/h directly away from this siren while it is emitting a 440.-Hz sound. What is the frequency of the sound heard by the driver as a function of the distance from the siren at which he starts? Plot this

frequency as a function of the car's position up to 1000. m. Explain this plot in terms of the Doppler effect.

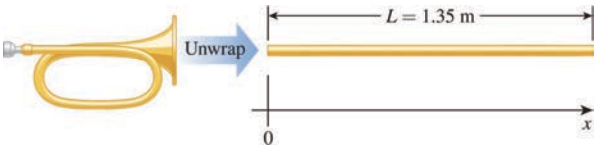
Section 16.5

16.51 A standing wave in a pipe with both ends open has a frequency of 440. Hz. The next higher overtone has a frequency of 660. Hz.

a) Determine the fundamental frequency.

b) How long is the pipe?

16.52 A bugle can be represented by a cylindrical pipe of length $L = 1.35$ m. The pipe is open at one end and closed at the other end (the end with the mouthpiece). Calculate the longest three wavelengths of standing waves inside the bugle. Also calculate the three lowest frequencies and the three longest wavelengths of the sound that is produced in the air around the bugle.



16.53 A soprano sings the note C6 (1047 Hz) across the mouth of a soda bottle. For a fundamental frequency equal to this note to be produced in the bottle, how far below the top of the bottle must the top of the liquid be?

16.54 A thin aluminum rod of length $L = 2.00$ m is clamped at its center. The speed of sound in aluminum is 5000. m/s. Find the lowest resonance frequency for vibrations in this rod.

• **16.55** Find the resonance frequency of the ear canal. Treat it as a half-open pipe of diameter 8.0 mm and length 25 mm. Assume that the temperature inside the ear canal is body temperature (37 °C).

• **16.56** A half-open pipe is constructed to produce a fundamental frequency of 262 Hz when the air temperature is 22.0 °C. It is used in an overheated building when the temperature is 35.0 °C. Neglecting thermal expansion in the pipe, what frequency will be heard?

Additional Exercises

16.57 A car horn emits a sound of frequency 400.0 Hz. The car is traveling at 20.0 m/s toward a stationary pedestrian when the driver sounds the horn. What frequency does the pedestrian hear?

16.58 An observer stands between two sound sources. Source A is moving away from the observer, and source B is moving toward the observer. Both sources emit sound of the same frequency. If both sources are moving with a speed $v_{\text{sound}}/2$, what is the ratio of the frequencies detected by the observer?

16.59 An F16 jet takes off from the deck of an aircraft carrier. A diver 1.00 km away from the ship is floating in the water with one ear below the surface and one ear above the surface. How much time elapses between the time he initially hears the jet's engines in one ear and the time he initially hears them in the other ear?

16.60 A train has a horn that produces a sound with a frequency of 311 Hz. Suppose you are standing next to a track when the train, horn blaring, approaches you at a speed of 22.3 m/s. By how much will the frequency of the sound you hear shift as the train passes you?

16.61 You have embarked on a project to build a five-pipe wind chime. The notes you have selected for your open pipes are presented in the table.

Note	Frequency (Hz)	Length (m)
G4	392	
A4	440	
B4	494	
F5	698	
C6	1047	

Calculate the length for each of the five pipes to achieve the desired frequency, and complete the table.

16.62 Two trains are traveling toward each other in still air at 25.0 m/s relative to the ground. One train is blowing a whistle at 300. Hz. Assume that the speed of sound is 343 m/s.

a) What frequency is heard by a man on the ground facing the whistle-blowing train?

b) What frequency is heard by a man on the other train?

• **16.63** At a distance of 20.0 m from a sound source, the intensity of the sound is 60.0 dB. What is the intensity (in dB) at a point 2.00 m from the source? Assume that the sound radiates equally in all directions from the source.

• **16.64** Two vehicles carrying speakers that produce a tone of frequency 1000.0 Hz are moving directly toward each other. Vehicle A is moving at 10.00 m/s and vehicle B is moving at 20.00 m/s. Assume that the speed of sound in air is 343.0 m/s, and find the frequencies that the driver of each vehicle hears.

•**16.65** You are standing between two speakers that are separated by 80.0 m. Both speakers are playing a pure tone of 286 Hz. You begin running directly toward one of the speakers, and you measure a beat frequency of 10.0 Hz. How fast are you running?

• **16.66** In a sound interference experiment, two identical loudspeakers are placed 4.00 m apart, facing in a direction perpendicular to the line that connects them. A microphone attached to a carrier sliding on a rail picks up the sound from the speakers at a distance of 400. m, as shown in the figure. The two speakers are driven in phase by the same signal generator at a frequency of 3400. Hz. Assume that the speed of sound in air is 340. m/s.

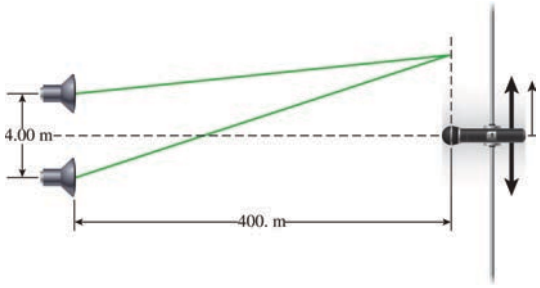
a) At what point(s) on the rail should the microphone be located for the sound reaching it to have maximum intensity?

b) At what point(s) should it be located for the sound reaching it to be zero?

c) What is the separation between two points of maximum intensity?

d) What is the separation between two points of zero intensity?

e) How would things change if the two loudspeakers produced sounds of the same frequency but different intensities?



• **16.67** A car traveling at 25.0 m/s honks its horn as it directly approaches the side of a large building. The horn produces a long sustained note of frequency $f_0 = 230.$ Hz. The sound is reflected off the building back to the car's driver. The sound wave from the original note and that reflected off the building combine to create a beat frequency. What is the beat frequency that the driver hears (which tells him that he had better hit the brakes!)?

• **16.68** Two identical half-open pipes each have a fundamental frequency of 500. Hz. What percentage change in the length of one of the pipes will cause a beat frequency of 10.0 Hz when they are sounded simultaneously?

•**16.69** A source traveling to the right at a speed of 10.00 m/s emits a sound wave at a frequency of 100.0 Hz. The sound wave bounces off a reflector, which is traveling to the left at a speed of 5.00 m/s. What is the frequency of the reflected sound wave detected by a listener back at the source?

• **16.70** In a suspense-thriller movie, two submarines, X and Y, approach each other, traveling at 10.0 m/s and 15.0 m/s, respectively. Submarine X "pings" submarine Y by sending a sonar wave of frequency 2000.0 Hz. Assume that the sound travels at 1500.0 m/s in the water.

a) Determine the frequency of the sonar wave detected by submarine Y.

b) What is the frequency detected by submarine X for the sonar wave reflected off submarine Y?

c) Suppose the submarines barely miss each other and begin to move away from each other. What frequency does submarine Y detect from the pings sent by X? How much is the Doppler shift?

••**16.71** Consider a sound wave (that is, a longitudinal displacement wave) in an elastic medium with Young's modulus Y (solid) or bulk modulus B (fluid) and unperturbed density ρ_0. Suppose this wave is described by the wave function $\delta x(x,t)$, where δx denotes the displacement of a point in the medium from its equilibrium position, x is position along the path of the wave at equilibrium, and t is time. The wave can also be regarded as a pressure wave, described by wave function $\delta p(x,t)$, where δp denotes the change of pressure in the medium from its equilibrium value.

a) Find the relationship between $\delta p(x,t)$ and $\delta x(x,t)$, in general.

b) If the displacement wave is a pure sinusoidal function, with amplitude A, wave number κ, and angular frequency ω, given by $\delta x(x,t) = A\cos(\kappa x - \omega t)$, what is the corresponding pressure wave function, $\delta p(x,t)$? What is the amplitude of the pressure wave?

••**16.72** Consider the sound wave of Problem 16.71.

a) Find the intensity, I, of the general wave, in terms of the wave functions $\delta x(x,t)$ and $\delta p(x,t)$.

b) Find the intensity of the sinusoidal wave of part (b), in terms of the displacement and amplitude of the pressure wave.

•**16.73** Using the results of Problems 16.71 and 16.72, determine the displacement and amplitude of the pressure wave

corresponding to a pure tone of frequency $f = 1.000\ \mathrm{kHz}$ in air (density $= 1.20\ \mathrm{kg/m^3}$, speed of sound $343\ \mathrm{m/s}$), at the threshold of hearing ($\beta = 0.00\ \mathrm{dB}$), and at the threshold of pain ($\beta = 120.\ \mathrm{dB}$).

MULTI-VERSION EXERCISES

16.74 A person in a parked car sounds the horn. The frequency of the horn's sound is 489 Hz. A driver in an approaching car measures the frequency of the horn's sound as 509.4 Hz. What is the speed of the approaching car? (Use 343 m/s for the speed of sound.)

16.75 A person in a parked car sounds the horn. A driver in an approaching car, which is moving at a speed of 15.1 m/s, measures the frequency of the horn's sound as 579.4 Hz. What is the frequency of the sound that the person in the parked car hears? (Use 343 m/s for the speed of sound.)

16.76 A person in a parked car sounds the horn. The frequency of the horn's sound is 333 Hz. A driver in an approaching car is moving at a speed of 15.7 m/s. What is the frequency of the sound that she hears? (Use 343 m/s for the speed of sound.)

16.77 The tuba typically produces the lowest-frequency sounds in an orchestra. Consider a tuba to be a coiled tube of length 7.373 m. What is the lowest-frequency sound a tuba can produce? Assume that the speed of sound is 343.0 m/s.

16.78 The tuba typically produces the lowest-frequency sounds in an orchestra. Consider a tuba to be a coiled tube. If the lowest frequency that the tuba can produce is 22.56 Hz, what is the length of the tube? Assume that the speed of sound is 343.0 m/s.

16.79 A metal bar has a Young's modulus of $266.3 \cdot 10^9$ N/m^2 and a mass density of 3497 kg/m^3. What is the speed of sound in this bar?

16.80 A metal bar has a Young's modulus of $112.1 \cdot 10^9\ \mathrm{N/m^2}$. The speed of sound in the bar is 5628 m/s. What is the mass density of this bar?

16.81 A metal bar has a mass density of $3579\ \mathrm{kg/m^3}$. The speed of sound in this bar is 6642 m/s. What is Young's modulus for this bar?

The Pleiades star cluster, shown in Figure 17.1, can be seen with the naked eye and was known to the ancient Greeks. What they could not know is that these stars exhibit some of the highest temperatures that occur in nature. Their surface temperatures range from 4000 °C to 10,000 °C, depending on size and other factors. However, their interior temperatures can reach over 10 million °C, hot enough to vaporize any substance. On the other end of the temperature range, space itself, far from any stars, registers a temperature of roughly −270 °C.

FIGURE 17.1 The star cluster known as the Pleiades, or Seven Sisters.

This chapter begins our study of thermodynamics, including the concepts of temperature, heat, and entropy. In its widest sense, thermodynamics is the physics of energy and energy transfer—how energy is stored, how it is transformed from one kind to another, and how it can be made available to do work. We'll examine energy at the atomic and molecular level as well as at the macroscopic level of engines and machines.

This chapter looks at temperature—how it is defined and measured and how changes in temperature can affect objects. We'll consider various scales with which to quantify temperature as well as the ranges of temperatures observed in nature and in the lab.

In practical terms, it is almost impossible to describe temperature without also discussing heat, which is the subject of Chapter 18. Be sure you keep in mind the differences between these concepts as you study the next few chapters.

WHAT WE WILL LEARN

- Temperature is measured using any of several different physical properties of certain materials.
- The Fahrenheit temperature scale sets the temperature of the freezing point of water at $32\ ^\circ\mathrm{F}$ and that of the boiling point of water at $212\ ^\circ\mathrm{F}$.
- The Celsius temperature scale sets the temperature of the freezing point of water at 0 °C and that of the boiling point of water at 100 °C.
- The Kelvin temperature scale is defined in terms of an absolute zero temperature, or the lowest temperature at which matter could theoretically exist. In the Kelvin temperature scale, the freezing point of water is 273.15 K, and the boiling point of water is 373.15 K.
- Heating a long, thin metal rod causes its length to increase linearly with the temperature, measured in K.
- Heating a liquid generally causes its volume to increase linearly with the temperature, measured in K.
- The Earth's average surface temperature in 2011 was approximately $14.46\ ^\circ\mathrm{C}$, and it is increasing at a rate of about $0.2\ ^\circ\mathrm{C}$ per decade.
- Analysis of the cosmic microwave background radiation shows the temperature of "empty" intergalactic space to be 2.725 K.

17.1 Definition of Temperature

Temperature is a concept we all understand from experience. We hear weather forecasters tell us that the temperature will be $72\ ^\circ\mathrm{F}$ today. We hear doctors tell us that our body temperature is $98.6\ ^\circ\mathrm{F}$. When we touch an object, we can tell whether it is hot or cold. If we put a hot object in contact with a cold object, the hot object will cool off and the cold object will warm up. If we measure the temperatures of the two objects after some time has passed, they will be equal. The two objects are then in **thermal equilibrium.**

Heat is the transfer between a system and its environment of **thermal energy**, which is energy in the form of random motion of the atoms and molecules making up the matter in question. Chapter 18 will quantify the concept of heat as thermal energy that is transferred because of a temperature difference.

The **temperature** of an object is related to the tendency of the object to transfer heat to or from its surroundings. Heat will transfer from the object to its surroundings if the object's temperature is higher than that of its surroundings. Heat will transfer to the object if its temperature is less than its surroundings. Note that cold is simply the absence of heat; there is no such thing as a flow of "coldness" between an object and its surroundings. If an object feels cold to your touch, this is simply a consequence of heat being transferred from your fingers to the object. (This is the macroscopic definition of temperature; we'll see in Chapter 19 that on a microscopic level, temperature is proportional to the kinetic energy of random motion of particles.)

Measuring temperature relies on the fact that if two objects are in thermal equilibrium with a third object, they are in thermal equilibrium with each other. This third object could be a **thermometer,** which measures temperature. This idea, often called the **Zeroth Law of Thermodynamics,** defines the concept of temperature and underlies the ability to measure temperature. That is, in order to find out if two objects have the same temperature, you do not need to bring them into thermal contact and monitor whether thermal energy transfers (which may be hard or even impossible in

some instances). Instead, you can use a thermometer and measure each object's temperature separately; if your readings are the same, you know that the objects have the same temperature.

Temperature measurements can be taken using any of several common scales. Let's examine these.

Temperature Scales

Fahrenheit Scale

Several systems have been proposed and used to quantify temperature; the most widely used are the Fahrenheit, Celsius, and Kelvin scales. The **Fahrenheit temperature scale** was proposed in 1724 by Gabriel Fahrenheit, a German-born scientist living in Amsterdam. Fahrenheit also invented the mercury-expansion thermometer. The Fahrenheit scale went through several iterations. Fahrenheit finally defined the unit of the Fahrenheit scale (°F) by fixing 32 °F for the freezing point of water and 96 °F for the temperature of the human body as measured under the arm. Later, other scientists refined the scale by defining the freezing point of water as 32 °F and the boiling point of water as 212 °F. This temperature scale is used widely in the United States.

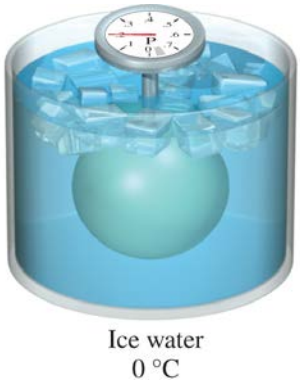
Celsius Scale

Anders Celsius, a Swedish astronomer, proposed the **Celsius temperature scale,** often called the *centigrade scale,* in 1742. Several iterations of this scale resulted in its unit (°C) being determined by setting the freezing point of water at 0 °C and the boiling point of water at 100 °C (at normal atmospheric pressure). This temperature scale is used worldwide, except in the United States.

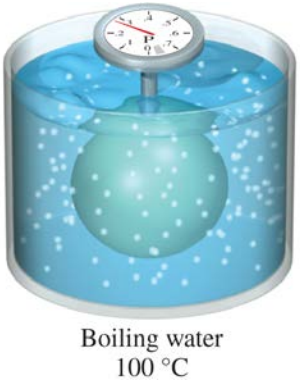
Kelvin Scale

In 1848, William Thomson (Lord Kelvin), a British physicist, proposed another temperature scale, which is now called the **Kelvin temperature scale.** This scale is based on the existence of **absolute zero,** the minimum possible temperature.

The behavior of the pressure of gases at fixed volume as a function of temperature was studied, and the observed behavior was extrapolated to zero pressure to establish this absolute zero temperature. To see how this works, suppose we have a fixed volume of nitrogen gas in a hollow spherical aluminum container connected to a pressure gauge (Figure 17.2). There is enough nitrogen gas in the container that when the container is immersed in an ice-water bath, the pressure gauge reads 0.200 atm. We then place the container in boiling water. The pressure gauge now reads 0.273 atm. Therefore, the pressure has increased while the volume has stayed constant. Suppose we repeat this procedure with different starting pressures. Figure 17.3 summarizes the results, with four solid lines representing the different starting pressures. You can see that the pressure of the gas goes down as the temperature decreases. Conversely, lowering the pressure of the gas must lower its temperature. Theoretically, the lowest temperature of the gas can be determined by extrapolating the measured behavior until the pressure becomes zero. The dashed lines in Figure 17.3 show the extrapolations.



(a)



(b)

FIGURE 17.2 A hollow aluminum sphere fitted with a pressure gauge and filled with nitrogen gas. (a) The container is held at $0\ ^\circ\mathrm{C}$ by placing it in ice water. (b) The container is held at $100\ ^\circ\mathrm{C}$ by placing it in boiling water.

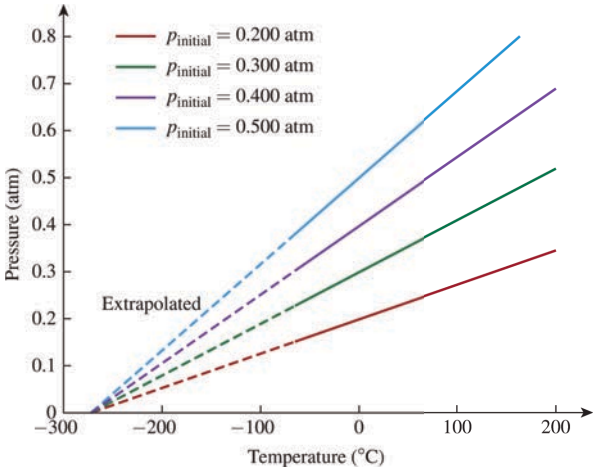


FIGURE 17.3 Solid lines: Pressures of a gas measured at fixed volume and different temperatures. Each line represents an experiment starting at a different initial pressure. Dashed lines: Extrapolation of the pressure of nitrogen gas in a fixed volume as the temperature is lowered.

The relationship among pressure, volume, and temperature for a gas is the focus of Chapter 19. However, for now, you only need to understand the following observation: The data from the four sets of measurements starting at different initial pressures extrapolate to the same temperature at zero pressure. This temperature is called *absolute zero* and corresponds to $-273.15\,^{\circ}\mathrm{C}$. When researchers attempt to lower the temperature of real nitrogen gas to very low temperatures, the linear relationship breaks down because the gaseous nitrogen liquefies, bringing subsequent interactions between the nitrogen molecules. In addition, different gases show slightly different behavior at very low temperatures. However, for low pressures and relatively high temperatures, this general result stands.

Absolute zero is the lowest temperature at which matter could theoretically exist. (Experimentally, it is impossible to reach absolute

zero, just as it is impossible to build a perpetual motion machine.) We'll see in Chapter 19 that temperature corresponds to motion at the atomic and molecular level, so making an object reach absolute zero would imply that all motion in the atoms and molecules of the object ceases. However, in Chapters 36 and 37, we'll see that some motion of this type is required by quantum mechanics. This requirement, sometimes called the **Third Law of Thermodynamics,** means that absolute zero is never actually attainable.

Concept Check 17.1

Which of the following temperatures is the coldest?

a) $10\ ^\circ\mathrm{C}$

b) $10\ ^\circ\mathrm{F}$

c) 10 K

Kelvin used the size of the Celsius degree ($^\circ\mathrm{C}$) as the size of the unit of his temperature scale, now called the **kelvin (K)**. On the Kelvin scale, the freezing point of water is 273.15 K and the boiling point of water is 373.15 K. This temperature scale is used in many scientific calculations, as we'll see in the next few chapters. Because of these considerations, the kelvin is the standard SI unit for temperature. To achieve greater consistency, scientists have proposed defining the kelvin in terms of other fundamental constants, rather than in terms of the properties of water. These new definitions went into effect in 2019, but for our purposes none of the values stated previously changed.

Concept Check 17.2

Which of the following temperatures is the warmest?

a) $300\ ^\circ\mathrm{C}$

b) $300\ ^\circ\mathrm{F}$

c) 300 K

17.2 Temperature Ranges

Temperature measurements span a huge range (shown in Figure 17.4, using a logarithmic scale), from the highest measured temperatures $\left(2 \cdot 10^{12}\ \mathrm{K}\right)$, observed in relativistic heavy ion collisions (RHIC), to the lowest measured temperatures $\left(1 \cdot 10^{-10}\ \mathrm{K}\right)$, observed in spin systems of rhodium atoms. The temperature in the center of the Sun is estimated to be $16 \cdot 10^{6}\ \mathrm{K}$, and at the surface of the Sun, it has been measured to be 5778 K. The lowest measured air temperature on the Earth's surface is $183.9\ \mathrm{K}\ (-89.2\ ^{\circ}\mathrm{C})$ in Antarctica; the highest measured air temperature on the Earth's surface is $330.9\ \mathrm{K}\ (57.8\ ^{\circ}\mathrm{C})$ in the Sahara desert in Libya. You can see from Figure 17.4 that the observed temperature range on the surface of the Earth covers only a very small fraction of the range of observed temperatures. The cosmic microwave background radiation left over from the Big Bang 13.7 billion years ago has a temperature of 2.725 K (which is the temperature of "empty" intergalactic space), an observation that will be explained in more detail in later chapters. From Figure 17.4, you can see that temperatures attained in relativistic heavy ion collisions are 300 million times higher than the surface temperature of the Sun and that temperatures of atoms measured in ion traps are more than a billion times lower than the temperature of intergalactic space.

Figure 17.5 shows some representative temperatures above absolute zero and below 400 K, expressed in the Fahrenheit, Celsius, and Kelvin scales. This temperature range is shown on a linear scale.

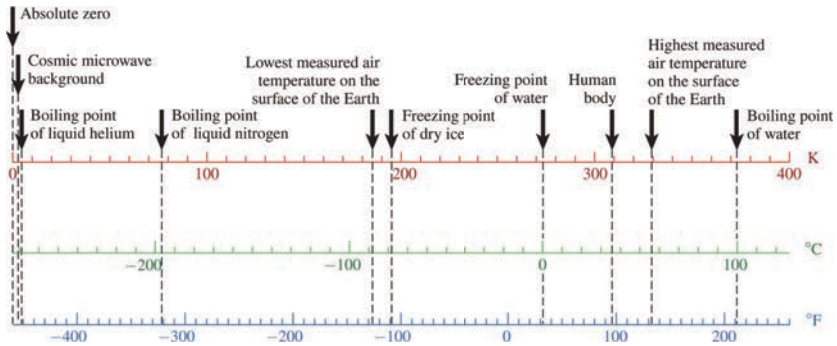

FIGURE 17.5 Representative temperatures, expressed in the three common temperature scales.

In the following formulas for converting between the various temperature scales, the Fahrenheit temperature is T_{F}, measured in $^{\circ}\mathrm{F}$; the Celsius temperature is T_{C}, measured in $^{\circ}\mathrm{C}$; and the Kelvin temperature is T_{K}, measured in K.

Fahrenheit to Celsius:

$$T_{\mathrm{C}} = \frac{5}{9}(T_{\mathrm{F}} - 32\ ^{\circ}\mathrm{F}). \qquad \textbf{(17.1)}$$

Celsius to Fahrenheit:

$$T_{\mathrm{F}} = \frac{9}{5}T_{\mathrm{C}} + 32\ ^{\circ}\mathrm{C}. \qquad \textbf{(17.2)}$$

Celsius to Kelvin:

$$T_{\mathrm{K}} = T_{\mathrm{C}} + 273.15\ ^{\circ}\mathrm{C}. \qquad \textbf{(17.3)}$$

Kelvin to Celsius:

$$T_{\mathrm{C}} = T_{\mathrm{K}} - 273.15\ \mathrm{K}. \qquad \textbf{(17.4)}$$

Self-Test Opportunity 17.1

At what temperature do the Fahrenheit and Celsius scales have the same numerical value?

The mean human body temperature taken orally is $36.8\ ^{\circ}\mathrm{C}$, which corresponds to $98.2\ ^{\circ}\mathrm{F}$. The often-quoted mean oral temperature of $98.6\ ^{\circ}\mathrm{F}$ corresponds to a 19th-century measurement of $37\ ^{\circ}\mathrm{C}$. This temperature is highlighted on the oral mercury thermometer in Figure 17.6. The difference between $98.6\ ^{\circ}\mathrm{F}$ and

98.2 °F thus corresponds to the error due to rounding the Celsius scale measurement of human body temperature to two digits. Table 17.1 lists human body temperature and other representative temperatures, expressed in the three temperature scales.

Various Temperatures, Expressed in the Three Most Commonly Used Temperature Scales

	Fahrenheit (°F)	Celsius (°C)	Kelvin (K)
Temperature at the center of the Sun	$28 \cdot 10^6$	$16 \cdot 10^6$	$16 \cdot 10^6$
Average temperature of the surface of the Earth	59	15	288
Temperature at the center of the Earth	9,800	5,400	5,700

EXAMPLE 17.1 Room Temperature

Room temperature is often taken to be 72.0 °F.

PROBLEM

What is room temperature in the Celsius and Kelvin scales?

SOLUTION

Using equation 17.1, we can convert room temperature from degrees Fahrenheit to degrees Celsius:

$$T_{\mathrm{C}} = \frac{5}{9}(72\ ^\circ\mathrm{F} - 32\ ^\circ\mathrm{F}) = 22.2\ ^\circ\mathrm{C}.$$

Using equation 17.3, we can then express room temperature in kelvins as

$$T_{\mathrm{K}} = 22\ ^\circ\mathrm{C} + 273.15\ ^\circ\mathrm{C} = 295.\ \mathrm{K}.$$

SOLVED PROBLEM 17.1 Temperature Conversion

PROBLEM

On a cold winter day, you notice that the temperature reading in Fahrenheit degrees is 10.0 degrees *higher* than that in Celsius degrees. By how many Celsius degrees does the temperature need to change for the Fahrenheit reading to be 10.0 degrees *lower* than the Celsius reading?

SOLUTION

THINK

This appears to be a straightforward temperature conversion problem. The easiest way to solve this problem is to first figure out the temperature that meets the 10-degree-higher condition and then find the temperature that fulfills the 10-degree-lower condition. Our final answer is then the difference of those two temperatures.

SKETCH

A sketch does not seem to help at first thought. However, as shown in Figure 17.7, we can graph the conversion line for Celsius and Fahrenheit temperatures and the two boundary conditions specified in the problem. This will allow us to solve the problem graphically.

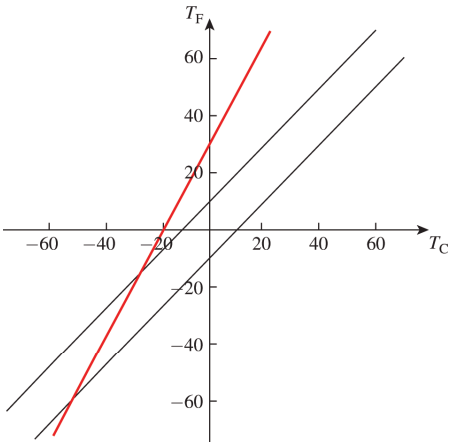

FIGURE 17.7 Conversion of Celsius temperatures to Fahrenheit (red line). The two black lines are the boundary conditions imposed in the problem.

RESEARCH

The formula for converting from Celsius to Fahrenheit temperatures is $T_F = \frac{9}{5}T_C + 32$. For the first set of temperature readings, we have $T_F = T_C + 10$, and for the second set of readings, we have $T_F = T_C - 10$.

SIMPLIFY

The temperature that meets the 10-degrees-higher condition can be obtained by setting the two expressions for T_F, $T_F = T_C + 10$ and $T_F = \frac{9}{5}T_C + 32$, equal, which results in

$$T_C + 10 = \frac{9}{5}T_C + 32 \Rightarrow -22 = \frac{4}{5}T_C \Rightarrow T_C = -27.5.$$

We find the temperature that meets the 10-degrees-lower condition in the same way:

$$T_C - 10 = \frac{9}{5}T_C + 32 \Rightarrow -42 = \frac{4}{5}T_C \Rightarrow T_C = -52.5.$$

CALCULATE

Now, all that is left to do is take the difference between the two temperatures:

$$\Delta T_{\mathrm{C}} = -52.5 - (-27.5) = -25.0.$$

ROUND

The problem statement gave the temperatures with three significant digits, and so we express our final answer to that precision: $\Delta T_{\mathrm{C}} = -25.0$. It would have to get colder by $25.0\ ^{\circ}\mathrm{C}$ for the Fahrenheit reading to be 10.0 degrees below the Celsius reading. (You might think that the number 32 in the temperature conversion equation has only two significant digits; however, this conversion constant is by definition exact, and so it does not degrade the precision of our final answer.)

DOUBLE-CHECK

Our sketch provides an easy double-check: The two points at which the red line crosses the two parallel black lines appear to be at (or at least close to) the values we found algebraically.

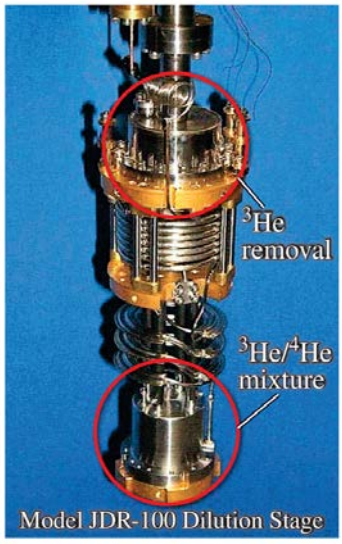
Research at the Low-Temperature Frontier

How are very low temperatures attained in a lab? Researchers start by taking advantage of the properties of gases related to their pressure, volume, and temperature (again, Chapter 19 will go into these properties in much greater depth). In addition, phase changes (discussed in Chapter 18) from liquid to gas and back to liquid are crucial in producing low temperatures in the lab. For this discussion, we can simply note that when a liquid evaporates, the energy required to change the liquid to a gas is taken from the liquid—therefore, the liquid cools. For example, air is liquefied through a multistep process in which the air is compressed and cooled by removing the heat produced in the compression stage. Then, the fact that different gases have different temperatures at which they liquefy allows liquid nitrogen and liquid oxygen to be separated. At normal atmospheric pressure, liquid nitrogen has a boiling point of 77 K, while liquid oxygen has a boiling point of 90 K. Liquid nitrogen has many applications, not the least of which is in classroom lecture demonstrations.

Even lower temperatures are achieved using the compression process, with liquid nitrogen extracting the heat as helium is compressed. Liquid helium boils at 4.2 K. Starting with liquid helium and reducing the pressure so that it evaporates, researchers can cool the remaining liquid down to about 1.2 K. For the isotope helium-3 $\left({}^{3}\mathrm{He}\right)$, a temperature as low as 0.3 K can be reached with this evaporative-cooling technique.

To reach still lower temperatures, researchers use an apparatus called a *dilution refrigerator* (see Figure 17.8). A dilution refrigerator uses two isotopes of helium: ^{3}He (two protons and one neutron) and ^{4}He (two protons and two neutrons). (Isotopes are discussed in Chapter 40 on nuclear physics.) When the temperature of a mixture of liquid ^{3}He and liquid ^{4}He is reduced below 0.7 K, the two gases separate into a ^{3}He-poor phase and a ^{4}He-poor phase. Energy is required to move ^{3}He atoms into the ^{3}He-poor phase. If the atoms can be forced to cross the boundary between the two phases, the mixture can be cooled in a way similar to evaporative cooling. A dilution refrigerator can cool to temperatures around 10 mK, and the best commercial models can reach 2 mK.

(a)



(b)

Janis Research Co., Inc.
www.janis.com

Still lower temperatures can be reached with a gas of atoms confined to a trap. To attain these temperatures, researchers use techniques such as laser cooling. Laser cooling takes advantage of the electronic structure of certain atoms. (Atoms, transitions between their electron energy levels, and lasers will be covered in detail in Chapter 38.) Transitions between specific electron energy levels in an atom can cause photons with a wavelength close to visible light to be emitted. The inverse process can also occur, in which the atoms absorb photons. (Light absorption and emission are explained in Chapters 36 through 38.) To cool atoms using laser cooling, researchers use a laser that emits light with a very specific wavelength that is longer than the wavelength of light emitted during an atomic transition. Thus, any atom moving toward the laser experiences a slightly shorter wavelength due to the Doppler effect (see Chapter 16 and Chapter 31), while any atom moving away from the laser experiences a longer wavelength. Atoms moving toward the laser absorb photons, but atoms moving away from the laser are not affected. Atoms that absorb photons re-emit them in random directions, effectively cooling the atoms. Temperatures approaching 10^{-9} K have been achieved using this method (Figure 17.9). Steven Chu, Claude Cohen-Tannoudji, and William D. Phillips were awarded the 1997 Nobel Prize in Physics for their work with laser cooling.

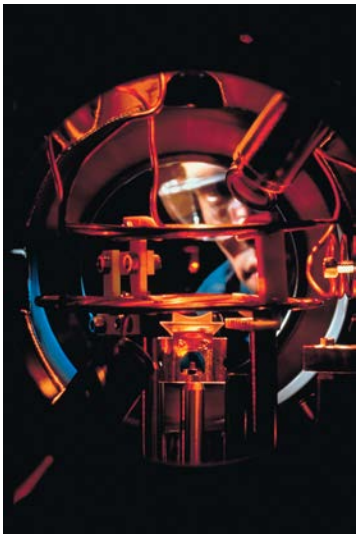

FIGURE 17.9 A laser-cooling device for cooling trapped sodium atoms.

H. Mark Helfer/NIST

The coldest temperatures achieved in a lab have been accomplished using a technique called *adiabatic nuclear demagnetization*. The sample, typically a piece of rhodium metal, is first cooled using a dilution refrigerator. A strong magnetic field is then applied. (Magnetic fields will be discussed in Chapters 27 and 28.) A small amount of heat is produced in the rhodium metal, which is removed by the dilution refrigerator. Then the magnetic field is slowly turned off. As the magnetic field is reduced, the rhodium metal cools further, reaching temperatures as low as 10^{-10} K.

Research at the High-Temperature Frontier

How are high temperatures attained in the lab? The most common methods are by burning fuels or by creating explosions. For example, the yellow part of a candle flame has a temperature of 1400 K.

The ITER fusion reactor under construction in Cadarache, France, and to be completed by 2025 (Figure 17.10) is designed to fuse the hydrogen isotopes deuterium $\left({}^{2}\mathrm{H}\right)$ and tritium $\left({}^{3}\mathrm{H}\right)$ to yield helium $\left({}^{4}\mathrm{He}\right)$ and a neutron, with a release of energy. This process of nuclear fusion (to be discussed in Chapter 40) is similar to the process that the Sun uses to fuse hydrogen into helium and thereby produce energy. In the Sun, the huge gravitational force compresses and heats the hydrogen nuclei to produce fusion. In ITER, magnetic confinement will be used to hold ionized hydrogen in the form of a plasma. A *plasma* is a state of matter in which electrons and nuclei move separately. A plasma cannot be contained in a physical container, because it is so hot that any contact with it would vaporize the container. In the fusion reactor, plasma is heated by flowing a current through it. In addition, the plasma is compressed and further heated by the applied magnetic field. At high temperatures, up to $9.9 \cdot 10^{7}$ K, and densities, ITER will produce usable energy from the fusion of hydrogen into helium.

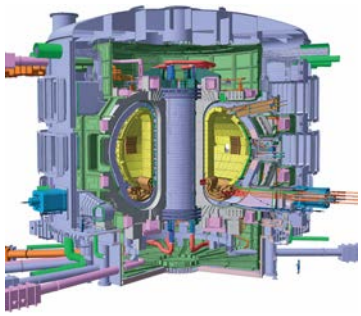

FIGURE 17.10
Cutaway drawing of the central core of ITER, the plasma fusion reactor to be completed in France by the year 2025. For size comparison, a person is shown standing at the bottom.

ITER

It is possible to achieve even higher temperatures in particle accelerators. The highest temperature has been reached by colliding gold nuclei accelerated by the Relativistic Heavy Ion Collider at Brookhaven National Laboratory and by the Large Hadron Collider at the European CERN laboratory. When two large nuclei collide, a very hot system with a temperature of $2 \cdot 10^{12}\ \mathrm{K}$ is created; this system is also very small $\left(\sim 10^{-14}\ \mathrm{m}\right)$ and exists for very short periods of time $\left(\sim 10^{-22}\ \mathrm{s}\right)$.

17.3 Measuring Temperature

How are temperatures measured? A device that measures temperature is called a *thermometer*. Any thermometer that can be calibrated directly by using a physical property is called a *primary thermometer*. A primary thermometer does not need calibration to external standard temperatures. An example of a primary thermometer is one based on the speed of sound in a gas. A *secondary thermometer* is one that requires external calibration to standard temperature references. Often, secondary thermometers are more sensitive than primary thermometers.

A common thermometer is the mercury-expansion thermometer, which is a secondary thermometer. This type of thermometer takes advantage of the thermal expansion of mercury (thermal expansion is discussed in Section 17.4). Other types of thermometers include bimetallic, thermocouple, chemoluminescence, and thermistor thermometers. It is also possible to measure the temperature of a material by studying the distribution of the speeds of the molecules inside that material.

To measure the temperature of an object or a system using a thermometer, the thermometer must be placed in thermal contact with the object or system. (*Thermal contact* is physical contact that allows relatively fast transfer of heat.) Heat will then transfer between the object or system and the thermometer, until they have the same temperature. A good thermometer should require as little thermal energy transfer as possible to reach thermal equilibrium, so that the temperature measurement does not significantly change the object's temperature. The thermometer should also be easily calibrated, so that anyone making the same measurement will get the same temperature.

Self-Test Opportunity 17.2

You have an uncalibrated thermometer, which is to be used to measure air temperatures. How would you calibrate the thermometer?

Calibrating a thermometer requires reproducible conditions. It is difficult to reproduce the freezing point of water exactly, so scientists use a condition called the *triple point of water*. Solid ice, liquid water, and gaseous water vapor can coexist at only one temperature and pressure. By international agreement, the temperature of the triple point of water has been assigned the temperature 273.16 K (and a pressure of 611.73 Pa) for the calibration of thermometers.

17.4 Thermal Expansion

Most of us are familiar in some way with **thermal expansion.** Perhaps you know that you can loosen a metal lid on a glass jar by heating the lid. You may have seen that bridge spans contain gaps in the roadway to allow for the expansion of sections of the bridge in warm weather. Or you may have observed that power lines sag in warm weather. And if you live in a colder climate, you may know that water can freeze in pipes in the winter and cause damage to the pipes as a result of its expansion.

Why do materials expand due to a change in temperature? In Chapter 13, we saw that all matter is made of atoms. The atoms vibrate, and the amplitude of their vibrations is a function of the temperature of the matter. The larger the amplitude of this vibrational motion, the greater the spaces between the atoms in solids and liquids. (Since gases occupy the entire space available to them, changes in vibrational amplitude have no effect on atomic spacing in gases. In Chapter 19, we will study the effect of temperature on gases.) As a very general rule, a higher temperature means larger vibrations and thus greater atomic spacing. Therefore, solids and liquids expand with increasing temperature. (The only exception to this general rule is at or close to the freezing or melting point, where some substances—most notably water—expand as they freeze and contract as they melt. This anomaly is due to the fact that the atoms assume places in an orderly crystal structure in the transition from liquid to solid phase.)

The thermal expansion of liquids and solids can be put to practical use. Bimetallic strips, which are often used in room thermostats, meat thermometers, and thermal protection devices in electrical equipment, take advantage of linear thermal expansion. (A bimetallic strip consists of two thin long strips of different metals, which are welded together.) A mercury thermometer uses volume expansion to provide precise measurements of temperature. Thermal expansion can occur as linear expansion, area expansion, or volume expansion; all three classifications describe the same phenomenon.

Linear Expansion

Let's consider a metal rod of length L (Figure 17.11). If we raise the temperature of the rod by $\Delta T = T_{\text{fianl}} - T_{\text{initial}}$, the length of the rod increases by the amount $\Delta L = L_{\text{final}} = L_{\text{initial}}$, given by

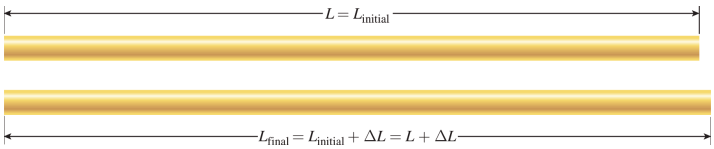

FIGURE 17.11 Thermal expansion of a rod with initial length *L*. (The thermally expanded rod at the bottom has been shifted so that the left edges coincide.)

$$\Delta L = \alpha L \Delta T, \tag{17.5}$$

where α is the **linear expansion coefficient** of the metal from which the rod is constructed and the temperature difference is expressed in degrees Celsius or kelvins. The linear expansion coefficient is a constant for a given material within normal temperature ranges. Some typical linear expansion coefficients are listed in Table 17.2.

Table 17.2 Linear Expansion Coefficients of Some Common Materials

Material	$\alpha\left(10^{-6}\,^{\circ}\mathrm{C}^{-1}\right)$
Aluminum	22
Brass	19
Concrete	15
Copper	17
Diamond	1
Gold	14
Lead	29
Plate glass	9
Rubber	77
Steel	13
Tungsten	4.5

EXAMPLE 17.2 Thermal Expansion of the Mackinac Bridge

The center span of the Mackinac Bridge (Figure 17.12) has a length of 1158 m. The bridge is built of steel. Assume that the lowest possible temperature experienced by the bridge is $-50\ ^\circ\text{C}$ and the highest possible temperature is $50\ ^\circ\text{C}$.

FIGURE 17.12 The Mackinac Bridge across the Straits of Mackinac in Michigan is the third-longest suspension bridge in the United States.

JamesBrey/iStock/Getty Images

PROBLEM

How much room must be made available for thermal expansion of the center span of the Mackinac Bridge?

SOLUTION

The linear expansion coefficient of steel is $\alpha = 13.10^{-6}\ ^\circ\text{C}^{-1}$. Thus, the linear expansion of the center span of the bridge that must be allowed for is given by

$$\Delta L = \alpha L \Delta T = \left(13.10^{-6}\ ^\circ\text{C}^{-1}\right)(1158\ \text{m})\left[50\ ^\circ\text{C} - (-50\ ^\circ\text{C}\right.$$

DISCUSSION

A change in length of 1.5 m is fairly large. How is this length change accommodated in practice? (Obviously, we cannot have gaps in the road surface.) The answer lies in expansion joints, which are metal connectors between bridge segments whose parts can move relative to each other. A popular type of expansion joint is the finger joint (see Figure 17.13). The Mackinac Bridge has two large finger joints at the towers to accommodate the expansion of the suspended parts of the roadway and eleven smaller finger joints and five sliding joints across the center span.

FIGURE 17.13 Finger joints between road segments: (a) open and (b) closed.

From Table 17.2, you can see that various metals, such as brass and steel, have different linear expansion coefficients. This makes them useful in bimetallic strips. The following solved problem considers the result of heating a bimetallic strip.

Concept Check 17.3

Modern train tracks have no expansion gaps. Which one of the following statements explains why this is possible?

a) The tracks are made of a new type of steel with a very low linear expansion coefficient.

b) Electrical current is run through the tracks to keep them at a constant temperature.

c) The tracks are laid in circular sections to accommodate expansion and contraction.

d) The tracks are laid when the temperature is moderate and fixed to nonmovable supports that prevent expansion or contraction.

SOLVED PROBLEM 17.2 Bimetallic Strip

A straight bimetallic strip consists of a steel strip and a brass strip, each 1.25 cm wide and 30.5 cm long, welded together (see Figure 17.14a). Each strip is $t = 0.500$ mm thick. The bimetallic strip is heated uniformly along its length, as shown in Figure 17.14c. (It doesn't matter that the flame is on the right; the heating is uniform throughout the strip. If the flame were on the left, the strip would bend in the same direction!) The strip curves such that the radius of curvature is $R = 36.9$ cm.

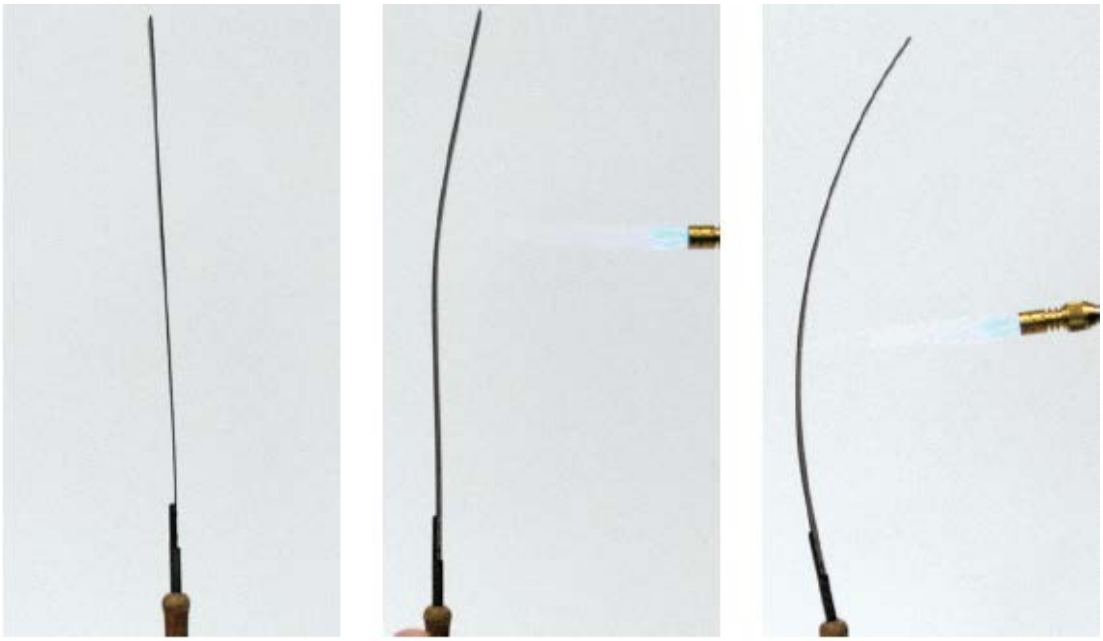

FIGURE 17.14 A bimetallic strip. (a) The bimetallic strip at room temperature. (b) The bimetallic strip as it begins to be heated by a gas torch (on the right edge of the frame). (c) The bimetallic strip heated to a uniform temperature over its full length.

W. Bauer and G. D. Westfall

PROBLEM

What is the temperature of the bimetallic strip after it is heated?

SOLUTION

THINK

The bimetallic strip is constructed from two metals, steel and brass, that have different linear expansion coefficients, listed in Table 17.2. As the temperature of the bimetallic strip increases, the brass expands more than the steel does, so the strip curves toward the steel side. When the bimetallic strip is heated uniformly, both the steel and brass strips lie along the arc of a circle, with the brass strip on the outside and the steel strip on the inside. The ends of the bimetallic strip subtend the same angle, measured from the center of the circle. The arc length of each metal strip then equals the length of the bimetallic strip at room temperature plus the length due to linear thermal expansion. Equating the angle subtended by the steel strip to the angle subtended by the brass strip allows the temperature to be calculated.

SKETCH

Figure 17.15 shows the bimetallic strip after it is heated. The angle subtended by the two ends of the strip is θ and the radius of the inner strip is r_1. The inner strip lies along a circle with radius $r_1 = 36.9$ cm.

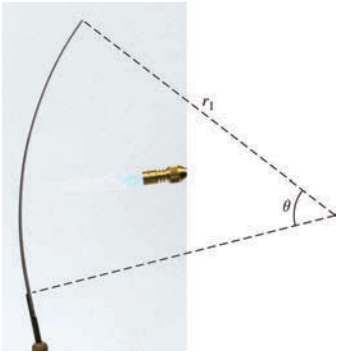

FIGURE 17.15 The bimetallic strip after it is heated, showing the angle subtended by the two ends of the strip.

W. Bauer and G. D. Westfall

RESEARCH

The arc length, s_1, of the heated steel strip is $s_1 = r_1\theta$, where r_1 is the radius of the circle along which the steel strip lies, and θ is the angle subtended by the steel strip. Also, the arc length, s_2, of the heated brass strip is $s_2 = r_2\theta$, where r_2 is the radius of the circle along which the brass strip lies and θ is the *same angle* as that subtended by the steel strip. The two radii differ by the thickness, *t*, of the steel strip:

$$r_2 = r_1 + t \Leftrightarrow t = r_2 - r_1. \qquad \text{(i)}$$

We can equate the expressions that are equal to the angle subtended by the two strips:

$$\theta = \frac{s_1}{r_1} = \frac{s_2}{r_2}. \qquad \text{(ii)}$$

The arc length, s_1, of the steel strip after it is heated is given by

$$s_1 = s + \Delta s_1 = s + \alpha_1 s \Delta T = s(1 + \alpha_1 \Delta T),$$

where s is the original length of the bimetallic strip. The factor α_1 is the linear expansion coefficient of steel, given in Table 17.2, and ΔT is the temperature difference between room temperature and the final temperature of the bimetallic strip. Correspondingly, the arc length, s_2, of the brass strip after being heated is given by

$$s_2 = s + \Delta s_2 = s + \alpha_2 s \Delta T = s(1 + \alpha_2 \Delta T),$$

where α_2 is the linear expansion coefficient of brass, given in Table 17.2.

SIMPLIFY

We substitute the expressions for the arc lengths of the two strips after heating, s_1 and s_2, into equation (ii) to get

$$\frac{s(1 + \alpha_1 \Delta T)}{r_1} = \frac{s(1 + \alpha_2 \Delta T)}{r_2}.$$

Dividing both sides of this equation by the common factor s and multiplying by $r_1 r_2$ gives

$$r_2 + r_2 \alpha_1 \Delta T = r_1 + r_1 \alpha_2 \Delta T.$$

We rearrange this equation and gather common terms to obtain

$$r_2 - r_1 = r_1 \alpha_2 \Delta T - r_2 \alpha_1 \Delta T.$$

Solving this equation for the temperature difference gives

$$\Delta T = \frac{r_2 - r_1}{r_1 \alpha_2 - r_2 \alpha_1}.$$

Using the relationship between the two radii from equation (i) leads to

$$\Delta T = \frac{t}{r_1(\alpha_2 - \alpha_1) - t\alpha_1}. \qquad \text{(iii)}$$

CALCULATE

From Table 17.2, the linear expansion coefficient for steel is $\alpha_1 = 13 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$, and the linear expansion coefficient for brass is $\alpha_2 = 19 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$. Inserting these and the other numerical values into equation (iii) gives us

$$\Delta T = \frac{0.500 \cdot 10^{-3}\ \text{m}}{(0.369\ \text{m})\left(19 \cdot 10^{-6}\ ^\circ\text{C}^{-1} - 13 \cdot 10^{-6}\ ^\circ\text{C}^{-1}\right) - (0.5}$$

ROUND

Taking room temperature to be 20 $^\circ$C and reporting our result to two significant figures gives us the temperature of the bimetallic strip after heating:

$$T = 20\ ^\circ\text{C} + \Delta T = 250\ ^\circ\text{C}.$$

DOUBLE-CHECK

First, we check that the magnitude of the calculated temperature is reasonable. Our answer of 250 $^\circ$C is well below the melting points of brass (900 $^\circ$C) and steel (1450 $^\circ$C), which is important because Figure 17.14c shows that the strip does not melt. Our answer is also significantly above room temperature, which is important because Figure 17.14a shows that the strip is straight at room temperature.

We can further check that the steel and brass strips do subtend the same angle. The angle subtended by the steel strip is

$$\theta_1 = \frac{s_1}{r_1} = \frac{30.5\ \text{cm} + (30.5\ \text{cm})\left(13 \cdot 10^{-6}\ ^\circ\text{C}^{-1}\right)(226.5\ ^\circ\text{C}}{36.9\ \text{cm}}$$

The angle subtended by the brass strip is

$$\theta_2 = \frac{s_2}{r_2} = \frac{30.5\ \text{cm} + (30.5\ \text{cm})\left(19 \cdot 10^{-6}\ ^\circ\text{C}^{-1}\right)(226.5\ ^\circ\text{C}}{36.9\ \text{cm} + 0.05\ \text{cm}}$$

Note that because the thickness of the strips is small compared with the radius of the circle, we can rewrite equation (iii) as follows:

$$\Delta T \approx \frac{t}{r_1(\alpha_2 - \alpha_1)} = \frac{0.500 \cdot 10^{-3}\ \text{m}}{(0.369\ \text{m})\left(19 \cdot 10^{-6}\ ^\circ\text{C}^{-1} - 13 \cdot 10\right.}$$

This agrees within rounding error with our calculated result. Thus, our answer seems reasonable.

Concept Check 17.4

Suppose the bimetallic strip in Figure 17.14 was made of aluminum on the right side and copper on the left side. Which way would the strip bend if it were heated in the same way as shown in the figure? (Consult Table 17.2 for the linear expansion coefficients of the two metals.)

a) It would bend to the right.

b) It would stay straight.

c) It would bend to the left.

Area Expansion

The effect of a change in temperature on the area of an object is analogous to using a copy machine to enlarge or reduce a picture. Each dimension of the object will change linearly with the change in temperature. Quantitatively, for a square object with side L (Figure 17.16), the area is given by $A = L^2$. Taking the differential of both sides of this equation, we get $dA = 2LdL$. If we make the approximations $\Delta A = dA$ and $\Delta L = dL$, we can write $\Delta A = 2L\Delta L$. Using equation 17.5, we then obtain

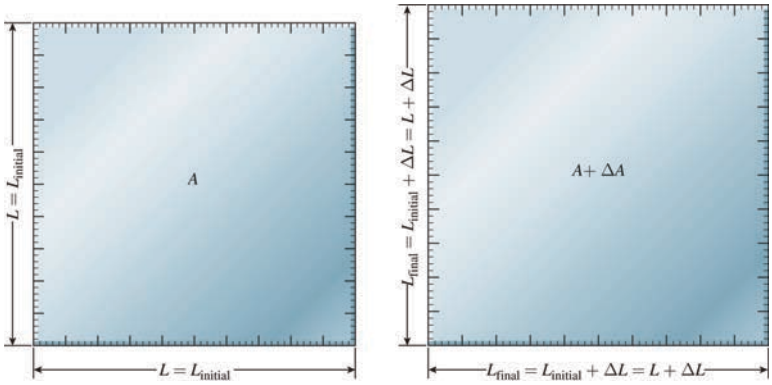

FIGURE 17.16 Thermal expansion of a square plate with side *L*.

$$\Delta A = 2L(\alpha L \Delta T) = 2\alpha A \Delta T. \qquad \textbf{(17.6)}$$

Although a square was used to derive equation 17.6, it holds for a change in area of any shape.

SOLVED PROBLEM 17.3 Expansion of a Plate with a Hole in It

A brass plate has a hole in it (Figure 17.17a); the hole has a diameter $d = 2.54$ cm. The hole is too small to allow a brass sphere to pass through (Figure 17.17b). However, when the plate is heated from $20.0\,^{\circ}\text{C}$ to $220.0\,^{\circ}\text{C}$, the brass sphere passes through the hole in the plate.

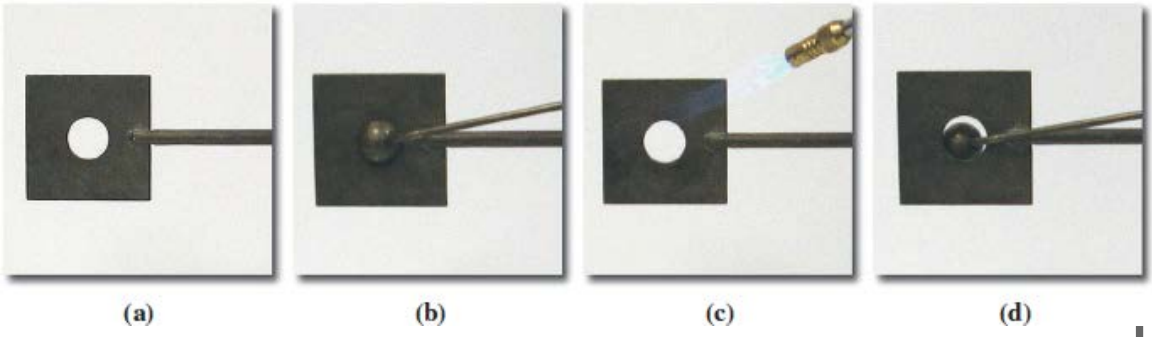

FIGURE 17.17 (a) The plate before it is heated. (b) A brass sphere will not pass through the hole in the unheated plate. (c) The plate is heated. (d) The same brass sphere passes through the hole in the heated brass plate.

W. Bauer and G. D. Westfall

PROBLEM

How much does the area of the hole in the brass plate increase as a result of heating?

SOLUTION

THINK

The area of the brass plate increases as the temperature of the plate increases. Correspondingly, the area of the hole in the plate also increases. We can calculate the increase in the area of the hole using equation 17.6.

SKETCH

Figure 17.18a shows the brass plate before it is heated, and Figure 17.18b shows the plate after it is heated.

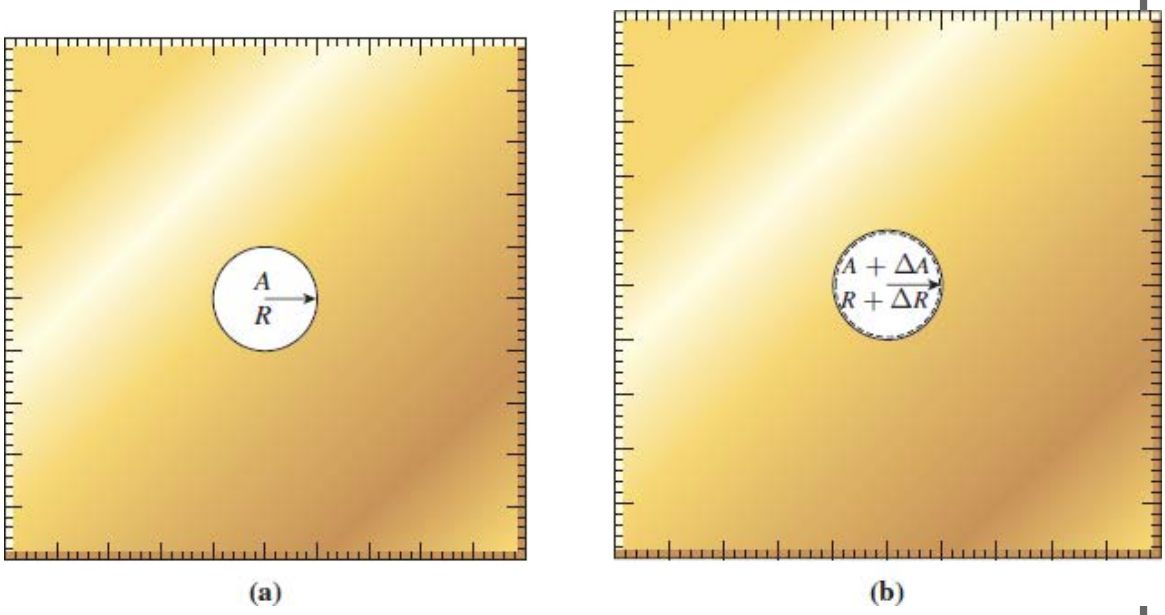

FIGURE 17.18 The thermal expansion of a plate with a hole in it: (a) before heating and (b) after heating.

RESEARCH

The area of the plate increases as the temperature increases, as given by equation 17.6. The area of the hole will increase proportionally. This increase in the area of the hole might seem surprising. However, you can convince yourself that the area of the hole will increase when the plate undergoes thermal expansion by looking at Figure 17.18. The plate with a hole at $T = 20\ ^\circ\text{C}$ is shown in part (a). The same plate scaled up by 5% in all dimensions is shown in part (b). The dashed circle in the hole in the plate in (b) is the same size as the hole in the original plate. Clearly, the hole in (b) is larger than the hole in (a). The area of the hole at $T = 20.0\ ^\circ\text{C}$ is $A = \pi R^2$. Equation 17.6 gives the change in the area of the hole:

$$\Delta A = 2\alpha A \Delta T,$$

where α is the linear expansion coefficient for brass and ΔT is the change in temperature of the brass plate.

SIMPLIFY

Using $A = \pi R^2$ in equation 17.6, we have the change in the area of the hole:

$$\Delta A = 2\alpha\left(\pi R^2\right)\Delta T.$$

Remembering that $R = d/2$, we get

$$\Delta A = 2\alpha\pi\left(\frac{1}{2}d\right)^2\Delta T = \frac{\pi\alpha d^2\Delta T}{2}.$$

CALCULATE

From Table 17.2, the linear expansion coefficient of brass is $\alpha = 19 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}$. Thus, the change in the area of the hole is

$$\Delta A = \frac{\pi\left(19 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}\right)(0.0254\ \mathrm{m})^2(220.0\ ^\circ\mathrm{C} - 20.0\ ^\circ\mathrm{C})}{2}$$

ROUND

We report our result to two significant figures:

$$\Delta A = 3.9 \cdot 10^{-6}\ \mathrm{m}^2.$$

DOUBLE-CHECK

From everyday experience with objects that are heated and cooled, we know that the relative changes in area are not very big. Since the original area of the hole is $A = \pi d^2/4 = \pi(0.0254\ \mathrm{m})^2/4 = 5.07 \cdot 10^{-4}\ \mathrm{m}^2$, we obtain for the fractional change $\Delta A/A = \left(3.9 \cdot 10^{-6}\ \mathrm{m}^2\right)/\left(5.07 \cdot 10^{-4}\ \mathrm{m}^2\right) = 7.6 \cdot 10^{-3}$, or less than 0.8%. Thus, the magnitude of our answer seems in line with physical intuition.

The change in the radius of the hole as the temperature increases is given by

$$\Delta R = \alpha R \Delta T = \left(19 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}\right)\left(\frac{0.0254\ \mathrm{m}}{2}\right)(200\ ^\circ\mathrm{C}) =$$

For that change in radius, the increase in the area of the hole is

$$\Delta A = \Delta\left(\pi R^2\right) = 2\pi R \Delta R = 2\pi\left(\frac{0.0254\ \mathrm{m}}{2}\right)\left(4.8 \cdot 10^{-5}\ \mathrm{m}\right.$$

which agrees within rounding error with our result. Thus, our answer seems reasonable.

Volume Expansion

Now let's consider the change in volume of an object with a change in temperature. For a cube with side L, the volume is given by $V = L^3$. Taking the differential of both sides of this equation, we get $dV = 3L^2 dL$. Making the approximations $\Delta V = dV$ and $\Delta L = dL$, we can write $\Delta V = 3L^2 \Delta L$. Then, using equation 17.5, we obtain

$$\Delta V = 3L^2(\alpha L \Delta T) = 3\alpha V \Delta T. \qquad \textbf{(17.7)}$$

Because the change in volume with a change in temperature is often of interest, it is convenient to define the **volume expansion coefficient:**

$$\beta = 3\alpha. \qquad \textbf{(17.8)}$$

Thus, we can rewrite equation 17.7 as

$$\Delta V = \beta V \Delta T. \qquad \textbf{(17.9)}$$

Although a cube was used to derive equation 17.9, the equation can be applied to a change in the volume of any shape. Some typical volume expansion coefficients are listed in Table 17.3.

Table 17.3	Volume Expansion Coefficients for Some Common Liquids
Material	$\beta\left(10^{-6}\cdot\mathrm{C}^{-1}\right)$
Mercury	181
Gasoline	950
Kerosene	990
Ethyl alcohol	750
Water (1 °C)	−47.8
Water (4 °C)	0
Water (7 °C)	45.3
Water (10 °C)	87.5
Water (15 °C)	151
Water (20 °C)	207

Equation 17.9 applies to the thermal expansion of most solids and liquids. However, it does not describe the thermal expansion of water. Between 0 °C and about 4 °C, water contracts as the temperature increases (Figure 17.19). Water with a temperature of 4 °C is denser than water with a temperature just below 4 °C. This property of water has a dramatic effect on the way a lake freezes in the winter. As the air temperature drops from warm summer to cold winter temperatures, the water in a lake cools from the surface down. The cooler, denser water sinks to the bottom of the lake. However, as the temperature of the water on the surface falls below 4 °C, the downward motion ceases, and the cooler water remains at the surface of the lake, with the denser, warmer water below. The top layer eventually cools to 0 °C and then freezes. Ice is less dense than water, so the ice floats on the water. This newly formed layer of ice acts as insulation, which slows the freezing of the rest of the water in the lake. If water had the same thermal expansion properties as other common materials, instead of freezing from the top down, the lake

would freeze from the bottom up, with warmer water remaining at the surface of the lake and cooler water sinking to the bottom. This would mean that lakes would freeze solid more often, and any forms of life in them that could not exist in ice would not survive the winter.

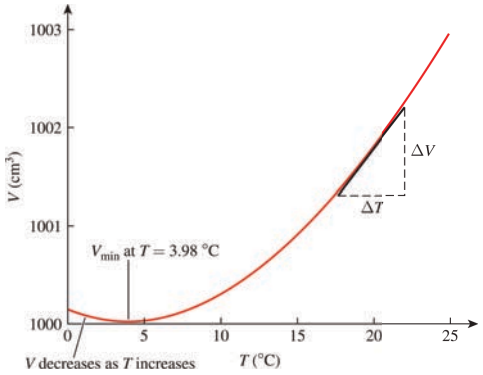

FIGURE 17.19 The dependence of the volume of 1 Kg of water on temperature.

In addition, you can see from Figure 17.19 that the volume of a given amount of water never depends linearly on the temperature. However, the linear dependence of the volume of water on temperature can be approximated by considering a small temperature interval. The slope of the volume-temperature curve is $\Delta V/\Delta T$, so we can extract an effective volume expansion coefficient for small temperature changes. For example, the volume expansion coefficient for water at six different temperatures is given in Table 17.3; note that at $1\ ^\circ\mathrm{C}, \beta = -47.8 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}$, which means that the volume of water will decrease as the temperature is increased.

EXAMPLE 17.3 Thermal Expansion of Gasoline

You pull your car into a gas station on a hot summer day, when the air temperature is 40 °C. You fill your empty 55-L gas tank with gasoline that comes from an underground storage tank where the temperature is 12 °C. After paying for the gas, you decide to walk to the restaurant next door and have lunch. Two hours later, you come back to your car, realize that you left the cap off the gas tank, and discover that gasoline has spilled out of the gas tank onto the ground.

PROBLEM

How much gasoline has spilled?

Page 544

SOLUTION

We know the following: The temperature of the gasoline you put in the tank starts out at 12 °C. The gasoline warms up to the outside air temperature of 40 °C. The volume expansion coefficient of gasoline is $950 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$.

While you were gone, the temperature of the gasoline changed from 12 °C to 40 °C. Using equation 17.9, we can find the change in volume of the gasoline as the temperature increases:

$$\Delta V = \beta V \Delta T = \left(950 \cdot 10^{-6}\ ^\circ\text{C}^{-1}\right)(55\ \text{L})(40\ ^\circ\text{C} - 12\ ^\circ\text{C}) =$$

Thus, the volume of the gasoline increases by 1.5 L as the temperature of the gasoline is raised from 12 °C to 40 °C. The gas tank was full when the temperature of the gasoline was 12 °C, so this excess volume spills out of the tank onto the ground.

Concept Check 17.5

You have a metal cube, which you heat. After heating, the area of one of the cube's surfaces has increased by 0.02%. Which statement about the volume of the cube after heating is correct?

a) It has decreased by 0.02%.

b) It has increased by 0.02%.

c) It has increased by 0.01%.

d) It has increased by 0.03%.

e) Not enough information is given to determine the volume change.

17.5 Surface Temperature of the Earth

A report on daily surface temperatures is part of every weather report in newspapers and TV and radio newscasts. It is clear that it is usually colder at night than during the day, colder in the winter than in the summer, and hotter close to the Equator than near the poles. A current topic of intense discussion is whether the temperature of Earth is rising. A conclusive answer to this question requires data giving appropriate averages. The first average that is useful is over time. Figure 17.20 shows a representative plot of the surface temperature of the Earth, time-averaged over one month (June 1992).

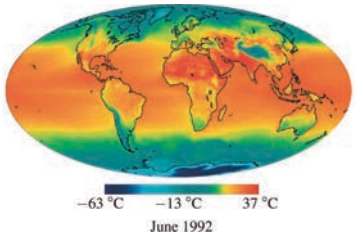

FIGURE 17.20
Time-averaged surface temperature of the Earth in June 1992. The colors represent a range of temperatures from $-63\ ^\circ\mathrm{C}$ to $+37\ ^\circ\mathrm{C}$.

WMAP Science Team/NASA

The time-averaged values of the temperature over the entire surface of Earth are obtained by systematically taking temperature measurements over the surface of the Earth, including the oceans. These measurements are then corrected for any systematic biases, such as the fact that many temperature-measuring stations are located in populated areas and many sparsely populated areas have

few temperature measurements. After all of the corrections are taken into account, the result is the average surface temperature of Earth in a given year. In 2020, the year-round average surface temperature of Earth was approximately 288.0 K (14.9 ˚C). In Figure 17.21, this average global temperature is plotted for the years 1880 to 2020. You can see that since around 1910, the temperature has been increasing with time, indicating global warming. The dotted blue horizontal line in the graph represents the average global temperature for the 20th century, 13.9 ˚C. The figure displays data compiled by an agency of the U.S. Department of Commerce. Agencies in other countries that have compiled similar data sets have arrived at slightly different average temperature values, mainly because of variations in averaging procedures. However, *all* estimates of the change in the average global temperature over time are virtually identical. For the past 40 years, the Earth has been warming up at a rate of 0.18 ˚C per decade as shown by the dashed green line in Figure 17.21.

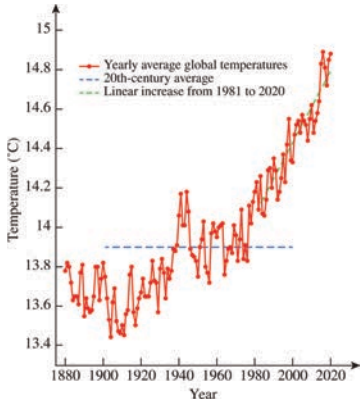

FIGURE 17.21
Annual average global surface temperature and the 20th-century average from 1880 to 2020 as measured by thermometers on land and in the ocean (red histogram). The blue horizontal line represents the average global temperature for the 20th century, 13.9 °C.

(Source: Data compiled by the National Climatic Data Center, National Oceanic and Atmospheric Administration, U.S. Department of Commerce.)

Several models predict that the average global surface temperature of Earth will continue to increase. The magnitude of the increase in average global temperature over the past 155 years is around 1 °C, which does not seem like a large increase. However,

combined with predicted future increases, it is sufficient to cause observable effects, such as the raising of ocean water levels, the disappearance of the Arctic ice cover in summers, climate shifts, and increased severity of storms and droughts around the world.

Figure 17.22 shows a record of the difference between the current average annual surface temperature in Antarctica and the average annual surface temperature over the last 420,000 years, which was determined from ice cores. Note that past temperatures were evaluated from measurements of carbon dioxide in the ice cores, that their values may be somewhat model-dependent, and that the resulting temperature differences may be significantly larger than the corresponding global temperature differences. Several distinct periods are apparent in Figure 17.22. An interval of time when the temperature difference is around $-7\ ^\circ\mathrm{C}$ corresponds to a period in which ice sheets covered parts of North America and Europe and is termed a *glacial period.* The last glacial period ended about 10,000 years ago. The warmer periods between glacial periods, called *interglacial periods,* correspond to temperature differences of around zero. In Figure 17.22, four glacial periods are visible, going back 400,000 years. An attempt to relate these temperature differences to differences in the heat received from the Sun due to variations in the Earth's orbit and the orientation of its rotational axis is known as the *Milankovitch Hypothesis*. However, these variations cannot account for all of the observed temperature differences.

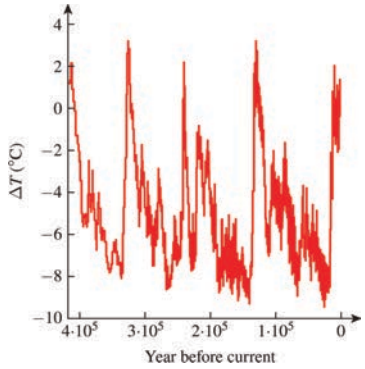

FIGURE 17.22
Average annual surface temperature of Antarctica in the past, extracted from carbon dioxide content of ice cores, relative to the present value.

The current warm, interglacial period began about 10,000 years ago and seems to be slightly cooler than previous interglacial periods. Previous interglacial periods have lasted from 10,000 to 25,000 years. However, human activities, such as the burning of fossil fuels and the resulting greenhouse effect (more on this in Chapter 18), are influencing the average global temperature. Models predict that the effect of these activities will be to warm the Earth, at least for the next several hundred years.

One effect of the warming of Earth's surface is a rise in sea level. Sea level has risen 120 m since the peak of the last glacial period, about 20,000 years ago, as a result of the melting of the glaciers that covered large areas of land. The melting of large amounts of ice resting on solid ground is the largest potential contributor to a further rise in sea level. For example, if all the ice in Antarctica melted, sea level would rise 61 m. If all the ice in Greenland melted, the rise in sea level would be 7 m. However, it would take several centuries for these large deposits of ice to melt completely, even if pessimistic predictions of climate models are correct. The rise in sea level due to thermal expansion is small compared with that due to the melting of large glaciers. The current rate of the rise in sea level is 3.2 ± 0.4 mm/yr, as measured by radar altimeters on the TOPEX

and Jason satellites. By the end of the 21st century, sea level is projected to rise by 1.0 ± 0.3 m.

Self-Test Opportunity 17.3

Identify the years corresponding to glacial and interglacial periods in Figure 17.22.

EXAMPLE 17.4 Rise in Sea Level Due to Thermal Expansion of Water

The rise in the level of the Earth's oceans is of current concern. Oceans cover $3.6 \cdot 10^8$ km^2, slightly more than 70% of Earth's surface area. The average ocean depth is 3790 m. The surface ocean temperature varies widely, between 35 °C in the summer in the Persian Gulf and -2 °C in the Arctic and Antarctic regions. However, even if the ocean surface temperature exceeds 20 °C, the water temperature rapidly falls off as a function of depth and approaches 4 °C at a depth of 1000 m (Figure 17.23). The global average temperature of all seawater is approximately 3 °C. Table 17.3 lists a volume expansion coefficient of zero for water at a temperature of 4 °C. Thus, it is safe to assume that the volume of ocean water changes very little at a depth greater than 1000 m. For the top 1000 m of ocean water, let's assume a global average temperature of 10.0 °C and calculate the effect of thermal expansion.

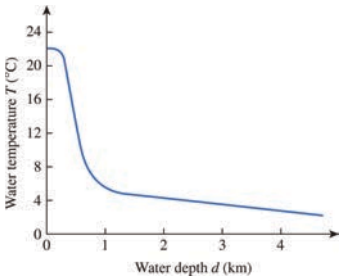

FIGURE 17.23 Average ocean water temperature as a function of depth below the surface.

PROBLEM

By how much would sea level change, solely as a result of the thermal expansion of water, if the water temperature of all the oceans increased by $\Delta T = 1.0$ °C?

SOLUTION

The volume expansion coefficient of water at $10.0\,^\circ\text{C}$ is $\beta = 87.5 \cdot 10^{-6}\,^\circ\text{C}^{-1}$ (from Table 17.3), and the volume change of the oceans is given by equation 17.9, $\Delta V = \beta V \Delta T$, or

$$\frac{\Delta V}{V} = \beta \Delta T. \qquad \text{(i)}$$

We can express the total surface area of the oceans as $A = (0.7)4\pi R^2$, where R is the radius of Earth and the factor 0.7 reflects the fact that about 70% of the surface of the sphere is covered by water. We assume that the surface area of the oceans increases only minutely from the water moving up the shores and neglect the change in surface area due to this effect. Then, essentially all of the change of the oceans' volume will result from the change in the depth, and we can write

$$\frac{\Delta V}{V} = \frac{\Delta d \cdot A}{d \cdot A} = \frac{\Delta d}{d}. \qquad \text{(ii)}$$

Combining equations (i) and (ii), we obtain an expression for the change in depth:

$$\frac{\Delta d}{d} = \beta \Delta T \Rightarrow \Delta d = \beta d \Delta T.$$

Inserting the numerical values, $d = 1000\text{ m}$, $\Delta T = 1.0\,^\circ\text{C}$, and $\beta = 87.5 \cdot 10^{-6}\,^\circ\text{C}^{-1}$, we obtain

$$\Delta d = (1000\text{ m})\left(87.5 \cdot 10^{-6}\,^\circ\text{C}^{-1}\right)(1.0\,^\circ\text{C}) = 9\text{ cm}.$$

So, for every increase of the average ocean temperature by $1\,^\circ\text{C}$, the sea level will rise by 9 cm (3.5 in). This rise is smaller than

the anticipated rise due to the melting of the ice cover on Greenland or Antarctica but will contribute to the problem of coastal flooding.

17.6 Temperature of the Universe

In 1965, while working on an early radio telescope, Arno Penzias and Robert Wilson discovered the **cosmic microwave background radiation.** They detected "noise," or "static," that seemed to come from all directions in the sky. Penzias and Wilson figured out what was producing this noise (which earned them the 1978 Nobel Prize): It was electromagnetic radiation left over from the Big Bang, which occurred 13.8 billion years ago. (We'll discuss electromagnetic radiation in Chapter 31.) It is astonishing to realize that an "echo" of the Big Bang still reverberates in "empty" intergalactic space after such a long time. The wavelength of the cosmic background radiation is similar to the wavelength of the electromagnetic radiation used in a microwave oven. An analysis of the distribution of wavelengths of this radiation led to the deduction that the background temperature of the universe is 2.726 K (exactly how this analysis was done is described in Chapter 36 on quantum physics). George Gamov had already predicted a cosmic background temperature of 2.7 K in 1948, when it was not yet clear that the Big Bang is a scientifically established fact.

In 2001, the Wilkinson Microwave Anisotropy Probe (WMAP) satellite measured variations in the background temperature of the universe. This mission followed the successful Cosmic Background Explorer (COBE) satellite, launched in 1989, which resulted in the 2006 Nobel Prize for Physics being awarded to John Mather and George Smoot. The COBE and WMAP missions found that the cosmic microwave background radiation was very uniform in all directions, but small differences in the temperature were superimposed on the smooth background. In 2013, the Planck observatory measured the temperature of the cosmic microwave background with higher precision. Figure 17.24 shows the Planck results for the range of temperatures below and above the average temperature of the universe. The effects of the Milky Way galaxy have been subtracted. You can see that the variation in the background temperature in the universe is very small, since

$\pm 300\ \mu\text{K}/2.726\ \text{K} = \pm 1.1 \cdot 10^{-4}$. From interpretation of these results and other observations, scientists deduced that the age of the universe is 13.81 billion years, with a margin of error of less than 0.3%. In addition, scientists were able to deduce that the universe is composed of 5% ordinary matter, 27% dark matter, and 68% dark energy. Dark matter is matter that exerts an observable gravitational pull but seems to be invisible, as discussed in Chapter 12. Dark energy seems to be causing the expansion of the universe to speed up. (Chapter 39, on particle physics and cosmology, covers these phenomena in detail.) Both dark matter and dark energy are under intense current investigation, and understanding of them should improve in the next decade.

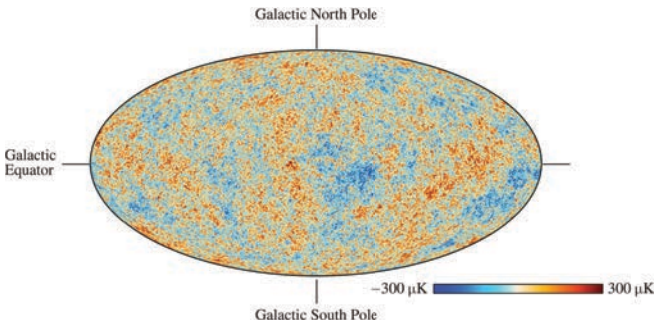

FIGURE 17.24 The temperature of the cosmic microwave background radiation everywhere in the universe. The colors represent a range of temperatures from 300 μK below to 300 μK above the average temperature of the cosmic microwave background radiation, which has an average temperature of 2.726 K.

Planck Collaboration 2020, A&A, 641, A4.

WHAT WE HAVE LEARNED EXAM STUDY GUIDE

- The three commonly used temperature scales are the Fahrenheit scale, the Celsius scale, and the Kelvin scale.
- The Fahrenheit scale is used in the United States and defines the freezing point of water as $32\ ^\circ\text{F}$ and the boiling point of water as $212\ ^\circ\text{F}$.
- The Celsius scale defines the freezing point of water as $0\ ^\circ\text{C}$ and the boiling point of water as $100\ ^\circ\text{C}$.
- The Kelvin scale defines 0 K as absolute zero and the freezing point of water as 273.15 K. The size of the kelvin and the Celsius degree are the same.
- The conversion from $^\circ\text{F}$ to $^\circ\text{C}$ is given by $T_\text{C} = \frac{5}{9}(T_\text{F} - 32\ ^\circ\text{F})$.
- The conversion from $^\circ\text{C}$ to $^\circ\text{F}$ is given by $T_\text{F} = \frac{9}{5}T_\text{C} + 32\ ^\circ\text{C}$.
- The conversion from $^\circ\text{C}$ to K is given by $T_\text{K} = T_\text{C} + 273.15\ ^\circ\text{C}$.
- The conversion from K to $^\circ\text{C}$ is given by $T_\text{C} = T_\text{K} - 273.15\ \text{K}$.
- The change in length, ΔL, of an object of length L as the temperature changes by ΔT is given by $\Delta L = \alpha L \Delta T$, where α is the linear expansion coefficient.
- The change in volume, ΔV, of an object with volume V as the temperature changes by ΔT is given by $\Delta V = \beta V \Delta T$, where β is the volume expansion coefficient.

ANSWERS TO SELF-TEST OPPORTUNITIES

17.1 Take $T = T_{\mathrm{F}} = T_{\mathrm{C}}$, and solve for T:

$$\begin{aligned} T &= \tfrac{9}{5}T + 32 \\ -\tfrac{4}{5}T &= 32 \\ T &= -40\ ^\circ\mathrm{C} \text{ or } ^\circ\mathrm{F}. \end{aligned}$$

17.2 Use an ice-and-water mixture, which is at 0 $^\circ$C, and boiling water, which is at 100 $^\circ$C. Take the measurements and mark the corresponding places on the uncalibrated thermometer.

17.3 The glacial periods in years ago:

12,000 to 120,000

150,000 to 230,000

250,000 to 310,000

330,000 to 400,000.

The interglacial periods in years ago:

0 to 12,000

110,000 to 130,000

230,000 to 250,000

310,000 to 330,000

400,000 to 410,000.

PROBLEM-SOLVING GUIDELINES

1. Be consistent in your use of Celsius, Kelvin, or Fahrenheit temperatures. For calculating a temperature change, a Celsius degree is equal to a kelvin. If you need to find a temperature value, however, remember which temperature scale is asked for.

2. Thermal expansion has an effect similar to enlarging a photograph: All parts of the picture get expanded in the same way. Remember that a hole in an object expands with increasing temperature just as the object itself does. Sometimes you can simplify a problem involving volume expansion to one dimension and then use linear expansion coefficients. Be alert for these kinds of situations.

MULTIPLE-CHOICE QUESTIONS

17.1 Two mercury-expansion thermometers have identical reservoirs and cylindrical tubes made of the same glass but of different diameters. Which of the two thermometers can be calibrated to a better resolution?

a) The thermometer with the smaller-diameter tube will have better resolution.

b) The thermometer with the larger-diameter tube will have better resolution.

c) The diameter of the tube is irrelevant; it is only the volume expansion coefficient of mercury that matters.

d) Not enough information is given to tell.

17.2 For a class demonstration, your physics instructor uniformly heats a bimetallic strip that is held in a horizontal orientation. As a result, the bimetallic strip bends upward. This tells you that the coefficient of linear thermal expansion for metal T, on the top is _____ that of metal B, on the bottom.

a) smaller than

b) larger than

c) equal to

17.3 Two solid objects, A and B, are in contact. In which case will thermal energy transfer from A to B?

a) A is at 20 $^\circ$C, and B is at 27 $^\circ$C.

b) A is at 15 $^\circ$C, and B is at 15 $^\circ$C.

c) A is at 0 $^\circ$C, and B is at -10 $^\circ$C.

17.4 Which of the following bimetallic strips will exhibit the greatest sensitivity to temperature changes? That is, which one will bend the most as temperature increases?

a) copper and steel

b) steel and aluminum

c) copper and aluminum

d) aluminum and brass

e) copper and brass

17.5 The background temperature of the universe is

a) 6000 K.

b) 288 K.

c) 3 K.

d) 2.725 K.

e) 0 K.

17.6 Which air temperature feels coldest?

a) $-40\ ^\circ\mathrm{C}$

b) $-40\ ^\circ\mathrm{F}$

c) 233 K

d) All three are equal.

17.7 At what temperature do the Celsius and Fahrenheit temperature scales have the same numeric value?

a) -40 degrees

b) 0 degrees

c) 40 degrees

d) 100 degrees

17.8 The city of Yellowknife in the Northwest Territories of Canada is on the shore of Great Slave Lake. The average high temperature in July is $21\ ^\circ\mathrm{C}$, and the average low in January is $-31\ ^\circ\mathrm{C}$. Great Slave Lake has a volume of 2090 km^3 and is the deepest lake in North America, with a depth of 614 m. What is the temperature of the water at the bottom of Great Slave Lake in January?

a) $-31\ ^\circ\mathrm{C}$

b) $-10\ ^\circ\mathrm{C}$

c) $0\ ^\circ\mathrm{C}$

d) 4 ˚C

e) 32 ˚C

17.9 Which object has the higher temperature after being left outside for an entire winter night: a metal door knob or a rug?

a) The metal door knob has the higher temperature.

b) The rug has the higher temperature.

c) Both have the same temperature.

d) It depends on the outside temperature.

17.10 A concrete section of a bridge has a length of 10.0 m at 10.0 ˚C. By how much will the length of the section increase if its temperature increases to 40.0 ˚C?

a) 0.025 cm

b) 0.051 cm

c) 0.075 cm

d) 0.22 cm

e) 0.45 cm

17.11 Which of the following temperatures corresponds to the boiling point of water?

a) 0 ˚C

b) 100 ˚C

c) 0 K

d) 100 K

e) 100 ˚F

17.12 Which of the following temperatures corresponds to the freezing point of water?

a) 0 K

b) 0 ˚C

c) 100 ˚C

d) 100 K

e) 100 ˚F

17.13 The Zeroth Law of Thermodynamics tells us that

a) there is a temperature of absolute zero.

b) the freezing point of water is $0\ ^\circ C$.

c) two systems cannot be in thermal equilibrium with a third system.

d) thermal energy is conserved.

e) it is possible to construct a thermometer to measure the temperature of any system.

CONCEPTUAL QUESTIONS

17.14 A common way of opening a tight lid on a glass jar is to place it under warm water. The thermal expansion of the metal lid is greater than that of the glass jar; thus, the space between the two expands, making it easier to open the jar. Will this work for a metal lid on a container of the same kind of metal?

17.15 Would it be possible to have a temperature scale defined in such a way that the hotter an object or system got, the lower (less positive or more negative) its temperature was?

17.16 The solar corona has a temperature of about $1 \cdot 10^6$ K. However, a spaceship flying in the corona will not be burned up. Why is this?

17.17 Explain why it might be difficult to weld aluminum to steel or to weld any two unlike metals together.

17.18 Two solid objects are made of different materials. Their volumes and volume expansion coefficients are V_1 and V_2 and β_1 and β_2, respectively. It is observed that during a temperature change of ΔT, the volume of each object changes by the same amount. If $V_1 = 2V_2$, what is the ratio of the volume expansion coefficients?

17.19 Some textbooks use the unit K^{-1} rather than $^\circ\mathrm{C}^{-1}$ for values of the linear expansion coefficient; see Table 17.2. How will the numerical values of the coefficient differ if expressed in K^{-1}?

17.20 You are outside on a hot day, with the air temperature at T_{o}. Your sports drink is at a temperature T_{d} in a sealed plastic bottle. There are a few remaining ice cubes in the sports drink, which are at a temperature T_{i}, but they are melting fast.

a) Write an inequality expressing the relationship among the three temperatures.

b) Give reasonable values for the three temperatures in degrees Celsius.

17.21 The Rankine temperature scale is an absolute temperature scale that uses Fahrenheit degrees; that is, temperatures are measured in Fahrenheit degrees, starting at absolute zero. Find the

relationships between temperature values on the Rankine scale and those on the Fahrenheit, Kelvin, and Celsius scales.

17.22 The Zeroth Law of Thermodynamics forms the basis for the definition of temperature with regard to thermal energy. But the concept of temperature is used in other areas of physics. In a system with energy levels, such as electrons in an atom or protons in a magnetic field, the population of a level with energy E is proportional to the factor $e^{-E/k_{\mathrm{B}}T}$, where T is the absolute temperature of the system and $k_{\mathrm{B}} = 1.381 \cdot 10^{-23}\ \mathrm{J/K}$ is Boltzmann's constant. In a two-level system with the levels' energies differing by ΔE, the ratio of the populations of the higher-energy and lower-energy levels is $p_{\mathrm{high}}/p_{\mathrm{low}} = e^{-\Delta E/k_{\mathrm{B}}T}$. Such a system can have an infinite or even a negative absolute temperature. Explain the meaning of such temperatures.

17.23 Suppose a bimetallic strip is constructed of two strips of metals with linear expansion coefficients α_1 and α_2, where $\alpha_1 > \alpha_2$.

a) If the temperature of the bimetallic strip is reduced by ΔT, which way will the strip bend (toward the side made of metal 1 or the side made of metal 2)? Briefly explain.

b) If the temperature is increased by ΔT, which way will the strip bend?

17.24 For food storage, what is the advantage of placing a metal lid on a glass jar? (*Hint:* Why does running the metal lid under hot water for a minute help you open such a jar?)

17.25 A solid cylinder and a cylindrical shell, of identical outer radius and length and made of the same material, experience the same temperature increase, ΔT. Which of the two will expand to a larger outer radius?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Sections 17.1 and 17.2

17.26 Express each of the following temperatures in degrees Celsius and in kelvins.

a) $-19\ ^\circ\text{F}$

b) $98.6\ ^\circ\text{F}$

c) $52\ ^\circ\text{F}$

17.27 One thermometer is calibrated in degrees Celsius, and another in degrees Fahrenheit. At what temperature is the reading on the thermometer calibrated in degrees Celsius three times the reading on the other thermometer?

17.28 During the summer of 2007, temperatures as high as $47\ ^\circ\text{C}$ were recorded in Southern Europe. The highest temperature ever recorded in the United States was $134\ ^\circ\text{F}$ (at Death Valley, California, in 1913). What is the difference between these two temperatures, in degrees Celsius?

17.29 The lowest air temperature recorded on Earth is $-129\ ^\circ\text{F}$ in Antarctica. Convert this temperature to the Celsius scale.

17.30 What air temperature will feel twice as warm as $0\ ^\circ\text{F}$?

17.31 A piece of dry ice (solid carbon dioxide) sitting in a classroom has a temperature of approximately $-79\ ^\circ\text{C}$.

a) What is this temperature in kelvins?

b) What is this temperature in degrees Fahrenheit?

17.32 In 1742, the Swedish astronomer Anders Celsius proposed a temperature scale on which water boils at 0.00 degrees and freezes at 100. degrees. In 1745, after the death of Celsius, Carolus Linnaeus (another Swedish scientist) reversed those standards, yielding the scale that is most commonly used today. Find room temperature ($77.0\ ^\circ\text{F}$) on Celsius's original temperature scale.

17.33 At what temperature do the Kelvin and Fahrenheit scales have the same numeric value?

Section 17.4

17.34 How does the density of copper that is just above its melting temperature of 1356 K compare to that of copper at room temperature?

17.35 The density of steel is 7800. kg/ m^3 at 20.0 $^\circ$C. Find the density at 100.0 $^\circ$C.

17.36 Two cubes with sides of length 100.0 mm fit in a space that is 201.0 mm wide, as shown in the figure. One cube is made of aluminum, and the other is made of brass. What temperature increase is required for the cubes to close the gap?

17.37 A brass piston ring is to be fitted onto a piston by first heating up the ring and then slipping it over the piston. The piston ring has an inner diameter of 10.00 cm and an outer diameter of 10.20 cm. The piston has an outer diameter of 10.10 cm, and a groove for the piston ring has an outer diameter of 10.00 cm. To what temperature must the piston ring be heated so that it will slip onto the piston?

17.38 An aluminum sphere of radius 10.0 cm is heated from 100.0 $^\circ$F to 200.0 $^\circ$F. Find (a) the volume change and (b) the radius change.

17.39 Steel rails for a train track are laid in a region subject to extremes of temperature. The distance from one juncture to the next is 5.2000 m, and the cross-sectional area of the rails is 60.0 cm^2. If the rails touch each other without buckling at the maximum temperature, 50.0 $^\circ$C, how much space will there be between the rails at -10.0 $^\circ$C?

17.40 Even though steel has a relatively low linear expansion coefficient $\left(\alpha_{\text{steel}} = 13 \cdot 10^{-6}\ ^\circ\text{C}^{-1}\right)$, the expansion of steel railroad tracks can potentially create significant problems on very hot summer days. To accommodate for the thermal expansion, a gap is left between consecutive sections of the track. If each section is 25.0 m long at 20.0 $^\circ$C and the gap between sections is 10.0 mm wide,

what is the highest temperature the tracks can take before the expansion creates compressive forces between sections?

17.41 A medical device used for handling tissue samples has two metal screws, one 20.0 cm long and made from brass $\left(\alpha_{\mathrm{b}} = 18.9 \cdot 10^{-6}\ ^{\circ}\mathrm{C}^{-1}\right)$. and the other 30.0 cm long and made from aluminum $\left(\alpha_{\mathrm{a}} = 23.0 \cdot 10^{-6}\ ^{\circ}\mathrm{C}^{-1}\right)$. A gap of 1.00 mm exists between the ends of the screws at 22.0 $^{\circ}$C. At what temperature will the two screws touch?

•**17.42** You are designing a precision mercury thermometer based on the thermal expansion of mercury $\left(\beta = 1.81 \cdot 10^{-4}\ ^{\circ}\mathrm{C}^{-1}\right)$, which causes the mercury to expand up a thin capillary as the temperature increases. The equation for the change in volume of the mercury as a function of temperature is $\Delta V = \beta V_0 \Delta T$, where V_0 is the initial volume of the mercury and ΔV is the change in volume due to a change in temperature, ΔT. In response to a temperature change of 1.00 $^{\circ}$C, the column of mercury in your precision thermometer should move a distance $D = 1.00$ cm up a cylindrical capillary of radius $r = 0.100$ mm. Determine the initial volume of mercury that allows this change. Then find the radius of a spherical bulb that contains this volume of mercury.

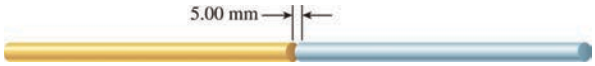
•**17.43** On a hot summer day, a cubical swimming pool is filled to within 1.00 cm of the top with water at 21.0 $^{\circ}$C. When the water warms to 37.0 $^{\circ}$C, the pool is completely full. What is the depth of the pool?

•**17.44** A steel rod of length 1.00 m is attached to the end of an aluminum rod of length 2.00 m (lengths measured at 22.0 $^{\circ}$C). The combination rod is then heated to 200. $^{\circ}$C. What is the change in length of the combination rod at 200. $^{\circ}$C?

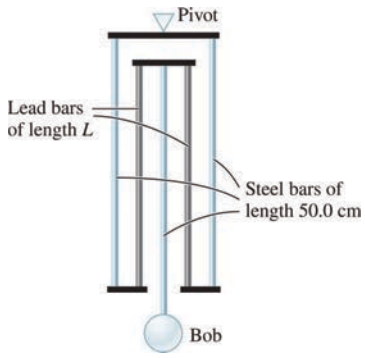
•**17.45** A clock based on a simple pendulum is situated outdoors in Anchorage, Alaska. The pendulum consists of a mass of 1.00 Kg that is hanging from a thin brass rod that is 2.000 m long. The clock is calibrated perfectly during a summer day with an average temperature of 25.0 $^{\circ}$C. During the winter, the average temperature over one 24-h period is -20.0 $^{\circ}$C. Find the time elapsed for that period according to the simple pendulum clock.

•**17.46** In a thermometer manufacturing plant, a type of mercury thermometer is built at room temperature $(20.0\ ^\circ\mathrm{C})$ to measure temperatures in the $20.0\ ^\circ\mathrm{C}$ to $70.0\ ^\circ\mathrm{C}$ range, with a 1.00-cm^3 spherical reservoir at the bottom and a 0.500-mm inner diameter expansion tube. The wall thickness of the reservoir and tube is negligible, and the $20.0\ ^\circ\mathrm{C}$ mark is at the junction between the spherical reservoir and the tube. The tubes and reservoirs are made of fused silica, a transparent *glass* form of $\mathrm{SiO_2}$ that has a very low linear expansion coefficient $\left(\alpha = 0.400 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}\right)$. By mistake, the material used for one batch of thermometers was *quartz,* a transparent *crystalline* form of $\mathrm{SiO_2}$ with a much higher linear expansion coefficient $\left(\alpha = 12.3 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}\right)$. Will the manufacturer have to scrap the batch, or will the thermometers work fine, within the expected uncertainty of 5% in reading the temperature? The volume expansion coefficient of mercury is $\beta = 181 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}$.

•**17.47** The ends of the two rods shown in the figure are separated by 5.00 mm at $25.0\ ^\circ\mathrm{C}$. The left-hand rod is brass and 1.00 m long; the right-hand rod is steel and 1.00 m long. Assuming that the outside ends of both rods rest firmly against rigid supports, at what temperature will the inside ends of the rods just touch?



•**17.48** The figure shows a temperature-compensated pendulum in which lead and steel rods are arranged so that the pendulum's length is unaffected by changes in the temperature. Determine the length L of the two lead bars.



•**17.49** Consider a bimetallic strip consisting of a 0.500-mm-thick brass upper strip attached to a 0.500-mm-thick steel lower strip. When the temperature of the bimetallic strip is increased by 20.0 K, the unattached tip deflects by 3.00 mm from its original straight position, as shown in the figure. What is the length of the strip at its original position?

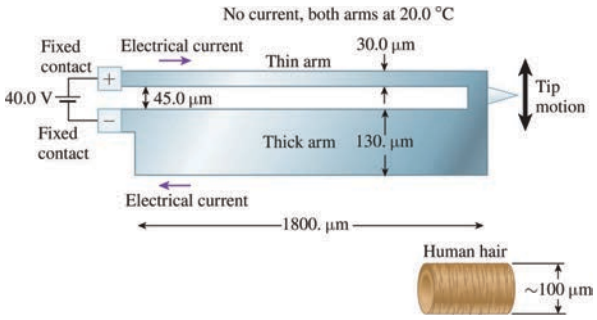
•**17.50** Thermal expansion seems like a small effect, but it can engender tremendous, often damaging, forces. For example, steel has a linear expansion coefficient of $\alpha = 1.2 \cdot 10^{-5}\ ^\circ\mathrm{C}^{-1}$ and a bulk modulus of $B = 160$ GPa. Calculate the pressure engendered in steel by a 1.0 $^\circ$C temperature increase if no expansion is permitted.

•**17.51** An iron horseshoe at room temperature is dunked into a cylindrical tank of water (radius of 10.0 cm) and causes the water level to rise by 0.250 cm. When the horseshoe is heated in the blacksmith's stove from room temperature to a temperature of $7.00 \cdot 10^2$ K, worked into its final shape, and then dunked back into the water, how much does the water level rise above the "no horseshoe" level (ignore any water that evaporates as the horseshoe enters the water)? *Note:* The linear expansion coefficient for iron is roughly that of steel: $11.0 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}$.

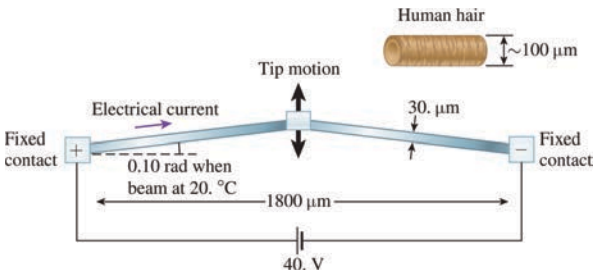
•**17.52** A clock has an aluminum pendulum with a period of 1.000 s at 20.0 $^\circ$C. Suppose the clock is moved to a location where the average temperature is 30.0 $^\circ$C. Determine (a) the new period of the clock's pendulum and (b) how much time the clock will lose or gain in 1 week.

•**17.53** Using techniques similar to those that were originally developed for miniaturized semiconductor electronics, scientists and engineers create Micro-Electro-Mechanical Systems (MEMS). An example is an electrothermal actuator that is driven by heating its different parts using an electrical current. The device is used to position 125-μm-diameter optical fibers with submicron resolution and consists of thin and thick silicon arms connected in the shape of a U, as shown in the figure. The arms are not attached to the substrate under the device but are free to move, whereas the electrical contacts (marked + and − in the figure) are attached to the

substrate and cannot move. The thin arm is 30.0 μm wide, and the thick arm is 130. μm wide. Both arms are 1800. μm long. Electrical current flows through the arms, causing them to heat up. Although the same current flows through both arms, the thin arm has a greater electrical resistance than the thick arm and therefore dissipates more electrical power and gets substantially hotter. When current is made to flow through the arms, the thin arm reaches a temperature of 400. °C, and the thick arm reaches a temperature of 200. °C. Assume that the temperature in each arm is constant along the entire length of that arm (strictly speaking, this is not the case) and that the two arms remain parallel and bend only in the plane of the page at higher temperatures. How much and in which direction will the tip move? The linear expansion coefficient for this silicon is $3.20 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$.



•**17.54** Another MEMS device, used for the same purpose as the one in Problem 17.53, has a different design. This electrothermal actuator consists of a thin V-shaped silicon beam, as shown in the figure. The beam is not attached to the substrate under the device but is free to move, whereas the electrical contacts (marked + and – in the figure) are attached to the substrate and cannot move. The beam spans a gap between the electrical contacts that is 1800 μm wide, and the two halves of the beam slant up from horizontal by 0.10 rad. Electrical current flows through the beam, causing it to heat up. When current is made to flow across the beam, the beam reaches a temperature of 500. °C. Assume that the temperature is constant along the entire length of the beam (strictly speaking, this is not the case). How much and in which direction will the tip move? The linear expansion coefficient for silicon is $3.2 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$.



•17.55 The volume of 1.00 Kg of liquid water over the temperature range from 0.00 ˚C to 50.0 ˚C fits reasonably well to the polynomial function $V = 1.00016 - \left(4.52 \cdot 10^{-5}\right)T + \left(5.68 \cdot 10^{-6}\right)T^2$, where the volume is measured in cubic meters and T is the temperature in degrees Celsius.

a) Use this information to calculate the volume expansion coefficient for liquid water as a function of temperature.

b) Evaluate your expression at 20.0 ˚C, and compare the value to that listed in Table 17.3.

••17.56 Suppose a bimetallic strip constructed of copper and steel strips of thickness 1.00 mm and length 25.0 mm has its temperature reduced by 5.00 K.

a) Determine the radius of curvature of the cooled strip (the radius of curvature of the interface between the two strips).

b) How far is the maximum deviation of the strip from its straight orientation?

Additional Exercises

17.57 A copper cube of side length 40. cm is heated from 20. $^\circ$C to 120 $^\circ$C. What is the change in the volume of the cube? The linear expansion coefficient of copper is $17 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$.

17.58 When a 50.0-m-long metal pipe is heated from 10.0 $^\circ$C to 40.0 $^\circ$C, it lengthens by 2.85 cm.

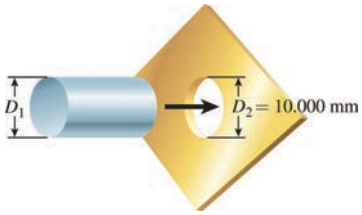
a) Determine the linear expansion coefficient.

b) What type of metal is the pipe made of?

17.59 On a cool morning, with the temperature at 15.0 $^\circ$C, a painter fills a 5.00-gal aluminum container to the brim with turpentine. When the temperature reaches 27.0 $^\circ$C, how much fluid spills out of the container? The volume expansion coefficient for this brand of turpentine is $9.00 \cdot 10^{-4}\ ^\circ\text{C}^{-1}$.

17.60 A building having a steel infrastructure is $6.00 \cdot 10^2$ m high on a day when the temperature is 0.00 $^\circ$C. How much taller is the building on a day when the temperature is 45.0 $^\circ$C? The linear expansion coefficient of steel is $1.30 \cdot 10^{-5}\ ^\circ\text{C}^{-1}$.

17.61 In order to create a tight fit between two metal parts, machinists sometimes make the interior part larger than the hole into which it will fit and then either cool the interior part or heat the exterior part until they fit together. Suppose an aluminum rod with diameter D_1 (at 20. $^\circ$C) is to be fit into a hole in a brass plate that has a diameter $D_2 = 10.000$ mm (at 20. $^\circ$C). The machinists can cool the rod to 77.0 K by immersing it in liquid nitrogen. What is the largest possible diameter that the rod can have at 20. $^\circ$C and just fit into the hole if the rod is cooled to 77.0 K and the brass plate is left at 20. $^\circ$C? The linear expansion coefficients for aluminum and brass are $22 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$ and $19 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$, respectively.



17.62 A military vehicle is fueled with gasoline in the United States, preparatory to being shipped overseas. Its fuel tank has a capacity of

213 L. When it is fueled, the temperature is 57 $^\circ$F. At its destination, it may be required to operate in temperatures as high as 120. $^\circ$F. What is the maximum volume of gasoline that should be put in its tank?

17.63 A mercury thermometer contains 8.00 mL of mercury. If the tube of the thermometer has a cross-sectional area of 1.00 mm^2, what should the spacing between the $^\circ$C marks be?

17.64 A 14-gal container is filled with gasoline. Neglect the change in volume of the container, and find how many gallons are lost if the temperature increases by 27 $^\circ$F. The volume expansion coefficient of gasoline is $9.6 \cdot 10^{-4}\ ^\circ\text{C}^{-1}$.

17.65 A highway of concrete slabs is to be built in the Libyan desert, where the highest air temperature recorded is 57.8 $^\circ$C. The temperature is 20.0 $^\circ$C during construction of the highway. The slabs are measured to be 12.0 m long at this temperature. How wide should the expansion cracks between the slabs be (at 20.0 $^\circ$C) in order to prevent buckling at the highest temperatures?

17.66 An aluminum vessel with a volume capacity of 500. cm^3 is filled with water to the brim at 20.0 $^\circ$C. The vessel and contents are heated to 50.0 $^\circ$C. As a result of the heating, will the water spill over the top, will there be room for more water to be added, or will the water level remain the same? Calculate the volume of water that will spill over or that could be added if either is the case.

17.67 By how much does the temperature of a given mass of kerosene need to change in order for its volume to increase by 1.00%?

17.68 A plastic-epoxy sheet has uniform holes of radius 1.99 cm. The holes are intended to allow solid ball bearings with an outer radius of 2.00 cm to just pass through. By how many degrees must the temperature of the plastic-epoxy sheet be raised so that the ball bearings will go through the holes? The linear expansion coefficient of plastic-epoxy is $1.30 \cdot 10^{-4}\ ^\circ\text{C}^{-1}$.

•**17.69** A uniform brass disk of radius R and mass M with a moment of inertia I about its cylindrical axis of symmetry is at a temperature $T = 20.0\ ^\circ$C. Determine the fractional change in its moment of inertia if it is heated to a temperature of 100. $^\circ$C.

•**17.70** A 25.01-mm-diameter brass ball sits at room temperature on a 25.00-mm-diameter hole made in an aluminum plate. The ball and plate are heated uniformly in a furnace, so both are at the same temperature at all times. At what temperature will the ball fall through the plate?

•**17.71** In a pickup basketball game, your friend cracked one of his teeth in a collision with another player while attempting to make a basket. To correct the problem, his dentist placed a steel band of initial internal diameter 4.40 mm, and a cross-sectional area of width 3.50 mm, and thickness 0.450 mm on the tooth. Before placing the band on the tooth, he heated the band to 70.0 $^\circ$C. What will be the tension in the band once it cools down to the temperature in your friend's mouth (36.8 $^\circ$C)? The steel used for the band has a linear expansion coefficient of $\alpha = 13.0 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$ and a Young's modulus of $Y = 200. \cdot 10^9\ \text{N/ m}^2$.

•**17.72** Your physics teacher assigned a thermometer-building project. He gave you a glass tube with an inside diameter of 1.00 mm and a receptacle at one end. He also gave you 8.63 cm^3 of mercury to pour into the tube, which filled the receptacle and some of the tube. You are to add marks indicating degrees Celsius on the glass tube. At what increments should the marks be put on? The volume expansion coefficient of mercury is $1.81 \cdot 10^{-4}\ ^\circ\text{C}^{-1}$.

•**17.73** You are building a device for monitoring ultracold environments. Because the device will be used in environments where its temperature will change by 200. $^\circ$C in 3.00 s, it must have the ability to withstand thermal shock (rapid temperature changes). The volume of the device is $5.00 \cdot 10^{-5}\ \text{m}^3$, and if the volume changes by $1.00 \cdot 10^{-7}\ \text{m}^3$ in a time interval of 5.00 s, the device will crack and be rendered useless. What is the maximum volume expansion coefficient that the material you use to build the device can have?

•**17.74** A steel rod of length 1.0000 m and cross-sectional area $5.00 \cdot 10^{-4}\ \text{m}^2$ is placed snugly against two immobile end points. The rod is initially placed when the temperature is 0.00 $^\circ$C. Find the stress in the rod when the temperature rises to 40.0 $^\circ$C.

•**17.75** A brass bugle can be thought of as a tube that is closed at one end and open at the other end. The brass from which the bugle is

made has a linear expansion coefficient of $\alpha = 19.0 \cdot 10^{-6}\ ^\circ\ \mathrm{C}^{-1}$. The overall length if the bugle is stretched out is 183.0 cm (at $20.0\ ^\circ\mathrm{C}$). A bugle is played on a hot summer day $(41.0\ ^\circ\mathrm{C})$. Find the fundamental frequency if

a) only the change in air temperature is considered,

b) only the change in the length of the bugle is considered, and

c) both effects in parts (a) and (b) are taken into account.

MULTI-VERSION EXERCISES

17.76 At 26.45 $^\circ$C, a steel bar is 268.67 cm long and a brass bar is 268.27 cm long. At what temperature will the two bars be the same length? Take the linear expansion coefficient of steel to be $13.00 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$ and the linear expansion coefficient of brass to be $19.00 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$.

17.77 A steel bar and a brass bar are both at a temperature of 28.73 $^\circ$C. The steel bar is 270.73 cm long. At a temperature of 214.07 $^\circ$C, the two bars have the same length. What is the length of the brass bar at 28.73 $^\circ$C? Take the linear expansion coefficient of steel to be $13.00 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$ and the linear expansion coefficient of brass to be $19.00 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$.

17.78 A steel bar and a brass bar are both at a temperature of 31.03 $^\circ$C. The brass bar is 272.47 cm long. At a temperature of 227.27 $^\circ$C, the two bars have the same length. What is the length of the steel bar at 31.03 $^\circ$C? Take the linear expansion coefficient of steel to be $13.00 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$ and the linear expansion coefficient of brass to be $19.00 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$.

17.79 The main mirror of a telescope has a diameter of 5.093 m. The mirror is made of glass with a linear expansion coefficient of $3.749 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$. If the temperature of the mirror is raised by 33.37 $^\circ$C, how much will the area of the mirror increase?

17.80 The main mirror of a telescope has a diameter of 4.553 m. When the temperature of the mirror is raised by 34.65 $^\circ$C, the area of the mirror increases by $4.253 \cdot 10^{-3}$ m^2. What is the linear expansion coefficient of the glass of which the mirror is made?

17.81 The main mirror of a telescope has a diameter of 4.713 m. The mirror is made of glass with a linear expansion coefficient of $3.789 \cdot 10^{-6}\ ^\circ\text{C}^{-1}$. By how much would the temperature of the

mirror need to be raised to increase the area of the mirror by $4.750 \cdot 10^{-3}\ \mathrm{m}^2$?

17.82 A steel antenna for television broadcasting is 501.9 m tall on a summer day, when the outside temperature is 28.09 $^\circ$C. The steel from which the antenna was constructed has a linear expansion coefficient of $13.89 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}$. On a cold winter day, the temperature is $-15.91\ ^\circ$C. What is the change in the height of the antenna?

17.83 A steel antenna for television broadcasting is 599.7 m tall on a summer day, when the outside temperature is 28.31 $^\circ$C. On a cold winter day, when the temperature is $-18.95\ ^\circ$C, the antenna is 0.4084 m shorter than on the summer day. What is the linear expansion coefficient of the steel from which the antenna was constructed?

17.84 A steel antenna for television broadcasting is 645.5 m tall on a summer day, when the outside temperature is 28.51 $^\circ$C. The steel from which the antenna was constructed has a linear expansion coefficient of $14.93 \cdot 10^{-6}\ ^\circ\mathrm{C}^{-1}$. On a cold winter day, the antenna is 0.3903 m shorter than on the summer day. What is the temperature on the winter day?

Earth's weather is driven by thermal energy in the atmosphere. The equatorial regions receive more of the Sun's radiation than the polar regions do; so warm air moves north and south from the Equator toward the poles to distribute the thermal energy more evenly. This transfer of thermal energy, called *convection*, sets up wind currents around the world, carrying clouds and rain as well as air. In extreme cases, rising warm air and sinking cooler air form dramatic storms, like the thunderstorm shown in Figure 18.1. Circular storms—tornados and hurricanes—are driven by the violent collision of warm air with cooler air.

FIGURE 18.1 A thunderstorm.

KSTFoto/Alamy Stock Photo

This chapter examines the nature of heat and the mechanisms of thermal energy transfer. Heat is a form of energy that is transferred into or out of a system. Thus, heat is governed by a more general form of the law of

conservation of energy, known as the First Law of Thermodynamics. We'll focus on this law in this chapter, along with some of its applications to thermodynamic processes and to changes in heat and temperature.

Heat is essential to life processes; no life could exist on Earth without heat from the Sun or from the Earth's interior. However, heat can also cause problems with the operation of electrical circuits, computers, motors, and other mechanical devices. Every branch of science and engineering has to deal with heat in one way or another, and thus the concepts in this chapter are important for all areas of research, design, and development.

WHAT WE WILL LEARN

- Heat is thermal energy that transfers between a system and its environment or between two systems, as a result of a temperature difference between them.
- The First Law of Thermodynamics states that the change in internal energy of a closed system is equal to the thermal energy absorbed by the system minus the work done by the system.
- Adding thermal energy to a substance in a given phase increases its temperature. This temperature increase is inversely proportional to the heat capacity, C, of the substance.
- During a phase change from solid to liquid or from liquid to gas, the addition of thermal energy does not change the temperature of the mixed phase. The amount of thermal energy needed to complete a phase change is called its *latent heat*.
- The three main modes of transferring thermal energy are conduction, convection, and radiation.

18.1 Definition of Heat

Heat is one of the most common forms of energy in the universe, and we all experience it every day. Yet many people have misconceptions about heat that often cause confusion. For instance, a burning object such as a candle flame does not "have" heat that it emits when it becomes hot enough. Instead, the candle flame transmits energy, in the form of heat, to the air around it. To clarify these ideas, we need to start with clear and precise definitions of heat and the units used to measure it.

If you pour cold water into a glass and then put the glass on the kitchen table, the water will slowly warm until it reaches the temperature of the air in the room. Similarly, if you pour hot water into a glass and place it on the kitchen table, the water will slowly cool until it reaches the temperature of the air in the room. The warming or cooling takes place rapidly at first and then more slowly as the water comes into thermal equilibrium with the air in the kitchen. At thermal equilibrium, the water, the glass, and the air in the room are all at the same temperature.

The water in the glass is a **system** with temperature T_s, and the air in the kitchen is an **environment** with temperature T_e. If $T_s \neq T_e$, then the temperature of the system changes until it is equal to the temperature of the environment. A system can be simple or complicated; it is just any object or collection of objects we wish to examine. The difference between the environment and the system is that the environment is large compared to the system. The temperature of the system affects the environment, but we'll assume that the environment is so large that any changes in its temperature are imperceptible.

The change in temperature of the system is due to a transfer of energy between the system and its environment. This type of energy is **thermal energy,** an internal energy related to the motion of the atoms, molecules, and electrons that make up the system or the environment. Thermal energy in the process of being transferred from one body to another is called **heat** and is symbolized by Q. If thermal energy is transferred into a system, then $Q > 0$ (Figure 18.2a). That is, the system gains thermal energy when it receives heat from its environment. If thermal energy is transferred from the system to its environment, then $Q < 0$ (Figure 18.2c). If the system and its environment have the same temperature (Figure 18.2b), then $Q = 0$.

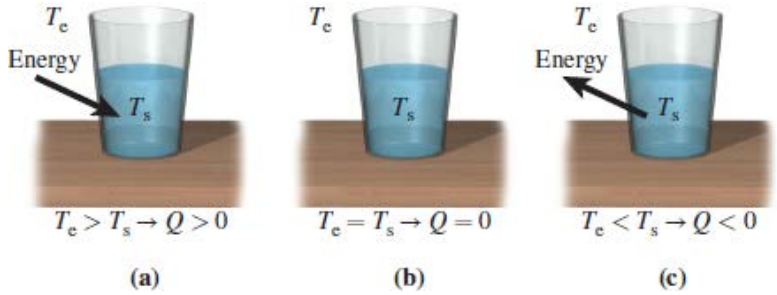

FIGURE 18.2 (a) A system embedded in an environment that has a higher temperature. (b) A system embedded in an environment that has the same temperature. (c) A system embedded in an environment that has a lower temperature.

Heat, Q, is the energy transferred between a system and its environment (or between two systems) because of a temperature difference between them. When energy flows into the system, $Q > 0$; when energy flows out of the system, $Q < 0$.

18.2 Mechanical Equivalent of Heat

Recall from Chapter 5 that energy can also be transferred between a system and its environment as work done by a force acting on a system or by a system. The concepts of heat and work, discussed in Section 18.3, can be defined in terms of the transfer of energy to or from a system. We can refer to the internal energy of a system, but not to the heat contained in a system. If we observe hot water in a glass, we do not know whether thermal energy was transferred to the water or work was done on the water.

Heat is transferred energy and can be quantified using the SI unit of energy, the joule. Originally, heat was measured in terms of its ability to raise the temperature of water. The **calorie (cal)** was defined as the amount of heat required to raise the temperature of 1 gram of water by 1 °C. Another common measure of heat, still used in the United States, is the British thermal unit (BTU), defined as the amount of heat required to raise the temperature of 1 pound of water by 1 °F. However, the change in temperature of water as a function of the amount of thermal energy transferred to it depends on the original temperature of the water. Reproducible definitions of the calorie and the British thermal unit required that the measurements be made at a specified starting temperature.

In a classic experiment performed in 1843, the English physicist James Prescott Joule showed that the mechanical energy of an object could be converted into thermal energy. The apparatus Joule used consisted of a large mass supported by a rope that was run over a pulley and wound around an axle (Figure 18.3). As the mass descended, the unwinding rope turned a pair of large paddles in a container of water. Joule showed that the rise in temperature of the water was directly related to the mechanical work done by the falling object. Thus, Joule demonstrated that mechanical work could be turned into thermal energy, and he obtained a relationship between the calorie and the joule (the energy unit named in his honor).

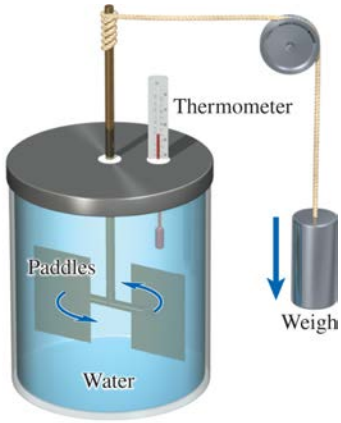

FIGURE 18.3
Apparatus for Joule's experiment to determine the mechanical equivalent of heat.

The modern definition of the calorie is based on the joule. The calorie is defined to be exactly 4.186 J, with no reference to the change in temperature of water. The following are some conversion factors for energy units:

$$\begin{aligned} 1\,\text{cal} &= 4.186\,\text{J} \\ 1\,\text{BTU} &= 1055\,\text{J} \\ 1\,\text{kWh} &= 3.60 \cdot 10^6\,\text{J} \\ 1\,\text{kWh} &= 3412\,\text{BTU}. \end{aligned} \qquad \textbf{(18.1)}$$

The energy content of food is usually expressed in terms of calories. A food calorie, often called a *Calorie* or a *kilocalorie*, is not equal to the calorie just defined; a food calorie is equivalent to 1000 cal. The cost of electrical energy is usually stated in cents per kilowatt-hour (kWh).

EXAMPLE 18.1 Candy Bar

PROBLEM

The label of a candy bar states that it has 275 Calories. What is the energy content of this candy bar in joules?

SOLUTION

Food calories are kilocalories and $1\,\text{kcal} = 4186\,\text{J}$. The candy bar has 275 kcal, or

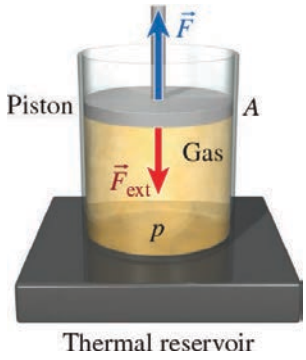
$$275\,\text{kcal}\left(\frac{4186\,\text{J}}{1\,\text{kcal}}\right) = 1.15 \cdot 10^6\,\text{J}.$$

DISCUSSION

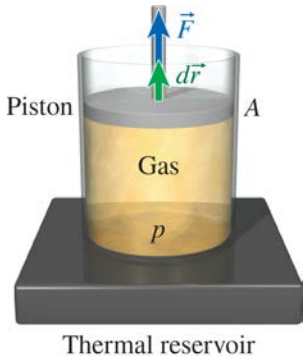
Note that this energy is enough to raise a small truck with a weight of 22.2 kN (5000 lb) a distance of 52 m.

18.3 Heat and Work

Let's look at how energy can be transferred as heat or work between a system and its environment. We'll consider a system consisting of a gas-filled cylinder with a piston (Figure 18.4). The gas in the cylinder is described by a temperature T, a pressure p, and a volume V. We assume that the side wall of the cylinder does not allow heat to penetrate it. The gas is in thermal contact with an infinite thermal reservoir, which is an object so large that its temperature does not change even though it experiences thermal energy flow into it or out of it. (A thermal reservoir is an idealized construct that cannot actually exist. However, some large real-world systems that behave like thermal reservoirs include the ocean, the atmosphere, and the Earth itself.) This reservoir also has temperature T. In Figure 18.4a, an external force, $\overrightarrow{F}_{\text{ext}}$, pushes on the piston. The gas then pushes back with a force, $\overrightarrow{F}$, given by the pressure of the gas, p, times the area, A, of the piston: $F = pA$ (see Chapter 13).



(a)



(b)

FIGURE 18.4 A gas-filled cylinder with a piston. The gas is in thermal contact with an infinite thermal reservoir. (a) An external force pushes on the piston, increasing the pressure in the gas. (b) The external force is removed, allowing the gas to push the piston out.

To describe the behavior of this system, we consider the change from an initial state specified by pressure p_{i}, volume V_{i}, and temperature T_{i} and a final state specified by pressure p_{f}, volume V_{f}, and temperature T_{f}. Imagine changes made slowly so that the gas remains close to equilibrium, allowing measurements of p, V, and T. The progression from the initial state to the final state is a **thermodynamic process.** During this process,

thermal energy may be transferred into the system (positive heat), or it may be transferred out of the system (negative heat).

When the external force is reduced (Figure 18.4b), the gas in the cylinder pushes the piston out a distance *dr*. The work done by the system in this process is

$$dW = \vec{F} \bullet \vec{dr} = (pA)\,(dr) = p\,(A\,dr) = pdV,$$

where $dV = Adr$ is the change in the volume of the system. Thus, the work done by the system in going from the initial configuration to the final configuration is given by

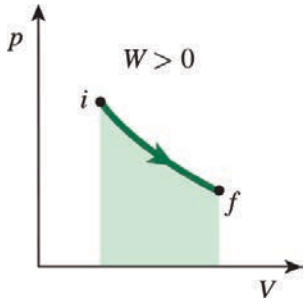
$$W = \int dW = \int_{V_\mathrm{i}}^{V_\mathrm{f}} pdV. \qquad \textbf{(18.2)}$$

Note that during this change in volume, the pressure may also change. To evaluate this integral, we need to know the relationship between pressure and volume for the process. For example, if the pressure remains constant, we obtain

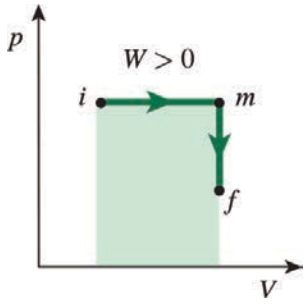
$$W = \int_{V_\mathrm{i}}^{V_\mathrm{f}} pdV = p\int_{V_\mathrm{i}}^{V_\mathrm{f}} dV = p\,(V_\mathrm{f} - V_\mathrm{i}) \ \ (\text{for constant pressure}).$$

Equation 18.3 indicates that, for constant pressure, a negative change in the volume corresponds to negative work done by the system.

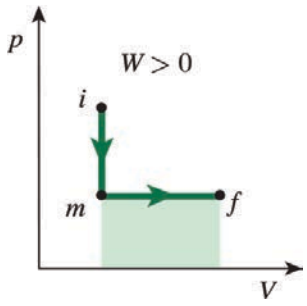
Figure 18.5 shows graphs of pressure versus volume, sometimes called **pV-diagrams.** The three parts of the figure show different paths, or ways to change the pressure and volume of a system from an initial condition to a final condition. Figure 18.5a illustrates a process that starts at an initial point i and proceeds to a final point f in such a way that the pressure decreases as the volume increases. The work done by the system is given by equation 18.2. The integral can be represented by the area under the curve, shown by the green shading in Figure 18.5a. In this case, the work done by the system is positive because the volume of the system increases.



(a)



(b)



(c)

FIGURE 18.5 The paths of three different processes in *pV*-diagrams. (a) A process in which the pressure decreases as the volume increases. (b) A two-step process in which the first step consists of increasing the volume while keeping the pressure constant

and the second step consists of decreasing the pressure while holding the volume constant. (c) Another two-step process, in which the first step consists of keeping the volume constant and decreasing the pressure and the second step consists of holding the pressure constant while increasing the volume. In all three cases, the green area below the curve represents the work done during the process.

Figure 18.5b illustrates a process that starts at an initial point *i* and proceeds to a final point *f* through an intermediate point *m*. The first step involves increasing the volume of the system while holding the pressure constant. One way to complete this step is to increase the temperature of the system as the volume increases, maintaining a constant pressure. The second step consists of decreasing the pressure while holding the volume constant. One way to accomplish this task is to lower the temperature by taking thermal energy away from the system. Again, the work done by the system can be represented by the area under the curve, shown by the green shading in Figure 18.5b. The work done by the system is positive because the volume of the system increases. However, the work done by the system

originates only in the first step. In the second step, the system does no work because the volume does not change.

Figure 18.5c illustrates another process that starts at an initial point *i* and proceeds to a final point *f* through an intermediate point *m*. The first step involves decreasing the pressure of the system while holding the volume constant. The second step consists of increasing the volume while holding the pressure constant. Again, the work done by the system can be represented by the area under the curve, shown by the green shading in Figure 18.5c. The work done by the system is again positive because the volume of the system increases. However, the work done by the system originates only in the second step. In the first step, the system does no work because the volume does not change. The net work done in this process is less than the work done by the process in Figure 18.5b, as the green area is smaller. The thermal energy absorbed must also be less because the initial and final states are the same in these two processes, so the change in internal energy is the same. (This connection between work, heat, and the change in internal energy is discussed in more detail in Section 18.4.)

Thus, the work done by a system and the thermal energy transferred to the system depend on the manner in which the system moves from an initial point to a final point in a *pV*-diagram. This type of process is thus referred to as a **path-dependent process.**

The *pV*-diagrams in Figure 18.6 reverse the processes shown in Figure 18.5 by starting at the final points in Figure 18.5 and proceeding along the same path to the initial points. In each of these cases, the area under the curve represents the negative of the work done by the system in moving from an initial point *i* to a final point *f*. In all three cases, the work done by the system is negative because the volume of the system decreases.

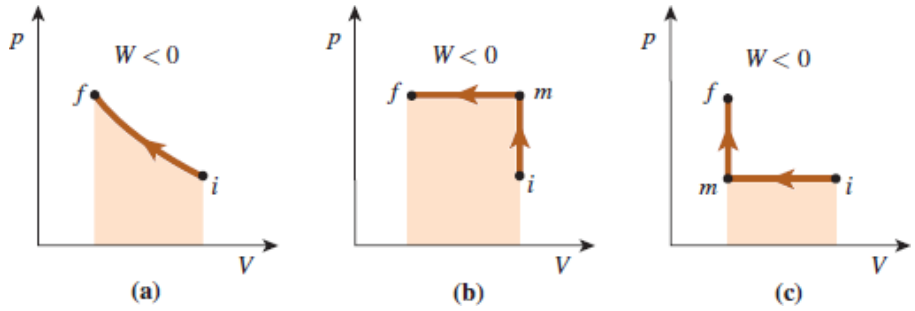


FIGURE 18.6 The paths of three processes in *pV*-diagrams. These are the reverse of the processes shown in Figure 18.5.

Suppose a process starts at some initial point on a *pV*-diagram, follows some path, and returns to the original point. A path that returns to its starting point is called a **closed path.** Two examples of closed paths are illustrated in Figure 18.7. In Figure 18.7a, a process starts at an initial point

i and proceeds to an intermediate point m_1; the volume is increased while the pressure is held constant. From m_1, the path goes to intermediate point m_2; the volume is held constant while the pressure decreases. From point m_2, the path goes to intermediate point m_3, with the pressure constant and the volume decreasing. Finally, the path goes from point m_3 to the final point, *f*, which is the same as the initial point, *i*. The area under the path from i to m_1 represents positive work done by the system (the volume increases), while the area under the path from m_2 to m_3 represents negative work done on the system (volume decreases). The addition of the positive and the negative work yields net positive work being done by the system, as depicted by the area of the green rectangle in Figure 18.7a. In this case, heat is positive.

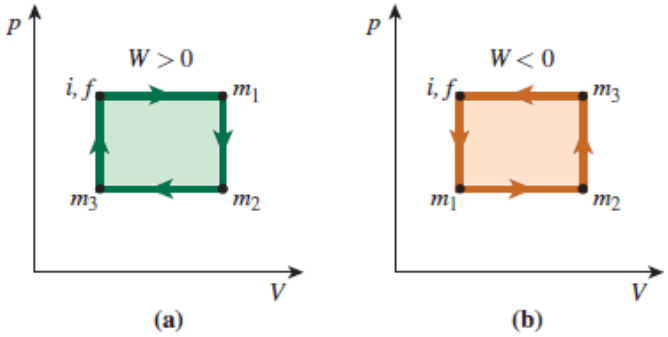

FIGURE 18.7 Two closed-path processes in *pV*-diagrams.

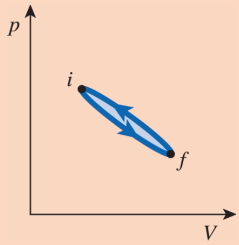
Figure 18.7b shows the same path on a *pV*-diagram as in Figure 18.7a, but the process occurs in the opposite direction. The area under the path from intermediate point m_1 to intermediate point m_2 corresponds to positive work done by the system. The area under the path from intermediate point m_3 to final point *f* corresponds to negative work done on the system. The net work done by the system in this case is negative, and its magnitude is represented by the area of the orange rectangle in Figure 18.7b. In this case, the heat is negative.

The amount of work done by the system and the thermal energy absorbed by the system depend on the path taken on a *pV*-diagram, as well as on the direction in which the path is taken.

Self-Test Opportunity 18.1

Consider the process shown in the *pV*-diagram. The path goes from point *i* to point *f* and back to point *i*. Is the work done by the system negative, zero, or positive?



18.4 First Law of Thermodynamics

Thermodynamic systems are classified according to how they interact with their environment. An **open system** can exchange heat, energy, and mass with its surroundings. A **closed system** is a system into or out of which thermal energy can be transferred but from which no constituents can escape and to which no additional constituents are added. An **isolated system** is a system that has no interactions or exchanges of constituents with its environment.

Combining several of the concepts already covered in this chapter allows us to express the change in internal energy of a closed system in terms of heat and work as

$$\Delta E_{\text{int}} = E_{\text{int,f}} - E_{\text{int,i}} = Q - W. \qquad \textbf{(18.4)}$$

This equation is known as the **First Law of Thermodynamics.** It can be stated as follows:

> The change in the internal energy of a closed system is equal to the heat acquired by the system minus the work done by the system.

In other words, energy is conserved. Heat and work can be transformed into internal energy, but no energy is lost. Note that here the work is done by the system, not done on the system. Essentially, the First Law of Thermodynamics extends the conservation of energy (first encountered in Chapter 6) beyond mechanical energy to include heat as well as work. (In other contexts, such as chemical reactions, work is defined as the work done on the system, which leads to a different sign convention for the work. The sign convention can be assigned in either way, as long as it is consistent.) Note also that the change in internal energy is path-independent, while changes in heat and work are path-dependent.

EXAMPLE 18.2 Weightlifter

PROBLEM

A weightlifter snatches a barbell with mass $m = 180.0\,\text{kg}$ and moves it a distance $h = 1.25\,\text{m}$ vertically, as illustrated in Figure 18.8. If we consider the weightlifter to be a thermodynamic system, how much heat must he give off if his internal energy decreases by 4000. J?

FIGURE 18.8 A weightlifter competes in the 2012 Olympic Games.

Hassan Ammar/AP Images

SOLUTION

We start with the First Law of Thermodynamics (equation 18.4):

$$\Delta E_{\text{int}} = Q - W.$$

The work is the mechanical work done on the weight by the weightlifter:

$$W = mgh.$$

The heat is then given by

$$Q = \Delta E_{\text{int}} + W = \Delta E_{\text{int}} + mgh = -4000\,\text{J} + (180.0\,\text{kg})\left(9.81\,\text{n}\right.$$
$$= -1790\,\text{J} = -0.428\,\text{kcal}.$$

The weightlifter cannot turn internal energy into useful work without giving off heat. Note that the decrease in internal energy of the weightlifter is less than 1 food calorie: $(4000\,\mathrm{J})/(4186\,\mathrm{J/kcal}) = 0.956\,\mathrm{kcal}$. The heat output is only 0.428 kcal. Thus, rather small amounts of internal energy and heat are associated with the large effort required to lift the weight.

EXAMPLE 18.3 Truck Sliding to a Stop

PROBLEM

The brakes of a moving truck with a mass $m = 3000.\,\text{kg}$ lock up. The truck skids to a stop on a horizontal road surface in a distance $L = 83.2\,\text{m}$. The coefficient of kinetic friction between the truck tires and the surface of the road is $\mu_\text{k} = 0.600$. What happens to the internal energy of the truck?

SOLUTION

The First Law of Thermodynamics (equation 18.4) relates the internal energy, the heat, and the work done on the system:

$$\Delta E_\text{int} = Q - W.$$

In this case, no thermal energy is transferred to or from the truck because the process of sliding to a complete stop is sufficiently fast that there is no time to transfer thermal energy in appreciable quantity. Thus, $Q = 0$. The dissipation of energy from the friction force, W_f, is always negative (see Chapter 6). In this case, the energy dissipated is equal to original kinetic energy of the truck. The energy dissipated by the friction force is

$$W_\text{f} = -\mu_\text{k} mgL,$$

where mg is the normal force exerted on the road by the truck. Using the work-kinetic energy theorem, we have $\Delta K = W = W_\text{f}$ and

$$\Delta E_\text{int} = 0 - (-\mu_\text{k} mgL) = \mu_\text{k} mgL.$$

Putting in the numerical values gives

$$\Delta E_\text{int} = (0.600)\,(3000.\,\text{kg})\left(9.81\,\text{m/s}^2\right)(83.2\,\text{m}) = 1.47\,\text{MJ}.$$

This increase in internal energy can warm the truck's tires. Chapter 6 discussed conservation of energy for conservative and nonconservative forces. Here we see that energy is conserved because mechanical work can be converted to internal energy.

DISCUSSION

Note that we have assumed that the truck is a closed system. However, when the truck begins to skid, the tires may leave skid marks on the

road, removing matter and energy from the system. The assumption that no thermal energy is transferred to or from the truck in this process is also not exactly valid. In addition, the internal energy of the road surface will also increase as a result of the friction between the tires and the road, taking some of the total energy available. So, the 1.47 MJ added to the internal energy of the truck should be considered an upper limit. However, the basic lesson from this example is that the mechanical energy lost because of the action of nonconservative forces is transformed to internal energy of parts or all of the system, and the total energy is conserved.

18.5 First Law for Special Processes

The First Law of Thermodynamics—that is, the basic conservation of energy—holds for all kinds of processes involving a closed system, but energy can be transformed and thermal energy transported in some special ways in which only a single or a few of the variables that characterize the state of the system change. Some special processes, which occur often in physical situations, can be described using the First Law of Thermodynamics. These special processes are also usually the only ones for which we can compute numerical values for heat and work. For this reason, they will be discussed several times in the following chapters. Keep in mind that these processes are simplifications or idealizations, but they often approximate real-world situations fairly closely.

Page 560

Adiabatic Processes

An **adiabatic process** is one in which no heat flows when the state of a system changes. This can happen, for example, if a process occurs quickly and there is not enough time for heat to be exchanged. Adiabatic processes are common because many physical processes do occur quickly enough that no thermal energy transfer takes place. For adiabatic processes, $Q = 0$ in equation 18.4, so

$$\Delta E_{\text{int}} = -W \text{ (for an adiabatic process).} \qquad \textbf{(18.5)}$$

Another situation in which an adiabatic process can occur is if the system is thermally insulated from its environment while pressure and volume changes occur. An example is compressing a gas in an insulated container or pumping air into a bicycle tire using a manual tire pump. The change in the internal energy of the gas is due only to the work done on the gas.

Constant-Volume Processes

Processes that occur at constant volume are called **isochoric processes.** For a process in which the volume is held constant, the system can do no work, so $W = 0$ in equation 18.4, giving

$$\Delta E_{\text{int}} = Q \ \text{(for a process at constant volume)}. \qquad \textbf{(18.6)}$$

An example of a constant-volume process is warming a gas in a rigid, closed container that is in contact with other bodies. No work can be done because the volume of the gas cannot change. The change in the internal energy of the gas occurs because of heat flowing into or out of the gas as a result of contact between the container and the other bodies. Cooking food in a pressure cooker is an isochoric process.

Closed-Path Processes

In a **closed-path process,** the system returns to the same state at which it started. Regardless of how the system reached that point, the internal energy must be the same as at the start, so $\Delta E_{\text{int}} = 0$ in equation 18.4. This gives

$$Q = W \ \text{(for a closed-path process)}. \qquad \textbf{(18.7)}$$

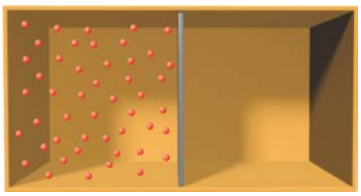
Thus, the net work done by a system during a closed-path process is equal to the thermal energy transferred into the system. Such cyclical processes form the basis of many kinds of heat engines (discussed in Chapter 20).

Free Expansion

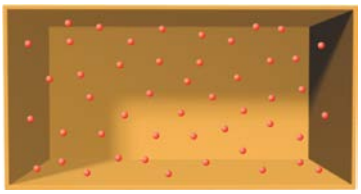
If the thermally insulated (so $Q = 0$) container for a gas suddenly increases in size, the gas will expand to fill the new volume. During this **free expansion,** the system does no work and no heat is absorbed. That is, $W = 0$ and $Q = 0$, and equation 18.4 becomes

$$\Delta E_{\text{int}} = 0 \quad (\text{for free expansion of a gas}). \qquad \textbf{(18.8)}$$

To illustrate this situation, consider a box with a barrier in the center (Figure 18.9). A gas is confined in the left half of the box. When the barrier between the two halves is removed, the gas fills the total volume. However, the gas performs no work. This last statement requires a bit of explanation: In its free expansion, the gas does not move a piston or any other material device; thus, it does no work on anything. During the expansion, the gas particles move freely until they encounter the walls of the expanded container. The gas is not in equilibrium while it is expanding. For this system, we can plot the initial state and the final state on a pV-diagram, but not the intermediate state.



(a)



(b)

FIGURE 18.9 (a) A gas is confined to half the volume of a box. (b) The barrier separating the two halves is removed, and the gas expands to fill the volume.

Constant-Pressure Processes

Constant-pressure processes are called **isobaric processes.** Such processes are common in the study of the specific heat of gases. In an isobaric process, the volume can change, allowing the system to do work. Since the pressure is kept constant, $W = p\,(V_\mathrm{f} - V_\mathrm{i}) = p\Delta V$, according to equation 18.3. Thus, equation 18.4 can be written as follows:

$$\Delta E_\mathrm{int} = Q - p\Delta V \quad \text{(for a process at constant pressure).} \textbf{(18.9)}$$

An example of an isobaric process is the slow warming of a gas in a cylinder fitted with a frictionless piston, which can move to keep the pressure constant. The path of an isobaric process on a *pV*-diagram is a horizontal straight line. If the system moves in the positive-volume direction, the system is expanding. If the system moves in the negative-volume direction, the system is contracting. Cooking food in an open saucepan is another example of an isobaric process.

Constant-Temperature Processes

Constant-temperature processes are called **isothermal processes.** The temperature of the system is held constant through contact with an external thermal reservoir. Isothermal processes take place slowly enough that heat can be exchanged with the external reservoir to maintain a constant temperature. For example, heat can flow from a warm reservoir to the system, allowing the system to do work. The path of an isothermal process in a *pV*-diagram is called an **isotherm.** As we'll see in Chapter 19, the product of the pressure and the volume is constant for an ideal gas undergoing an isothermal process, giving the isotherm the form of a hyperbola. In addition, as we'll see in Chapter 20, isothermal processes play an important part in the analysis of devices that produce useful work from sources of heat.

18.6 Specific Heats of Solids and Fluids

Suppose a block of aluminum is at room temperature. If heat, Q, is then transferred to the block, the temperature of the block goes up proportionally to the amount of heat. The proportionality constant between the temperature difference and the heat is the **heat capacity,** C, of the block (or other object). Thus,

$$Q = C\Delta T, \tag{18.10}$$

where ΔT is the change in temperature.

The term *heat capacity* does not imply that an object contains a certain amount of heat. Rather, it tells how much heat is required to raise the temperature of the object by a given amount. The SI units for heat capacity are joules per kelvin $(\mathrm{J/K})$.

The temperature change of an object due to heat can be described by the **specific heat,** c, which is defined as the heat capacity per unit mass, m:

$$c = \frac{C}{m}. \tag{18.11}$$

With this definition, the relationship between temperature change and heat can be written as

$$Q = cm\Delta T. \tag{18.12}$$

The SI units for the specific heat are $\mathrm{J/(kg\,K)}$. In practical applications, specific heat is also often expressed in $\mathrm{cal/(g\,K)}$. The units $\mathrm{J/(kg\,K)}$ and $\mathrm{J/(kg\,^\circ C)}$ can be used interchangeably for specific heat since it is defined in terms of ΔT. The specific heats of various materials are given in Table 18.1.

Table 18.1 Specific Heats for Selected Materials

	Specific Heat, c	
Material	**kJ/(kg K)**	**cal/(g K)**
Aluminum	0.900	0.215
Asphalt	0.92	0.22
Basalt	0.84	0.20
Copper	0.386	0.0922
Glass	0.840	0.20
Granite	0.790	0.189
Ice	2.06	0.500
Iron	0.450	0.107
Lead	0.129	0.0308
Limestone	0.217	0.908
Nickel	0.461	0.110
Sandstone	0.92	0.22
Steam	2.01	0.48
Steel	0.448	0.107
Water	4.19	1.00

Note that specific heat and heat capacity are usually measured in two ways. For most substances, they are measured under constant pressure (as in Table 18.1) and denoted by c_p and C_p. However, for fluids (gases and liquids), the specific heat and heat capacity can also be measured at constant volume and denoted by c_V and C_V. In general, measurements under constant pressure produce larger values, because mechanical work has to be performed in the process, and the difference is particularly large for gases. We'll discuss this in greater detail in Chapter 19.

The specific heat of a substance can also be defined in terms of the number of moles of the substance rather than its mass. This type of specific heat is called the *molar specific heat*, and is also discussed in Chapter 19.

The effect of differences in specific heats of substances can be observed readily at the seashore, where the sunlight transfers energy to the land and to the water roughly equally during the day. The specific heat of the land is about five times lower than the specific heat of the water. Thus, the land warms up more quickly than the water, and it warms the air above it more than the water warms the air above it. This temperature difference creates an onshore breeze during the day. The high specific heat of water helps to moderate climates around oceans and large lakes.

Concept Check 18.1

Suppose you raise the temperature of copper block 1 from -10°C to $+10^{\circ}\text{C}$, of copper block 2 from $+20^{\circ}\text{C}$ to $+40^{\circ}\text{C}$, and of copper block 3 from $+90^{\circ}\text{C}$ to $+110^{\circ}\text{C}$. Assuming that the blocks have the same mass, to which one did you add the most heat?

a) block 1

b) block 2

c) block 3

d) All of the blocks received the same amount of heat.

EXAMPLE 18.4 Warming Water

PROBLEM

You have 2.00 L of water at a temperature of 20.0 °C. How much energy is required to raise the temperature of that water to 95.0 °C? Assuming that you use electricity to warm the water, how much will it cost at 10.0 cents per kilowatt-hour?

SOLUTION

The mass of 1.00 L of water is 1.00 kg. From Table 18.1, $c_{\text{water}} = 4.19\ \text{kJ}/\left(\text{kg K}\right)$. Therefore, the energy required to warm 2.00 kg of water from 20.0 °C to 95.0 °C is

$$\begin{aligned} Q &= c_{\text{water}} m_{\text{water}}\, \Delta T = \left[4.19\ \text{KJ}/\left(\text{kg K}\right)\right] (2.00\ \text{kg})\ (95.0\ ^\circ\text{C} - 20 \\ &= 629,000\ \text{J}. \end{aligned}$$

Using the conversion factor for converting joules to kilowatt-hours (equation 18.1), we calculate the cost of warming the water as

$$\text{Cost} = (629,000\ \text{J}) \left(\frac{10.0\ \text{cents}}{1\ \text{kWh}}\right) \left(\frac{1\ \text{kWh}}{3.60 \cdot 10^6\ \text{J}}\right) = 1.75\ \text{cents}.$$

Calorimetry

A **calorimeter** is a device used to study internal energy changes by measuring thermal energy transfers. The thermal energy transfer and internal energy change may result from a chemical reaction, a physical change, or differences in temperature and specific heat. A simple calorimeter consists of an insulated container and a thermometer. For simple measurements, a Styrofoam cup and an ordinary alcohol thermometer will do. We'll assume that no heat is lost or gained in the calorimeter or the thermometer.

When two materials with different temperatures are placed in a calorimeter, heat will flow from the warmer substance to the cooler substance until the temperatures of the two substances are the same. No heat will flow into or out of the calorimeter. The heat lost by the warmer substance will be equal to the heat gained by the cooler substance.

A substance such as water with a high specific heat, $c = 4.19\,\mathrm{kJ/(kg\,K)}$, requires more heat to raise its temperature by the same amount than does a substance with a low specific heat, like steel, with $c = 0.448\,\mathrm{kJ/(kg\,K)}$. Solved Problem 18.1 illustrates the concepts of calorimetry.

SOLVED PROBLEM 18.1 Water and Lead

PROBLEM

A metalsmith pours 3.00 kg of lead shot (which is the material used to fill shotgun shells) at a temperature of 94.7 °C into 1.00 kg of water at 27.5 °C in an insulated container, which acts as a calorimeter. What is the final temperature of the mixture?

SOLUTION

THINK

The lead shot will give up heat and the water will absorb heat until both are at the same temperature. (Something that may not occur to you is that lead shot has a melting temperature, but it is significantly above 94.7 °C; so we do not have to deal with a phase change in this situation. The water will stay liquid, and the lead shot will stay solid. Section 18.7 addresses situations involving phase changes.)

Page 563

SKETCH

Figure 18.10 shows the problem situation before and after the lead shot is added to the water.

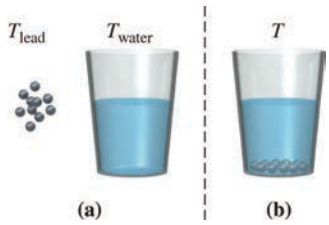


FIGURE 18.10 Lead shot and water (a) before and (b) after the lead shot is added to the water.

RESEARCH

The heat lost by the lead shot, Q_{lead}, to its environment is given by $Q_{\text{lead}} = m_{\text{lead}} c_{\text{lead}} (T - T_{\text{lead}})$, where c_{lead} is the specific heat of lead, m_{lead} is the mass of the lead shot, T_{lead} is the original temperature of the lead shot, and T is the final equilibrium temperature.

The heat gained by the water, Q_{water}, is given by $Q_{\text{water}} = m_{\text{water}} c_{\text{water}} (T - T_{\text{water}})$, where c_{water} is the specific heat of water, m_{water} is the mass of the water, and T_{water} is the original temperature of the water.

The sum of the heat lost by the lead shot and the heat gained by the water is zero, because the process took place in an insulated container and because the total energy is conserved, a consequence of the First Law of Thermodynamics. So we can write

$$Q_{\text{lead}} + Q_{\text{water}} = 0 = m_{\text{lead}} c_{\text{lead}} (T - T_{\text{lead}}) + m_{\text{water}} c_{\text{water}} (T - T$$

SIMPLIFY

We multiply through on both sides and reorder so that all of the terms containing the unknown temperature, T, are on the right side of the equation:

$$m_{\text{lead}} c_{\text{lead}} T_{\text{lead}} + m_{\text{water}} c_{\text{water}} T_{\text{water}} = m_{\text{water}} c_{\text{water}} T + m_{\text{lead}} c_{\text{lead}} T$$

We can solve this equation for T by dividing both sides by $m_{\text{lead}} c_{\text{lead}} + m_{\text{water}} c_{\text{water}}$:

$$T = \frac{m_{\text{lead}} c_{\text{lead}} T_{\text{lead}} + m_{\text{water}} c_{\text{water}} T_{\text{water}}}{m_{\text{lead}} c_{\text{lead}} + m_{\text{water}} c_{\text{water}}}.$$

CALCULATE

Putting in the numerical values gives

$$T = \frac{(3.00\ \text{kg})\,[0.129\ \text{kJ}/\,(\text{kg K})]\,(94.7\ ^\circ\text{C}) + (1.00\ \text{kg})\,[4.19\ \text{kJ}/\,($$
$$(3.00\ \text{kg})\,[0.129\ \text{kJ}/\,(\text{kg K})] + (1.00\ \text{kg})\,[4.19\ \text{kJ}/\,($$
$$= 33.182\ ^\circ\text{C}.$$

ROUND

We report our result to three significant figures:

$$T = 33.2\ ^\circ\text{C}.$$

DOUBLE-CHECK

The final temperature of the mixture of lead shot and water is only $5.7\ ^\circ\mathrm{C}$ higher than the original temperature of the water. The masses of the lead shot and water differ by a factor of 3, but the specific heat of lead is much lower than the specific heat of water. Thus, it is reasonable that the lead has a large change in temperature and the water has a small change in temperature. To double-check, we calculate the heat lost by the lead,

$$\begin{aligned} Q_{\text{lead}} &= m_{\text{lead}} c_{\text{lead}} \left(T - T_{\text{lead}}\right) = (3.00\,\text{kg})\left[0.129\,\text{kJ}/\left(\text{kg}\,\text{K}\right)\right](33.2 \\ &= -23.8\,\text{kJ}, \end{aligned}$$

and compare the result to the heat gained by the water,

$$\begin{aligned} Q_{\text{water}} &= m_{\text{water}} c_{\text{water}} \left(T - T_{\text{water}}\right) = (1.00\,\text{kg})\left[4.19\,\text{kJ}/\left(\text{kg}\,\text{K}\right)\right](3 \\ &= 23.9\,\text{kJ}. \end{aligned}$$

These results add up to zero within rounding error, as required.

18.7 Latent Heat and Phase Transitions

As noted in Chapter 13, the three common **states of matter** (sometimes also called **phases**) are solid, liquid, and gas. We have been considering objects for which the change in temperature is proportional to the amount of heat that is added. This linear relationship between heat and temperature is, strictly speaking, an approximation, but it has high accuracy for solids and liquids. For a gas, adding heat will raise the temperature but may also change the pressure or volume, depending on whether and how the gas is contained. Substances can have different specific heats depending on whether they are in a solid, liquid, or gaseous state.

If enough heat is added to a solid, it melts into a liquid. If enough heat is added to a liquid, it vaporizes into a gas. These are examples of **phase changes,** or **phase transitions** (Figure 18.11). During a phase change, the temperature of an object remains constant. The heat that is required to melt a solid, divided by its mass, is called the **latent heat of fusion,** L_{fusion}. Melting changes a substance from a solid to a liquid. The heat that is required to vaporize a liquid, divided by its mass, is called the **latent heat of vaporization,** $L_{\text{vaporization}}$. Vaporizing changes a substance from a liquid to a gas.

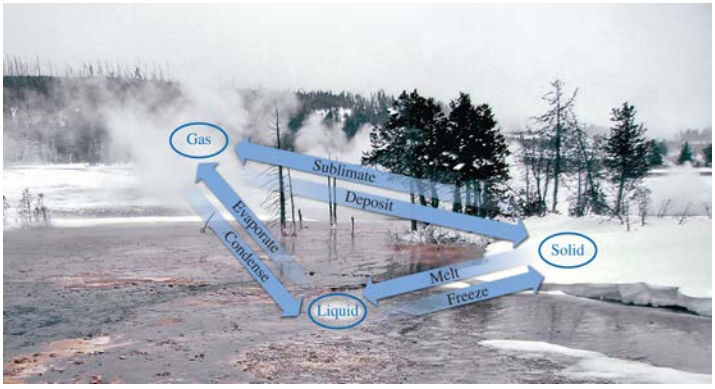

FIGURE 18.11 Phase changes involving three states of water are occurring simultaneously in this scene from Yellowstone National Park.

W. Bauer and G. D. Westfall

The temperature at which a solid melts to a liquid is the melting point, T_{melting}. The temperature at which a liquid vaporizes to a gas is the boiling point, T_{boiling}. The relationship between the mass of an object at its melting point and the heat needed to change the object from a solid to a liquid is given by

$$Q = mL_{\text{fusion}} \quad (\text{for } T = T_{\text{melting}}). \tag{18.13}$$

Similarly, the relationship between the mass of an object at its boiling point and the heat needed to change the object from a liquid to a gas is given by

$$Q = mL_{\text{vaporization}} \quad (\text{for } T = T_{\text{boiling}}). \tag{18.14}$$

The SI units for latent heats of fusion and vaporization are joules per kilogram (J/kg); units of calories per gram (cal/g) are also often used. The latent heat of fusion for a given substance is different from the latent heat of vaporization for that substance. Representative values for melting point, latent heat of fusion, boiling point, and latent heat of vaporization are listed in Table 18.2.

Table 18.2 Some Representative Melting Points, Boiling Points, Latent Heats of Fusion, and Latent Heats of Vaporization

	Melting Point	Latent Heat of Fusion, L_{fusion}		Boiling Point	Latent Heat of Vaporization, $L_{\text{vaporization}}$	
Material	**(K)**	**(kJ/kg)**	**(cal/g)**	**(K)**	**(kJ/kg)**	**(cal/**
Hydrogen	13.8	58.6	14.0	20.3	452	108
Ethyl alcohol	156	104	24.9	351	858	205
Mercury	234	11.3	2.70	630	293	70.0
Water	273	334	79.7	373	2260	539
Aluminum	932	396	94.5	2740	10,500	2500
Copper	1359	205	49.0	2840	4730	1130

It is also possible for a substance to change directly from a solid to a gas. This process is called **sublimation.** For example, sublimation occurs when dry ice, which is solid (frozen) carbon dioxide, changes directly to gaseous carbon dioxide without passing through the liquid state. When a comet approaches the Sun, some of its frozen carbon dioxide sublimates, helping to produce the comet's visible tail.

If we continue to heat a gas, it will become ionized, which means that some or all of the electrons in the atoms of the gas are removed. An ionized gas and its free electrons form a state of matter called a **plasma.** Plasmas are very common in the universe; in fact, as much as 99% of the mass of the Solar System exists in the form of a plasma. The dusty cloud of gas known as the Omega/Swan Nebula (M17), shown in Figure 18.12, is also a plasma.

FIGURE 18.12 Image of the Omega/Swan Nebula (M17), taken by the Hubble Space Telescope, shows an immense region of gas ionized by radiation from young stars.

NASA, ESA and J. Hester (ASU)

As mentioned in Chapter 13, there are other states of matter besides solid, liquid, gas, and plasma. For example, matter in a granular state has specific properties that differentiate it from the four major states of matter. Matter can also exist as a Bose-Einstein condensate in which individual atoms become indistinguishable, under very specific conditions at very low temperatures, as we'll see in Chapter 36 on quantum physics. American physicists Eric Cornell and Carl Wieman, along with German physicist Wolfgang Ketterle, were awarded the Nobel Prize in Physics in 2001 for their studies of a Bose-Einstein condensate.

Cooling an object means reducing the internal energy of the object. As thermal energy is removed from a substance in the gaseous state, the temperature of the gas decreases, in relation to the specific heat of the gas, until the gas begins to condense into a liquid. This change takes place at a temperature called the *condensation point*, which is the same temperature as the boiling point of the substance. To convert all the gas to liquid requires the removal of an amount of heat corresponding to the latent heat of vaporization times the mass of the gas. If thermal energy continues to be removed, the temperature of the liquid will go down, as determined by the specific heat of the liquid, until the temperature reaches the freezing point, which is the same temperature as the melting point of the substance. To convert all of the liquid to a solid requires removing an amount of heat corresponding to the latent heat of fusion times the mass. If heat then continues to be removed from the solid, its temperature will decrease in relation to its specific heat.

Concept Check 18.2

Suppose you raise the temperature of 1 kg of H_2O from $-10\ ^\circ C$ to $+10\ ^\circ C$, of another 1 kg of H_2O from $+20\ ^\circ C$ to $+40\ ^\circ C$, and of another 1 kg of H_2O from $+90\ ^\circ C$ to $+110\ ^\circ C$. Which of the three changes in temperature requires the addition of the most heat?

a) first change

b) second change

c) third change

d) All three changes require the addition of the same amount of heat.

EXAMPLE 18.5 Warming Ice to Water and Water to Steam

PROBLEM

How much heat, Q, is required to convert 0.500 kg of ice (frozen water) at a temperature of $-30\ ^\circ\text{C}$ to steam at $140\ ^\circ\text{C}$?

SOLUTION

We solve this problem in steps, with each step corresponding to either a rise in temperature or a phase change. We first calculate how much heat is required to raise the temperature of the ice from $-30\ ^\circ\text{C}$ to $0\ ^\circ\text{C}$. The specific heat of ice is $2.06\ \text{kJ}/\left(\text{kg K}\right)$, so the heat required is

$$Q_1 = cm\Delta T = \left[2.06\ \text{kJ}/\left(\text{kg K}\right)\right]\left(0.500\ \text{kg}\right)\left(30\ \text{K}\right) = 30.9\ \text{kJ}.$$

We continue to add heat to the ice until it melts. The temperature remains at $0\ ^\circ\text{C}$ until all the ice is melted. The latent heat of fusion for ice is $334\ \text{kJ/kg}$, so the heat required to melt all of the ice is

$$Q_2 = mL_{\text{fusion}} = \left(0.500\ \text{kg}\right)\left(334\ \text{kJ/kg}\right) = 167\ \text{kJ}.$$

Once all the ice has melted to water, we continue to add heat until the water reaches the boiling point, at $100\ ^\circ\text{C}$. The required heat for this step is

$$Q_3 = cm\Delta T = \left[4.19\ \text{kJ}/\left(\text{kg K}\right)\right]\left(0.500\ \text{kg}\right)\left(100\ \text{K}\right) = 209.5\ \text{kJ}.$$

We continue to add heat to the water until it vaporizes. The heat required for vaporization is

$$Q_4 = mL_{\text{vaporization}} = \left(0.500\ \text{kg}\right)\left(2260\ \text{kJ/kg}\right) = 1130\ \text{kJ}.$$

We now warm the steam and raise its temperature from $100\ ^\circ\text{C}$ to $140\ ^\circ\text{C}$. The heat necessary for this step is

$$Q_5 = cm\Delta T = \left[2.01\ \text{kJ}/\left(\text{kg K}\right)\right]\left(0.500\ \text{kg}\right)\left(40\ \text{K}\right) = 40.2\ \text{kJ}.$$

Thus, the total heat required is

$$Q = Q_1 + Q_2 + Q_3 + Q_4 + Q_5$$
$$= 30.9\ \text{kJ} + 167\ \text{kJ} + 209.5\ \text{kJ} + 1130\ \text{kJ} + 40.2\ \text{kJ} = 1580\ \text{k}$$

Figure 18.13 shows a graph of the temperature of the water as a function of the heat added. In region (a), the temperature of the ice increases from $-30\ ^\circ\text{C}$ to $0\ ^\circ\text{C}$. In region (b), the ice melts to water while the temperature remains at $0\ ^\circ\text{C}$. In region (c), the water warms from $0\ ^\circ\text{C}$ to $100\ ^\circ\text{C}$. In region (d), the water boils and changes to steam while the temperature remains at $100\ ^\circ\text{C}$. In region (e), the temperature of the steam increases from $100\ ^\circ\text{C}$ to $140\ ^\circ\text{C}$.

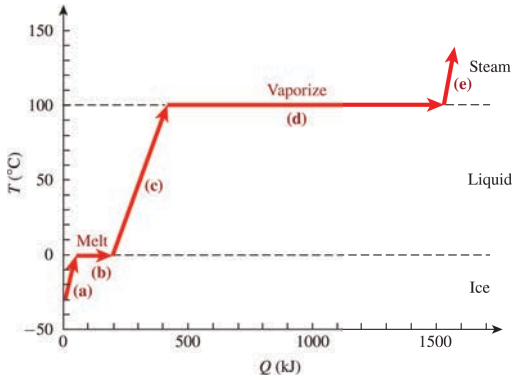

FIGURE 18.13 Plot of temperature versus heat added to change 0.500 kg of ice starting at a temperature of $-30\ ^\circ\text{C}$ to steam at $140\ ^\circ\text{C}$. The horizontal sections of the graph represent the latent heats of the two phase changes. The slopes of the other sections of the graph are the specific heats of water in its three phases (ice, liquid water, and steam).

Note that almost three quarters of the total heat in this entire process of warming the sample from $-30\ ^\circ\text{C}$ to $140\ ^\circ\text{C}$ has to be spent to convert the liquid water to steam in the process of vaporization.

Concept Check 18.3

You have a block of ice of mass m at a temperature of $-3\ ^\circ\text{C}$ in a thermally insulated container and you add the same mass m of liquid water at a temperature of $6\ ^\circ\text{C}$ and let the mixture come to equilibrium. What is the final temperature of the mixture?

a) $-3\ ^\circ\text{C}$

b) $0\ ^\circ\text{C}$

c) $+3\ ^\circ\text{C}$

d) $+4.5\ ^\circ\text{C}$

e) $+6\ ^\circ\text{C}$

EXAMPLE 18.6 Work Done Vaporizing Water

Suppose 10.0 g of water at a temperature of 100.0 °C is in an insulated cylinder equipped with a piston that maintains a constant pressure of $p = 101.3$ kPa. Enough heat is added to the water to vaporize it to steam at a temperature of 100.0 °C. The volume of the water is $V_{\text{water}} = 10.0\ \text{cm}^3$, and the volume of the steam is $V_{\text{steam}} = 16,900\ \text{cm}^3$.

PROBLEM

What is the work done by the water as it vaporizes? What is the change in internal energy of the water?

SOLUTION

This process is carried out at a constant pressure. The work done by the vaporizing water is given by equation 18.3:

$$W = \int_{V_\text{i}}^{V_\text{f}} p dV = p \int_{V_\text{i}}^{V_\text{f}} dV = p\left(V_{\text{steam}} - V_{\text{water}}\right).$$

Putting in the numerical values gives the work done by the water as it increases in volume at a constant pressure:

$$W = \left(101.3 \cdot 10^3\ \text{Pa}\right)\left(16,900\ \cdot 10^{-6}\ \text{m}^3 - 10.0 \cdot 10^{-6}\ \text{m}^3\right) = 17$$

The change in the internal energy of the water is given by the First Law of Thermodynamics (equation 18.4)

$$\Delta E_{\text{int}} = Q - W.$$

In this case, the thermal energy transferred is the heat required to vaporize the water. From Table 18.2, the latent heat of vaporization of water is $L_{\text{vaporization}} = 2260\ \text{kJ/kg}$. Thus, the thermal energy transferred to the water is

$$Q = mL_{\text{vaporization}} = \left(10.0 \cdot 10^{-3}\ \text{kg}\right)\left(2.260 \cdot 10^6\ \text{J/kg}\right) = 22,60$$

The change in the internal energy of the water is then

$$\Delta E_{\text{int}} = 22,600 \text{ J} - 1710 \text{ J} = 20,900 \text{ J}.$$

Most of the added energy remains in the water as increased internal energy. This internal energy is related to the phase change of water to steam. The energy is used to overcome the attractive forces between the water molecules in the liquid state as it changes to the gaseous state.

18.8 Modes of Thermal Energy Transfer

The three main modes of thermal energy transfer are conduction, convection, and radiation. All three are illustrated by the campfire shown in Figure 18.14. **Radiation** is the transfer of thermal energy via electromagnetic waves. You can feel heat radiating from a campfire when you sit near it. **Convection** involves the physical movement of a substance (such as water or air) from thermal contact with one system to thermal contact with another system. The moving substance carries internal energy. You can see the thermal energy rising in the form of flames and hot air above the flames in the campfire. **Conduction** involves the transfer of thermal energy within an object (such as thermal energy transfer along a fire poker whose tip is hot) or the transfer of heat between two (or more) objects in thermal contact. Heat is conducted through a substance by the vibration of atoms and molecules and by motion of electrons. The water and food in the pots on the campfire are heated by conduction. The pots themselves are warmed by convection and radiation.

FIGURE 18.14 A campfire illustrates the three main modes of thermal energy transfer: conduction, convection, and radiation.

Dmitry Naumov/iStock-360/Getty Images

Conduction

Consider a bar of material with cross-sectional area A and length L (Figure 18.15a). This bar is put in physical contact with a thermal reservoir at a hotter temperature, T_{h}, and a thermal reservoir at a colder temperature, T_{c}, which means $T_{\mathrm{h}} > T_{\mathrm{c}}$ (Figure 18.15b). Heat then flows from the reservoir at the higher temperature to the reservoir at the lower temperature. The thermal energy transferred per unit time, P_{cond}, by the bar connecting the two heat reservoirs has been found to be given by

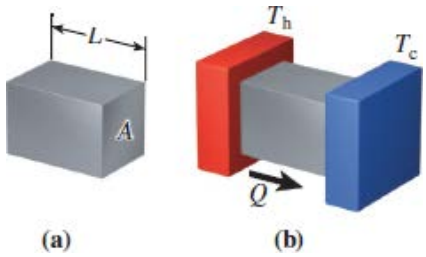

FIGURE 18.15 (a) A bar with cross-sectional area A and length L. (b) The bar is placed between two thermal reservoirs with temperatures T_{h} and T_{c}.

$$P_{\mathrm{cond}} = \frac{Q}{t} = kA\frac{T_{\mathrm{h}} - T_{\mathrm{c}}}{L}, \qquad \textbf{(18.15)}$$

where k is the **thermal conductivity** of the material of the bar. The SI units of thermal conductivity are $\mathrm{W/(m\,K)}$. Some typical values of thermal conductivity are listed in Table 18.3. Note the huge range of conductivities! The highest values are those for forms of pure carbon (diamond, carbon nanotubes, and especially graphene). The coinage metals (silver, gold, and copper) have very high thermal conductivities, but they are an order of magnitude lower than those of the forms of pure carbon. The materials at the bottom of the table (rubber, wood, paper, and polyurethane foam) are used for thermal insulation.

Table 18.3 Some Representative Thermal Conductivities

Material	$k\,[\mathrm{W/(m\,K)}]$
Graphene	5000
Carbon nanotube	3500
Diamond	2000
Silver	420
Copper	390
Gold	320
Aluminum	220
Nickel	91
Iron	80
Lead	35
Stainless steel	20
Granite	3
Ice	2
Limestone	1.3
Concrete	0.8
Glass	0.8
Water	0.5
Rubber	0.16
Wood	0.16
Paper	0.05
Air	0.025
Polyurethane foam	0.02

We can rearrange equation 18.15:

$$P_{\text{cond}} = \frac{Q}{t} = A\frac{T_{\text{h}} - T_{\text{c}}}{L/k} = A\frac{T_{\text{h}} - T_{\text{c}}}{R}, \qquad \textbf{(18.16)}$$

where the **thermal resistance,** R, is defined to be

$$R = \frac{L}{k}. \qquad \textbf{(18.17)}$$

The SI units of R are $\text{m}^2\,\text{K/W}$. A higher R value means a lower rate of thermal energy transfer. A good insulator has a high R value. In the United States, thermal resistance is often specified by an R factor, which has the units $\text{ft}^2\,^\circ\text{F}\,\text{h/BTU}$. A common insulating material with an R factor of R-30 is shown in Figure 18.16. To convert an R factor from $\text{ft}^2\,^\circ\text{F}\,\text{h/BTU}$ to $\text{m}^2\,\text{K/W}$, divide the R factor by 5.678.

(a) (b)

FIGURE 18.16 (a) A common insulating material with an R factor of R-30. (b) Insulation being installed in an attic.

a: Diane39/iStock/Getty Images; **b:** Kuchina/Shutterstock

Self-Test Opportunity 18.2

Show that the conversion factor for changing from $ft^2\ ^\circ F\ h/BTU$ to $m^2\ K/W$ is 5.678.

SOLVED PROBLEM 18.2 Thermal Energy Flow through a Copper/Aluminum Bar

PROBLEM

A copper (Cu) bar of length $L = 90.0\,\text{cm}$ and cross-sectional area $A = 3.00\,\text{cm}^2$ is in thermal contact at one end with a thermal reservoir at a temperature of $100.\,^\circ\text{C}$. The other end of the copper bar is in thermal contact with an aluminum (Al) bar of the same cross-sectional area and a length of 10.0 cm. The other end of the aluminum bar is in thermal contact with a thermal reservoir at a temperature of $1.00\,^\circ\text{C}$. What is the thermal energy flow through the composite bar? The thermal conductivity of the copper is $k_{\text{Cu}} = 386\ \text{W}/(\text{m K})$ and thermal conductivity of the aluminum is $k_{\text{Al}} = 220.\ \text{W}/(\text{m K})$.

SOLUTION

THINK

The thermal energy flow depends on the temperature difference between the two ends of the bar, the length and cross-sectional area of the bar, and the thermal conductivity of the materials. All the heat that flows from the high-temperature end must flow through both the copper and aluminum segments.

SKETCH

Figure 18.17 is a sketch of the copper/aluminum bar.

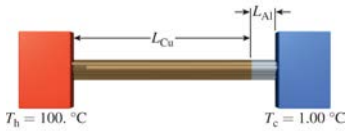

FIGURE 18.17
Copper/aluminum bar held at $100.\,^\circ\text{C}$ at one end and $1.00\,^\circ\text{C}$ at the other end.

RESEARCH

We can use equation 18.15 to describe the thermal energy flow through a bar of length L and cross-sectional area A:

$$P_{\text{cond}} = kA\frac{T_{\text{h}} - T_{\text{c}}}{L}.$$

We have $T_\mathrm{h} = 100.\ ^\circ\mathrm{C}$ and $T_\mathrm{c} = 100.\ ^\circ\mathrm{C}$. We identify the temperature at the interface between the copper and aluminum segments as T. The thermal energy flow through the copper segment is then

$$P_\mathrm{Cu} = k_\mathrm{Cu} A \frac{T_\mathrm{h} - T}{L_\mathrm{Cu}}.$$

The thermal energy flow through the aluminum segment is

$$P_\mathrm{Al} = k_\mathrm{Al} A \frac{T - T_\mathrm{c}}{L_\mathrm{Al}}.$$

The thermal energy flow through the copper segment must equal the thermal energy flow through the aluminum segment, so we have

$$\begin{aligned} P_\mathrm{Cu} &= P_\mathrm{Al} \\ &= k_\mathrm{Cu} A \frac{T_\mathrm{h} - T}{L_\mathrm{Cu}} = k_\mathrm{Al} A \frac{T - T_\mathrm{c}}{L_\mathrm{Al}}. \end{aligned} \qquad \text{(i)}$$

SIMPLIFY

We can solve this equation for T. First, we divide through by A and then multiply both sides by $L_\mathrm{Cu} L_\mathrm{Al}$

$$k_\mathrm{Cu} L_\mathrm{Al} \left(T_\mathrm{h} - T\right) = k_\mathrm{Al} L_\mathrm{Cu} \left(T - T_\mathrm{c}\right).$$

Next, we multiply through on both sides and collect all terms with T on one side:

$$\begin{aligned} k_\mathrm{Cu} L_\mathrm{Al} T_\mathrm{h} - k_\mathrm{Cu} L_\mathrm{Al} T &= k_\mathrm{Al} L_\mathrm{Cu} T - k_\mathrm{Al} L_\mathrm{Cu} T_\mathrm{c} \\ k_\mathrm{Al} L_\mathrm{Cu} T + k_\mathrm{Cu} L_\mathrm{Al} T &= k_\mathrm{Cu} L_\mathrm{Al} T_\mathrm{h} + k_\mathrm{Al} L_\mathrm{Cu} T_\mathrm{c} \\ T\left(k_\mathrm{Al} L_\mathrm{Cu} + k_\mathrm{Cu} L_\mathrm{Al}\right) &= k_\mathrm{Cu} L_\mathrm{Al} T_\mathrm{h} + k_\mathrm{Al} L_\mathrm{Cu} T_\mathrm{c} \\ T &= \frac{k_\mathrm{Cu} L_\mathrm{Al} T_\mathrm{h} + k_\mathrm{Al} L_\mathrm{Cu} T_\mathrm{c}}{k_\mathrm{Cu} L_\mathrm{Al} + k_\mathrm{Al} L_\mathrm{Cu}}. \end{aligned}$$

Substituting this expression for T into equation (i) gives us the thermal energy flow through the copper/aluminum bar.

CALCULATE

Putting in the numerical values gives us

$$\begin{aligned} T &= \frac{k_{\mathrm{Cu}} L_{\mathrm{Al}} T_{\mathrm{h}} + k_{\mathrm{Al}} L_{\mathrm{Cu}} T_{\mathrm{c}}}{k_{\mathrm{Cu}} L_{\mathrm{Al}} + k_{\mathrm{Al}} L_{\mathrm{Cu}}} \\ &= \frac{[386\ \mathrm{W/(m\,K)}]\,(0.100\ \mathrm{m})\,(373\ \mathrm{K}) + [220.\mathrm{W/(m\,K)}]\,(0.900}{[386\ \mathrm{W/(m\,K)}]\,(0.100\ \mathrm{m}) + [220.\mathrm{W/(m\,K)}]\,(0.900} \\ &= 290.1513\ \mathrm{K}. \end{aligned}$$

Putting this result for T into equation (i) gives us the thermal energy flow through the copper segment:

$$\begin{aligned} P_{\mathrm{Cu}} &= k_{\mathrm{Cu}} A \frac{T_{\mathrm{h}} - T}{L_{\mathrm{Cu}}} \\ &= [386\ \mathrm{W/(m\,K)}]\left(3.00 \cdot 10^{-4}\ \mathrm{m}^2\right) \frac{373\ \mathrm{K} - 290.1513\ \mathrm{K}}{0.900\ \mathrm{m}} \\ &= 10.6599\ \mathrm{W}. \end{aligned}$$

ROUND

We report our result to three significant figures:

$$P_{\mathrm{Cu}} = 10.7\ \mathrm{W}.$$

DOUBLE-CHECK

To double-check, let's calculate the thermal energy flow through the aluminum segment:

$$P_{\mathrm{Al}} = k_{\mathrm{Al}} A \frac{T - T_{\mathrm{c}}}{L_{\mathrm{Al}}} = [220\ \mathrm{W/(m\,K)}]\left(3.00 \cdot 10^{-4}\ \mathrm{m}^2\right) \frac{290.1513}{0.1(}$$

This agrees with our result for the copper segment.

EXAMPLE 18.7 Roof Insulation

Suppose you insulate above the ceiling of a room with an insulation material having an R factor of R-30. The ceiling measures 5.00 m by 5.00 m. The temperature inside the room is 21.0 °C, and the temperature above the insulation is 40.0 °C.

PROBLEM

How much heat enters the room through the ceiling in a day if the room is maintained at a temperature of 21.0 °C?

SOLUTION

We solve equation 18.16 for the heat:

$$Q = At\frac{T_\text{h} - T_\text{c}}{R}.$$

Putting in the numerical values, we obtain (1 day has 86,400 s):

$$Q = (5.00\ \text{m} \cdot 5.00\ \text{m})\,(86,400\ \text{s})\frac{313\ \text{K} - 294\ \text{K}}{(30/5.678)\text{m}^2\ \text{K/W}} = 7.77 \cdot 10$$

Concept Check 18.4

If you double the temperature (measured in kelvins) of an object, the thermal energy transferred away from it per unit time will

a) decrease by a factor of 2.

b) stay the same.

c) increase by a factor of 2.

d) increase by a factor of 4.

e) change by an amount that cannot be determined without knowing the temperature of the object's surroundings.

Thermal insulation is a key component of spacecraft that have to reenter the Earth's atmosphere. The reentry process creates thermal energy from friction with air molecules. As a result of the high speed, a shock wave forms in front of the spacecraft, which deflects most of the thermal energy created in the process. However, excellent thermal insulation is still required to prevent this heat from being conducted to the frame of the spacecraft, which is basically made of aluminum and cannot stand temperatures significantly higher than 180 °C. The thermal protection system has to be of very low mass, like all parts of a spacecraft, and must be able to protect the spacecraft from very high temperatures, up to 1650 °C. In the spacecraft for Apollo missions, in which astronauts performed the Moon landings in the late 1960s and 1970s, and in planetary probes like the *Mars Rover*, the heat protection is simply an ablative heat shield, which burns off during entry into the atmosphere. For a reusable spacecraft like the Space Shuttle, such a shield is not an option, because it would require prohibitively expensive maintenance after each trip. The nose and wing edges of the Space Shuttle are instead covered with reinforced carbon, able to withstand the high reentry temperatures. The underside of the Space Shuttle is covered with passive heat protection, consisting of over 20,000 ceramic tiles made of 10% silica fibers and 90% empty space. They are such good thermal insulators that after being warmed to a temperature of 1260 °C (which is the maximum temperature the underside of the Space Shuttle encounters during reentry), they can be held by unprotected hands (see Figure 18.18). Thermal insulation to prevent heat loss is a very important consideration for homeowners. The following solved problem shows how such insulation can directly affect their pocketbooks.

FIGURE 18.18 White-hot $(1260\ ^{\circ}\mathrm{C})$ ceramic tile used for the thermal protection system of the Space Shuttle is held by an unprotected hand.

NASA

SOLVED PROBLEM 18.3 Cost of Warming a House in Winter

You build a small house with four rooms (Figure 18.19a). Each room is 10.0 ft by 10.0 ft, and the ceiling is 8.00 ft high. The exterior walls are insulated with a material with an R factor of R-19, and the floor and ceiling are insulated with a material with an R factor of R-30. During the winter, the average temperature inside the house is 20.0 °C, and the average temperature outside the house is 0.00 °C. You warm the house for 6 months in winter using electricity that costs 9.5 cents per kilowatt-hour.

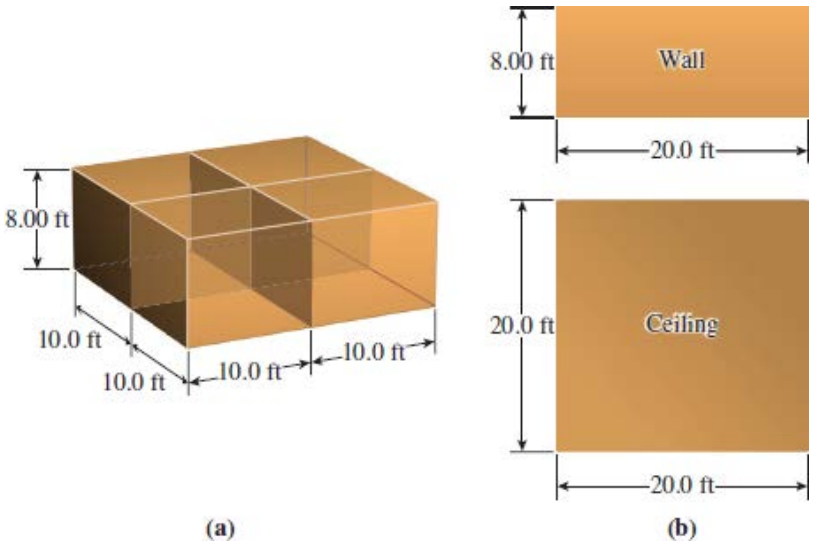

FIGURE 18.19 (a) An insulated four-room house. (b) One wall and the ceiling of the house.

PROBLEM

How much do you pay to warm your house for the winter?

SOLUTION

THINK

Using equation 18.16, we can calculate the total heat lost over 6 months through the walls (R-19) and through the floor and ceiling (R-30). We can then calculate how much it will cost to add this amount of heat to the house.

SKETCH

The dimensions of one wall and the ceiling are shown in Figure 18.19b.

RESEARCH

Each of the four exterior walls, as shown in Figure 18.19b, has an area of A_{wall}. The ceiling has an area of A_{ceiling}, shown in Figure 18.19b. The floor and ceiling have the same area. The thermal resistance of the walls is given by R-19; the thermal resistance of the floor and ceiling is given by R-30. Thus, the thermal resistance of the walls in SI units is

$$R_{\text{wall}} = \frac{19}{5.678}\text{m}^2\text{K/W} = 3.346\,\text{m}^2\text{K/W},$$

and the thermal resistance of the floor and ceiling is

$$R_{\text{celling}} = \frac{30}{5.678}\text{m}^2\text{K/W} = 5.284\,\text{m}^2\text{K/W}.$$

SIMPLIFY

We can calculate the heat lost per unit time using equation 18.16, taking the total area of the walls to be four times the area of one wall and the total area of the floor and ceiling as twice the area of the ceiling:

$$\frac{Q}{t} = 4\,A_{\text{wall}}\left(\frac{T_{\text{h}} - T_{\text{c}}}{R_{\text{wall}}}\right) + 2\,A_{\text{ceiling}}\left(\frac{T_{\text{h}} - T_{\text{c}}}{R_{\text{ceiling}}}\right) = 2\,(T_{\text{h}} - T_{\text{c}})\,($$

CALCULATE

The area of each exterior wall is $A_{\text{wall}} = (8.00\,\text{ft})\,(20.0\,\text{ft}) = 160.0\,\text{ft}^2 = 14.864\,\text{m}^2$. The area of the ceiling is $A_{\text{ceiling}} = (20.0\,\text{ft})\,(20.0\,\text{ft}) = 400.0\,\text{ft}^2 = 37.161\,\text{m}^2$. The number of seconds in 6 months is

$$t = (6\,\text{months})\,(30\,\text{days/month})\,(24\,\text{h/day})\,(3600\,\text{s/h}) = 1.5552$$

The amount of heat lost in 6 months is then

$$
\begin{aligned}
Q &= 2t\left(T_\mathrm{h} - T_\mathrm{c}\right)\left(\frac{2\,A_\mathrm{wall}}{R_\mathrm{wall}} + \frac{A_\mathrm{ceiling}}{R_\mathrm{ceiling}}\right) \\
&= 2\left(1.5552 \cdot 10^7 \mathrm{s}\right)(293\,\mathrm{K} - 273\,\mathrm{K})\left(\frac{2\left(14.864\,\mathrm{m}^2\right)}{3.346\,\mathrm{m}^2\,\mathrm{K/W}} + \frac{37}{5.28}\right. \\
&= 9.902 \cdot 10^9\,\mathrm{J}.
\end{aligned}
$$

Calculating the total cost for 6 months of electricity for warming, we get

$$
\mathrm{Cost} = \left(\frac{\$0.095}{1\,\mathrm{kWh}}\right)\left(\frac{1\,\mathrm{kWh}}{3.60 \cdot 10^6\,\mathrm{J}}\right)\left(9.902 \cdot 10^9\,\mathrm{J}\right) = \$261.3041.
$$

ROUND

Since the input data were given to two significant figures, we report our result to two significant figures as well:

$$
\mathrm{Cost} = \$260.
$$

(However, rounding down the amount on a bill is not acceptable to the utility company, and you would have to pay \$261.30.)

DOUBLE-CHECK

To double-check, let's use the R values the way a contractor in the United States might. The total area of the walls is $4\left(160\,\mathrm{ft}^2\right)$, and the total area of the floor and ceiling is $2\left(400\,\mathrm{ft}^2\right)$. The heat lost per hour through the walls is

$$
\frac{Q}{t} = 4\left(160\,\mathrm{ft}^2\right)\frac{20\left(\frac{9}{5}\right)^\circ\mathrm{F}}{19\,\mathrm{ft}^2\,^\circ\mathrm{F\,h/BTU}} = 1213\,\mathrm{BTU/h}.
$$

The heat lost through the ceiling and floor is

$$
\frac{Q}{t} = 2\left(400\,\mathrm{ft}^2\right)\frac{20\left(\frac{9}{5}\right)^\circ\mathrm{F}}{30\,\mathrm{ft}^2\,^\circ\mathrm{F\,h/BTU}} = 960\,\mathrm{BTU/h}.
$$

The total heat lost in 6 months (4320 h) is

$$
\begin{aligned}
Q &= (4320\,\mathrm{h})\,(1213 + 960)\mathrm{BTU/h} \\
&= 9,387,360\,\mathrm{BTU}.
\end{aligned}
$$

The cost is then

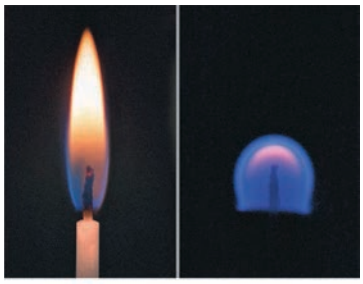
$$\text{Cost} = \left(\frac{\$0.095}{1\,\text{kWh}}\right)\left(\frac{1\,\text{kWh}}{3412\,\text{BTU}}\right)(9,387,360\,\text{BTU}) = \$261.37.$$

This is close to our answer and seems reasonable.

Note that the cost of warming the small house for the winter seems low compared with real-world experience. The lowness of the cost is due to the fact that the house has no doors or windows and is well insulated.

Convection

If you hold your hand above a burning candle, you can feel the thermal energy transferred from the flame. The warmed air is less dense than the surrounding air and rises. The rising air carries thermal energy upward from the candle flame. This type of thermal energy transfer is called *convection*. Figure 18.20 shows a candle flame on Earth and on the orbiting Space Shuttle. You can see that the thermal energy travels upward from the candle burning on Earth but expands almost spherically from the candle aboard the Space Shuttle. The air in the Space Shuttle (actually in a small container on the Space Shuttle) has the same density in all directions, so the warmed air does not have a preferential direction in which to travel. The bottom of the flame on the candle aboard the Space Shuffle is extinguished because the wick carries thermal energy away. (In addition to convection involving a large-scale flow of mass, convection can occur via individual particles in a process called *diffusion*, which is not covered in this chapter.)



(a) (b)

FIGURE 18.20 Candle flames under (a) terrestrial conditions and (b) microgravity conditions.

NASA Glenn Research Center

Most houses and office buildings in the United States have forced-air heating; that is, warm air is blown through heating ducts into rooms. This is an excellent example of thermal energy transfer via convection. The same air ducts are used in the summer for cooling the structures by blowing cooler air through the ducts and into the rooms, which is another example of convective thermal energy transfer. (But, of course, then the heat has the opposite sign, because the temperature in the room is lowered.)

Large amounts of energy are transferred by convection in the Earth's atmosphere and in the oceans. For example, the Gulf Stream carries warm water from the Gulf of Mexico northward through the Straits of Florida and up the east coast of the United States. The warmer temperature of the water in the Gulf Stream is revealed in the NASA satellite image in Figure 18.21. The Gulf Stream has a temperature around 20 °C as it flows with a speed of approximately 2m/s up the east coast of the United States into the North Atlantic. The Gulf Stream then splits. One part continues to flow toward Britain and Western Europe, while the other part turns south along the African coast. The average temperature of Britain and Western Europe is approximately 5 °C higher than it would be without the thermal energy carried by the warmer waters of the Gulf Stream.

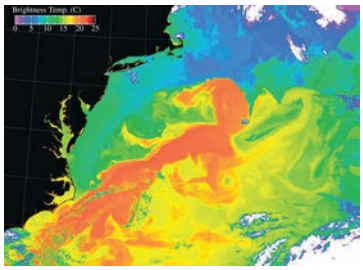


FIGURE 18.21 A satellite image taken by the NASA TERRA satellite on May 5, 2001, uses false colors to show the temperature range of the water in the Atlantic Ocean off the east coast of the United States. The warm Gulf Stream is shown in orange and red, and the east coast of the United States is shown in black.

NASA Goddard Space Flight Center, Visible Earth

Some climate models predict that global warming may possibly threaten the Gulf Stream because of the melting of ice at the North Pole. The extra fresh water from the melting polar ice cap reduces the salinity of the water at the northern end of the Gulf Stream, which interferes with the

mechanism that allows the cooled water from the Gulf Stream to sink and return to the south. Paradoxically, global warming could make Northern Europe colder.

SOLVED PROBLEM 18.4 Gulf Stream

Let's assume that a rectangular pipe of water 100 km wide and 500 m deep can approximate the Gulf Stream. The water in this pipe is moving with a speed of 2.0 m/s. The temperature of the water is 5.0 °C warmer than the surrounding water.

PROBLEM

Estimate how much power the Gulf Stream is carrying to the North Atlantic Ocean.

SOLUTION

THINK

We can calculate the volume flow rate by taking the product of the speed of the flow and the cross-sectional area of the pipe. Using the density of water, we can then calculate the mass flow rate. Using the specific heat of water and the temperature difference between the Gulf Stream water and the surrounding water, we can calculate the power carried by the Gulf Stream to the North Atlantic.

SKETCH

Figure 18.22 shows the idealized Gulf Stream flowing to the northeast in the Atlantic Ocean.

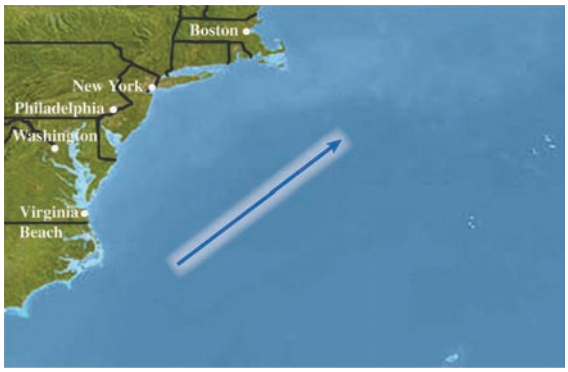

FIGURE 18.22 Idealized Gulf Stream flowing along the eastern coastline of the United States toward the North Atlantic.

RESEARCH

We assume that the Gulf Stream has a rectangular cross section of width $w = 100\,\text{km}$ and depth $d = 500\,\text{m}$. The area of the Gulf Stream flow is then

$$A = wd.$$

The speed of the flow of the Gulf Stream is assumed to be $v = 2.0\,\text{m/s}$. The volume flow rate is given by

$$R_V = vA.$$

The density of seawater is $\rho = 1025\,\text{kg/m}^3$. We can express the mass flow rate as

$$R_m = \rho R_V.$$

The specific heat of water is $c = 4186\,\text{J/ (kg K)}$. The heat required to raise the temperature of a mass m byΔT is given by

$$Q = cm\Delta T.$$

The power carried by the Gulf Stream is equal to the heat per unit time:

$$\frac{Q}{t} = P = \frac{cm\Delta T}{t} = cR_m\Delta T.$$

(*Note:* The capital P symbolizes power; do not confuse this with the lowercase p used for pressure.)

SIMPLIFY

The power carried by the Gulf Stream is given by

$$P = cR_m\Delta T = c\rho R_V\Delta T = c\rho vwd\Delta T.$$

CALCULATE

The temperature difference is $\Delta T = 5\,^\circ\text{C} = 5\,\text{K}$. Putting in the numerical values gives

$$\begin{aligned} P &= [4186\,\text{J/ (kg K)}]\left(1025\,\text{kg/m}^3\right)(2.0\,\text{m/s})\left(100.10^3\,\text{m}\right)(500\,\text{m} \\ &= 2.1453.10^{15}\,\text{W}. \end{aligned}$$

ROUND

We report our result to two significant figures:

$$P = 2.1 \cdot 10^{15}\ \text{W} = 2.1\ \text{PW}\ \left(1\ \text{PW} = 1\ \text{petawatt} = 10^{15}\ \text{W}\right).$$

DOUBLE-CHECK

To double-check this result, let's calculate how much power is incident on the Earth from the Sun. This total power is given by the cross-sectional area of Earth times the power incident on Earth per unit area:

$$P_{\text{total}} = \pi\left(6.4 \cdot 10^{6}\ \text{m}\right)^{2}\left(1400\ \text{W/m}^{2}\right) = 180\ \text{PW}.$$

Let's calculate how much of this power could be absorbed by the Gulf of Mexico. The intensity of sunlight at a distance from the Sun corresponding to the radius of Earth's orbit around the Sun is $S = 1400\ \text{W/m}^2$. We can estimate the area of the Gulf of Mexico as $1.0 \cdot 10^{6}\ \text{km}^2 = 1.0 \cdot 10^{12}\ \text{m}^2$. If the water of the Gulf of Mexico absorbed all the energy incident from the Sun for half of each day, then the power available from the Gulf would be

$$P = \frac{\left(1.0 \cdot 10^{12}\ \text{m}^2\right)\left(1400\ \text{W/m}^2\right)}{2} = 7.0 \cdot 10^{14}\ \text{W} = 0.7\ \text{PW},$$

which is less than our estimate of the power carried by the Gulf Stream. Thus, more of the Atlantic Ocean must be involved in providing energy for the Gulf Stream than just the Gulf of Mexico. In fact, the Gulf Stream gets its energy from a large fraction of the Atlantic Ocean. The Gulf Stream is part of a network of currents flowing in the Earth's oceans, induced by prevailing winds, temperature differences, and the Earth's topology and rotation.

Concept Check 18.5

The power carried by the Gulf Stream could be doubled by

a) decreasing its speed by a factor of 2.

b) decreasing its temperature by a factor of 2.

c) increasing its temperature by a factor of 2.

d) increasing its speed by a factor of 4.

e) none of the above.

Self-Test Opportunity 18.3

List some other convection phenomena encountered in everyday life.

Radiation

Radiation occurs via the transmission of electromagnetic waves. (In Chapter 31, we'll see how electromagnetic waves carry energy; for now, you can just accept this as an empirical fact.) Further, unlike mechanical and sound waves (covered in Chapters 15 and 16), these waves need no medium to support them. Thus, electromagnetic waves can carry energy from one site to another without any matter having to be present between the two sites. One example of the transport of energy via electromagnetic radiation occurs during a cell phone conversation; a cell phone acts as both a transmitter of radiation to the nearest cell tower and a receiver of radiation originating from that tower.

All objects emit electromagnetic radiation in the form of thermal radiation. The temperature of the object determines the radiated power of the object, P_{radiated}, which is given by the **Stefan-Boltzmann equation:**

$$P_{\text{radiated}} = \sigma \varepsilon A T^4, \qquad \textbf{(18.18)}$$

where $\sigma = 5.67 \cdot 10^{-8}\,\text{W/K}^4\text{m}^2$ is called the **Stefan-Boltzmann constant,** ε is the **emissivity,** which has no units, and A is the surface (radiating) area. The temperature in equation 18.18 must be in kelvins, and it is assumed to be constant. The emissivity varies between 0 and 1, with 1 being the emissivity of an idealized object called a **blackbody.** A blackbody radiates 100% of its power, as given by equation 18.18, and absorbs 100% of any radiation incident on it. Although some real-world objects are close to being a blackbody, no perfect blackbodies exist; thus, the emissivity is always less than 1.

The earlier subsection on conduction discussed how the insulating ability of various materials is quantified by the *R* value. The heat loss of a house in winter or the heat gain in summer depends not only on conduction but also on radiation. New building techniques have aimed at increasing the efficiency of house insulation by using radiant barriers. A *radiant barrier* is a layer of material that effectively reflects electromagnetic waves, especially infrared radiation (which is the radiation we usually feel as warmth). The use of radiant barriers in house insulation is illustrated in Figure 18.23.

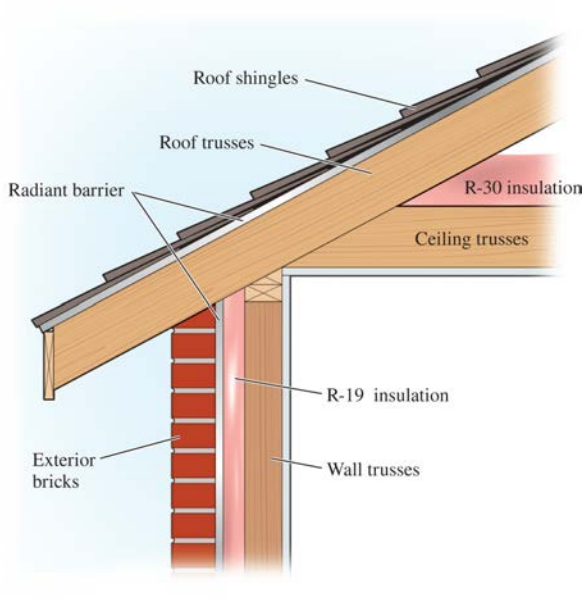

FIGURE 18.23 A schematic drawing of the corner of a house, showing part of the roof, part of the ceiling, and part of a wall. The roof consists of an outer layer of shingles, a radiant barrier, and trusses supporting the roof. The ceiling consists of ceiling trusses supporting insulation with an *R* factor of R-30. The wall consists of exterior bricks, a radiant barrier, insulation with an *R* factor of R-19, and supporting wall trusses.

A radiant barrier is constructed of a reflective substance, usually aluminum. A typical commercial radiant barrier is shown in Figure 18.24. Its material is aluminum-coated polyolefin, which reflects 97% of infrared radiation. Tests by Oak Ridge National Laboratory of houses in Florida with and without radiant barriers have shown that summer heat gains of ceilings with R-19 insulation can be reduced by 16% to 42%, resulting in the reduction of air-conditioning costs by as much as 17%.

FIGURE 18.24 One type of radiant barrier material, ARMA foil, produced by Energy Efficient Solutions.

Courtesy of www.EnergyEfficientSolutions.com

The house illustrated in Figure 18.23 is designed to prevent heat from entering or leaving by conduction through its insulating layers, which have high *R* factors. The radiant barriers block heat from entering the house in the form of radiation. Unfortunately, this type of barrier also prevents the house from being warmed by the Sun in the winter. Heat gain or loss by convection is reduced by the dead space between the ceiling and the roof. Thus, the house is designed to reduce heat gain or loss by any of the three modes of thermal energy transfer: conduction, convection, or radiation. It is relatively straightforward to find out where a house is losing heat due to radiation by taking its picture with an infrared camera. Such images are called *thermograms*, and an example is shown in Figure 18.25. The red areas in the image show that this particular house loses the most heat through its roof, and thus an investment in better roof insulation might be called for.

EXAMPLE 18.8 Earth as a Blackbody

Suppose that the Earth absorbed 100% of the incident energy from the Sun and then radiated all the energy back into space, just as a blackbody would.

PROBLEM

What would the temperature of the surface of Earth be?

SOLUTION

The intensity of sunlight arriving at the Earth is approximately $S = 1400\ \mathrm{W/m^2}$. The Earth absorbs energy as a disk with the radius of the Earth, R, whereas it radiates energy from its entire surface. At equilibrium, the energy absorbed equals the energy emitted:

$$(S)\left(\pi R^2\right) = (\sigma)\,(1)\left(4\pi R^2\right)T^4.$$

Solving for the temperature, we get

$$T = \sqrt[4]{\frac{S}{4\sigma}} = \sqrt[4]{\frac{1400\ \mathrm{W/m^2}}{4\left(5.67 \cdot 10^{-8}\ \mathrm{W/K^4 m^2}\right)}} = 280\ \mathrm{K}.$$

This simple calculation gives a result close to the actual value of the average temperature of the surface of the Earth, which is about 288 K.

Concept Check 18.6

If the temperature (measured in kelvins) of an object is doubled, the heat it radiates per unit time will

a) decrease by a factor of 2.

b) stay the same.

c) increase by a factor of 2.

d) increase by a factor of 4.

e) increase by a factor of 16.

Global Warming

The difference between the temperature calculated for Earth as a blackbody in Example 18.8 and the actual temperature of the Earth's surface is partly due to the Earth's atmosphere, as illustrated in Figure 18.26.

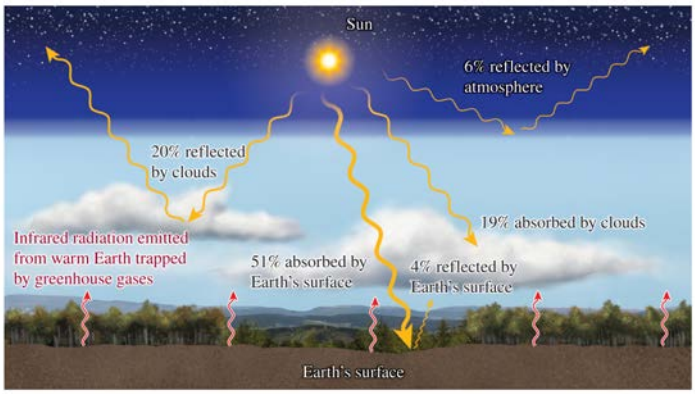

FIGURE 18.26 The Earth's atmosphere strongly affects the amount of energy absorbed by the Earth from the Sun.

Clouds in the Earth's atmosphere reflect 20% and absorb 19% of the Sun's energy. The atmosphere reflects 6% of the Sun's energy, and 4% is reflected by the surface of the Earth. The Earth's atmosphere transmits 51% of the energy from the Sun to the surface of the Earth. This solar energy is absorbed by the surface of the Earth and warms it, causing the surface to give off infrared radiation. Certain gases in the atmosphere—notably water vapor and carbon dioxide, in addition to other gases—absorb some of this infrared radiation, thereby trapping a fraction of the energy that would otherwise be radiated back into space. This trapping of thermal energy is called the **greenhouse effect.** The greenhouse effect keeps the Earth warmer than it would otherwise be and minimizes day-to-night temperature variations.

The two photographs in Figure 18.27 illustrate how radiation of different wavelengths can penetrate materials differently. In Figure 18.27a, a NASA scientist has his arm inside a black plastic bag. The camera was sensitive to visible light, and his arm is not visible inside the bag. In Figure 18.27b, the same person was photographed with the lights off, using a camera sensitive to infrared radiation. The human body emits infrared radiation because its metabolism produces heat. This radiation passes through the black plastic that blocks visible light and the previously concealed arm is visible.

(a)

(b)

FIGURE 18.27 (a) A NASA scientist with his arm inside a black plastic bag, illuminated with visible light. (b) The same NASA scientist photographed with an infrared camera. The scientist radiated infrared radiation that passed through the black plastic bag.

NASA/IPAC/Caltech

The burning of fossil fuels and other human activities have increased the amount of carbon dioxide in the Earth's atmosphere and increase the surface temperature by trapping infrared radiation that would otherwise be emitted into space.

Figure 18.28a shows the concentration of carbon dioxide in the air for the past 400,000 years. For this figure we have combined direct measurement from air samples at Mauna Loa station in Hawaii (green symbols) and the South Pole (orange symbols) with measurements from several ice core samples in Antarctica. Visible in this plot are glacial periods (= ice ages) with relatively low carbon dioxide concentrations around 200 ppmv and interglacial periods with relatively high carbon dioxide concentrations around 275 ppmv. Part (b) of this figure shows the same

data, but displayed only since the year 1000, which highlights the exponential growth of atmospheric CO_2 during the past two centuries. In part (c) of this figure we only display the data since the year 2000. At this resolution one can see the seasonal variation of the CO_2 concentration due to the growing seasons of the plants, mainly in the Northern Hemisphere, where the majority of the Earth's landmass resides. The combination of direct measurements in the last 60 years and inferred concentrations from studies of ice cores indicates that the current concentration of carbon dioxide in the atmosphere is more than 30% higher than at any time in the 400,000 years before the Industrial Revolution (which occurred in the middle of the 18th century). This rise of atmospheric carbon dioxide is human-made and a result of burning fossil fuels. Humans currently alive on Earth have added more greenhouse gases to our planet's atmosphere than all humans before us in the entire history of the world. Some researchers estimate that the current concentration of carbon dioxide is at its highest level in the past 20 million years. Models of the composition of the Earth's atmosphere based on current trends predict that the concentration of carbon dioxide will continue to increase in the next 100 years. This increase in the atmospheric concentration of carbon dioxide contributes to the observed global warming described in Chapter 17. The causal relationship between increased carbon dioxide concentration in the atmosphere and global warming has worried scientists for the past two centuries and was finally proven in the 1960s by Syukuro Manabe, who received the 2021 Nobel Prize in Physics for this achievement.

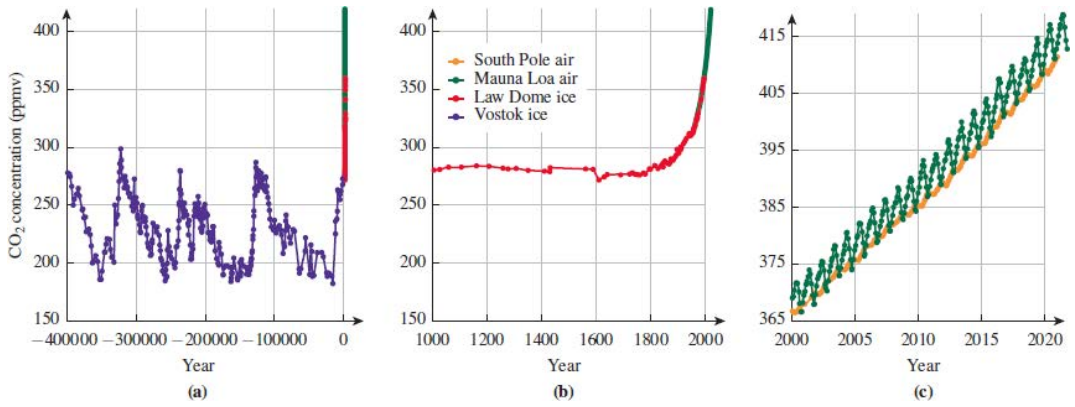

FIGURE 18.28 Concentration of carbon dioxide (CO_2) in the Earth's atmosphere in parts per million by volume (ppmv). (a) Concentration of carbon dioxide in the atmosphere during the last 400,000 years. The measurements shown are from air samples at Mauna Loa in Hawaii (green) and the South Pole (orange) and various ice core samples from Antarctica. (b) Display of the same data as in part (a), but only from 1000 AD to the present. (c) Display of the same data as in part (b), but only from 2000 to the present.

Worldwide, governments are reacting to these observations and predictions in many ways, including the Kyoto Protocol, which went into effect in 2005. In the Kyoto Protocol, signing nations agreed to make substantial cuts in their greenhouse gas emissions by the year 2012. In 2015, this international agreement was followed up by the Paris Agreement, which was signed by 194 nations and the European Union. The stated goal of this agreement is to reduce greenhouse gas emissions in such a way as to limit global warming "to well below 2 degrees C."

Concept Check 18.7

Indicate whether each of the following statements is true (T) or false (F).

1. A cold object will not radiate energy.
2. When heat is added to a system, the temperature must rise.
3. When the Celsius temperature doubles, the Fahrenheit temperature also doubles.
4. The temperature of the melting point is the same as the temperature of the freezing point.

Heat in Computers

Thinking about thermal energy transfer may not bring your computer to mind right away. But cooling a computer is a major engineering problem. A typical desktop computer consumes between 100 and 150 W of electrical power, and a laptop uses between 25 and 70 W. As a general guideline, the higher the computer chips' frequency, the higher the power consumption. Most of this electrical power is converted into thermal energy and has to be removed from the computer. To accomplish this, computers have passive heat sinks, which consist of pieces of metal with large surface areas attached to the parts of the computer in need of cooling, mainly CPU and graphics chips (Figure 18.29). Passive heat sinks apply conduction to move the thermal energy away from the computer parts and then radiation to transfer the thermal energy to the surrounding air. An active heat sink includes a small fan to move more air past the metal surfaces to increase the thermal energy transfer. Of course, the fan also consumes electrical power and thus reduces the charge period of the battery in laptop computers.

FIGURE 18.29 Active and passive heat sink technology mounted on a computer CPU.

David J. Green - technology/Alamy Stock Photo

While it may be only a slight annoyance to have a laptop computer warming your lap, cooling large computer clusters in data centers is very expensive. If a server farm contains 10,000 individual CPUs, its electrical power consumption is on the order of 1 MW, most of which is transformed to heat that has to be removed by very large air-conditioning systems. Thus, development of more efficient computer components, from power supplies

to CPU chips, and more efficient cooling methods is currently the focus of much research.

Geothermal Power Resources

Earth has a solid inner core with a radius of approximately 1200 km, predominantly composed of iron (80%) and nickel. The inner core is encased by a liquid outer core with a radius of about 3400 km. Around the outer core is the mantle, which is mainly composed of oxygen, silicon, and magnesium and has a thickness of about 2800–2900 km. Earth's outermost layer is the crust, composed of solid tectonic plates with a thickness between 5 km and 70 km. Figure 18.30 shows these layers inside Earth.

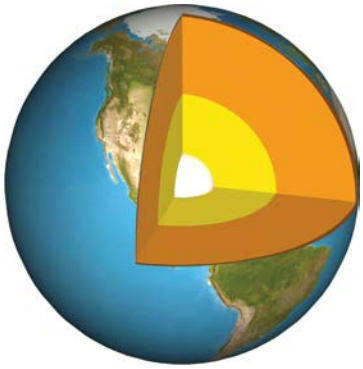

FIGURE 18.30
Structure of the Earth's interior (drawn to approximate scale), showing (from inside to outside) solid inner iron core, liquid outer core, mantle, and the comparatively thin crust.

Currently, the best estimate of the temperature at Earth's center is approximately 6000 K. This high temperature is mainly due to the radioactive decay of very long-lived isotopes of uranium, potassium, and thorium (radioactive decay is discussed in Chapter 40). The average surface temperature of Earth is approximately 290 K, so a very important question is how Earth's temperature varies with depth. Near the edges of the tectonic plates, relatively high temperatures can be found fairly close to the surface; these are the source of volcanic events. Away from the plate edges, however, a simple rule of thumb is that the temperature in the crust

increases by 25–30 K per kilometer of depth. This number is called the *geothermal gradient*. The temperature at the boundary between crust and mantle is between 800 K and 1200 K. Figure 18.31 shows the expected temperatures at a depth of 6 km below ground level in the continental United States.

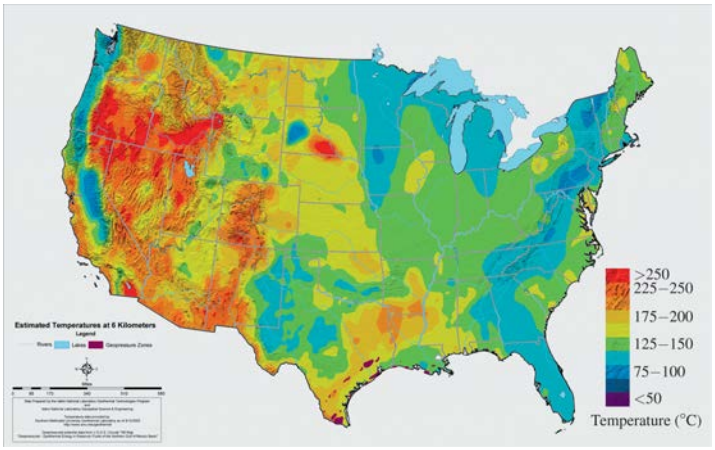

FIGURE 18.31 Estimated temperatures at a depth of 6 km below ground level in the continental United States.

INL and SMU

EXAMPLE 18.9 Estimate of Earth's Internal Thermal Energy

Since Earth's core and mantle are at very high temperatures relative to its surface, there must be a lot of thermal energy available inside Earth.

PROBLEM

What is the thermal energy stored in Earth's interior?

SOLUTION

Obviously, we can make only a rough estimate, because the exact radial temperature profile of Earth is not known. Let's assume an average temperature of 3000 K, which is approximately half of the difference between the surface and core temperatures.

The specific heats (see Table 18.1) for the materials in the Earth's interior range from $0.45\,\mathrm{kJ/(kg\,K)}$ for iron to $0.92\,\mathrm{kJ/(kg\,K)}$ for rocks in the crust. In order to make our estimate, we will use an average value of $0.7\,\mathrm{kJ/(kg\,K)}$. The total mass of Earth is (see Table 12.1) $5.97 \cdot 10^{24}\,\mathrm{kg}$.

Inserting the numbers into equation 18.12, we find

$$Q_{\text{Earth}} = m_{\text{Earth}} c \Delta T = \left(6.10^{24}\,\mathrm{kg}\right)\left[0.7\,\mathrm{kJ/(kg\,K)}\right](3000\,\mathrm{K}) = 1$$

Does it matter that some part of Earth's core is liquid and not solid? Should we account for the latent heat of fusion in our estimate? The answer is yes, in principle, but since the latent heat of fusion for metals is typically on the order of a few hundred kilojoules per kilogram, it would contribute only 10–20% of what the specific heat does in this case. For our order-of-magnitude estimate, we can safely neglect this contribution.

Since the interior of Earth is hotter than the surface, we expect heat to flow to the surface from the interior. How much heat flows per time unit cannot be determined solely from our estimate in Example 18.9. However, analysis of available data shows a global average of $87\,\mathrm{mW/m^2}$ ($65\,\mathrm{mW/m^2}$ for the continents and $101\,\mathrm{mW/m^2}$ for the oceans). Since the

surface area of Earth is approximately $5.1 \cdot 10^{14}$ m^2, a total power of 44 TW emerges from below our feet. (For comparison, the entire power consumption of all humans is currently almost 16 TW. On the other hand, 44 TW represents only approximately 0.025% of the 175 PW of solar energy incident on Earth.)

Thus, tremendously large thermal resources are available in Earth's interior, and there is a huge flow of heat through the Earth's surface. The question is how to use these resources. In some countries, utilization of geothermal power is quite actively pursued; foremost among them is Iceland. Iceland has the advantage of being located where the Earth's crust is very thin; thus, the thermal resources of the Earth's interior can be tapped into comparatively easily. Five large geothermal power plants, like the one depicted in Figure 18.32, supply 25% of Iceland's electrical power and almost 90% of its hot water and home heating.

FIGURE 18.32 Nesjavellir Geothermal Power Station in Southwest Iceland, which generates 120 MW of electrical power.

Poelzer Wolfgang/Alamy Stock Photo

SOLVED PROBLEM 18.5 Enhanced Geothermal System

One way to tap into Earth's geothermal resources is by means of an *enhanced geothermal system* (EGS), in which two or more holes are drilled to a depth of several kilometers and then water is forced down one of the holes. If enough pressure is applied, the bedrock at the bottom of that borehole will develop small fissures that allow the water to percolate to the other borehole(s). This process is known as *hydraulic fracking*, or simply *fracking*. On the way through the bedrock, the water warms up to the temperature of that rock and emerges from the other borehole(s) as hot water or steam.

PROBLEM

How much thermal power does an enhanced geothermal system deliver, if it circulates 12.5 L of water per second and the water is heated from 35.1 °C to 126.5 °C?

SOLUTION

THINK

We are asked to calculate the power, which is defined as energy per unit time. We are given the flow rate, which we can translate into mass per unit time. From this mass rate and the temperature difference, we can calculate the heat transported to the surface by the water per unit time, which is our answer.

SKETCH

Figure 18.33 shows an enhanced geothermal system with three boreholes. The cold water is represented in blue, and the hot water or steam in red.

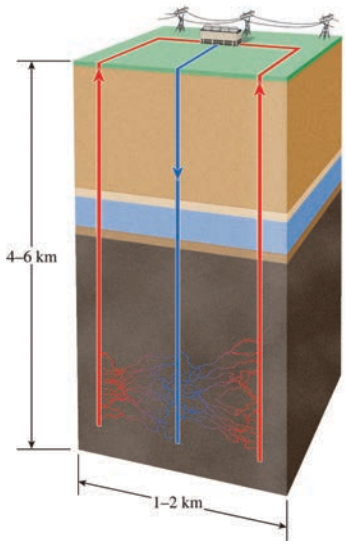

FIGURE 18.33
Diagram of an enhanced geothermal system.

RESEARCH

In Example 18.5, we found the heat required to raise the temperature of water through the phase change of vaporization. Following the approach of that example, we can calculate the heat required to raise the temperature of some mass, m, of water from T_1 to T_2:

$$Q = Q_1 + Q_2 + Q_3 = c_{\text{water}} m\,(100\ ^\circ\text{C} - T_1) + mL_{\text{vaporization}} + c_{\text{}}$$

The average power is given by $\overline{P} = \Delta Q/\Delta t$, where ΔQ is

$$\Delta Q = [c_{\text{water}}\,(100\ ^\circ\text{C} - T_1) + L_{\text{vaporization}} + c_{\text{steam}}\,(T_2 - 100\ ^\circ\text{C})]$$

We know the volume flow rate, $R_{\text{V,}}$ which is related to the mass flow rate, $R_m \equiv \Delta m/\Delta t$, via $R_m = R_{V\rho}$, where ρ is the mass density of water.

SIMPLIFY

We can put all of the above together to obtain an expression for the average thermal power delivered by this system:

$$\begin{aligned}\overline{P} &= \frac{\Delta Q}{\Delta t} = [c_{\text{water}}\,(100\ ^\circ\text{C} - T_1) + L_{\text{vaporization}} + c_{\text{steam}}\,(T_2 - 10(\\ &= [c_{\text{water}}\,(100\ ^\circ\text{C} - T_1) + L_{\text{vaporization}} + c_{\text{steam}}\,(T_2 - 100\ ^\circ\text{C})]R\end{aligned}$$

CALCULATE

Now we insert the numerical values:

$$\begin{aligned}\overline{P} &= ([4.19\,\text{kJ}/\,(\text{kg K})]\,(100\ ^\circ\text{C} - 35.1\ ^\circ\text{C}) + (2260\,\text{kJ/kg}) + [2.(\\ &\quad (12.5\,\text{L/s})\,(1.00\,\text{kg/L})\\ &= (272\,\text{kJ/kg} + 2260\,\text{kJ/kg} + 53.3\,\text{kJ/kg})\,(12.5\,\text{kg/s})\\ &= 3.231625 \cdot 10^7\,\text{J/s}.\end{aligned}$$

ROUND

We round to three significant digits and obtain $\overline{P} = 32.3\,\text{MW}$.

DOUBLE-CHECK

Can we really expect to get 32.3 MW from this enhanced geothermal system? Not quite, because we have only determined the thermal power. Converting this power into electrical power leads to losses of more than 50%. In addition, the system's pumps and other equipment consume significant power. Thus, we can say that this system could deliver 5–10 MW, which is within the range of existing systems in operation around the world. Note that the main contribution to the power from this system arises from the latent heat of vaporization; this shows the importance of drilling into rock that is hot enough to generate steam, that is, at least 100 °C. But, as Figure 18.31 shows, this condition can be met in most of the continental United States, if the boreholes are drilled to a depth of 6 km.

As Solved Problem 18.5 shows, enhanced geothermal systems can make a significant contribution toward solving the global energy problem. To be sure, there are some risks involved in operating EGS power plants. For example, there have been instances of induced seismism (earthquake activity), and it is not entirely clear how much groundwater can be contaminated by the fracking process. However, recent experiments have used CO_2 as the pumping fluid instead of water, which has the advantages of contributing to carbon sequestration and avoiding the loss of water that is inherent in the fracking process.

WHAT WE HAVE LEARNED EXAM STUDY GUIDE

- Heat is energy transferred between a system and its environment or between two systems because of a temperature difference between them.
- A calorie is defined in terms of the joule: $1\text{ cal} = 4.186\text{ J}$.
- The work done by a system in going from an initial volume V_i to a final volume V_f is $W = \int dW = \int_{V_\text{i}}^{V_\text{f}} p dV$.
- The First Law of Thermodynamics states that the change in internal energy of a closed system is equal to the heat flowing into a system minus the work done by the system, or $\Delta E_\text{int} = Q - W$. The First Law of Thermodynamics states that energy in a closed system is conserved.
- An adiabatic process is one in which $Q = 0$.
- In a constant-volume process, $W = 0$.
- In a closed-loop process, $Q = W$.
- In an adiabatic free expansion, $Q = W = \Delta E_\text{int} = 0$.
- If heat, Q, is added to an object, its change in temperature, ΔT, is given by $\Delta T = \dfrac{Q}{C}$, where C is the heat capacity of the object.
- If heat, Q, is added to an object with mass m, its change in temperature, ΔT, is given by $\Delta T = \dfrac{Q}{cm}$, where c is the specific heat of the substance of which the object is made.
- The energy required to melt a solid to a liquid, divided by its mass, is the latent heat of fusion, L_fusion. During the melting process, the temperature of the system remains at the melting point, $T = T_\text{melting}$.
- The energy required to vaporize a liquid to a gas, divided by its mass, is the latent heat of vaporization, $L_\text{vaporization}$. During the vaporization process, the temperature of the system remains at the boiling point, $T = T_\text{boiling}$.

- If a bar of cross-sectional area A is placed between a thermal reservoir with temperature T_h and a thermal reservoir with temperature T_c, where $T_\text{h} > T_\text{c}$, the rate of heat through the bar is

$P_{\text{cond}} = \frac{Q}{t} = A\frac{T_\text{h} - T_\text{c}}{R}$, where R is the thermal resistance of the material of the bar.

- The radiated power from an object with temperature T and surface area A is given by the Stefan-Boltzmann equation: $P_{\text{radiated}} = \sigma\varepsilon AT^4$, where $\sigma = 5.67 \cdot 10^{-8}\ \text{W}/\text{K}^4\text{m}^2$ is the Stefan-Boltzmann constant and ε is the emissivity.

ANSWERS TO SELF-TEST OPPORTUNITIES

18.1 The work is negative.

18.2

$$\left(\frac{1\,\mathrm{m^2\,K}}{1\,\mathrm{W}}\right)\left(\frac{(3.2808)^2\,\mathrm{ft^2}}{\mathrm{m^2}}\right)\left(\frac{\frac{9}{5}\,^\circ\mathrm{F}}{1\,\mathrm{K}}\right)\left(\frac{1\,\mathrm{W\,s}}{1\,\mathrm{J}}\right)\left(\frac{1055\,\mathrm{J}}{1\,\mathrm{BTU}}\right)\left(\frac{1\,\mathrm{h}}{3600\,\mathrm{s}}\right)$$

$$= 5.678\frac{\mathrm{ft^2\,^\circ F\,h}}{\mathrm{BTU}}.$$

18.3 thunderstorms, jet stream, heating water in a pan, heating a house

PROBLEM-SOLVING GUIDELINES

1. When using the First Law of Thermodynamics, always check the signs of work and heat. In this book, work done on a system is positive, and work done by a system is negative; heat added to a system is positive, and heat given off to a system is negative. Some books define the signs of work and heat differently; be sure you know what sign convention applies for a particular problem.

2. Work and heat are path-dependent quantities, but a system's change in internal energy is path-independent. Thus, to calculate a change in internal energy, you can use any processes that start from the same initial position and end at the same final position in a pV-diagram. Work and heat may vary, depending on the path in the diagram, but their difference, $Q - W$, will remain the same. For these kinds of problems, be sure to clearly define the system and identify the initial and final conditions for each step of a process.

3. For calorimetry problems, conservation of energy demands that transfers of energy sum to zero. In other words, heat gained by one system must equal heat lost by the surroundings or some other system. This fact sets up the basic equation describing any transfer of heat between systems or objects.

4. For calculating amounts of heat and corresponding temperature changes, remember that specific heat refers to a heat change per unit mass of a substance, corresponding to a temperature change; for an object of known mass, you need to use the heat capacity. Also be aware of the possibility of a phase change. If a phase change is possible, break up the heat transfer process into steps, calculating heat corresponding to temperature changes and latent heat corresponding to phase changes. Remember that temperature changes are always final temperature minus initial temperature.

5. Be sure to check calorimetry calculations against reality. For example, if a final temperature is higher than an initial temperature, even though heat was extracted from a system, you may have overlooked a phase change.

MULTIPLE-CHOICE QUESTIONS

18.1 A 2.0-kg metal object with a temperature of 90 $^\circ$C is submerged in 1.0 kg of water at 20 $^\circ$C. The water-metal system reaches equilibrium at 32 $^\circ$C. What is the specific heat of the metal?

a) 0.840 kJ/ (kg K)

b) 0.129 kJ/ (kg K)

c) 0.512 kJ/ (kg K)

d) 0.433 kJ/ (kg K)

18.2 A gas enclosed in a cylinder by a piston that can move without friction is warmed, and 1000 J of heat enters the gas. Assuming that the volume of the gas is constant, the change in the internal energy of the gas is

a) 0.

b) 1000 J.

c) -1000 J.

d) none of the above.

18.3 In the isothermal compression of a gas, the volume occupied by the gas is decreasing, but the temperature of the gas remains constant. In order for this to happen,

a) heat must enter the gas.

b) heat must exit the gas.

c) no heat exchange should take place between the gas and the surroundings.

18.4 Which surface should you set a pot on to keep it hotter for a longer time?

a) a smooth glass surface

b) a smooth steel surface

c) a smooth wood surface

d) a rough wood surface

18.5 Assuming that the severity of a burn increases as the amount of energy put into the skin increases, which of the following would cause the most severe burn (assume equal masses)?

a) water at 90 $^\circ$C

b) copper at 110 $^\circ$C

c) steam at 180 $^\circ$C

d) aluminum at 100 $^\circ$C

e) lead at 100 $^\circ$C

18.6 In which type of process is no work done on a gas?

a) isothermal

b) isochoric

c) isobaric

d) none of the above

18.7 An aluminum block of $m_{\mathrm{Al}} = 2.0\ \mathrm{kg}$ and specific heat $c_{\mathrm{Al}} = 910\ \mathrm{J/(kg\ K)}$ is at an initial temperature of 1000 °C and is dropped into a bucket of water. The water has mass $m_{\mathrm{H_2O}} = 12\ \mathrm{kg}$ and specific heat $c_{\mathrm{H_2O}} = 4190\ \mathrm{J/(kg\ K)}$ and is at room temperature (25 $^\circ$C). What is the approximate final temperature of the system when it reaches thermal equilibrium? (Neglect heat loss out of the system.)

a) 50 $^\circ$C

b) 60 $^\circ$C

c) 70 $^\circ$C

d) 80 $^\circ$C

18.8 A material has mass density ρ, volume V, and specific heat c. Which of the following is a correct expression for the heat exchange that occurs when the material's temperature changes by ΔT in degrees Celsius?

a) $(\rho c/V)\Delta T$

b) $(\rho c V)\,(\Delta T + 273.15)$

c) $(\rho c V)/\Delta T$

d) $\rho c V \Delta T$

18.9 Which of the following *does not* radiate heat?

a) ice cube

b) liquid nitrogen

c) liquid helium

d) a device at $T = 0.010\ \mathrm{K}$

e) all of the above

f) none of the above

18.10 Which of the following statements is (are) true?

a) When a system does work, its internal energy always decreases.

b) Work done on a system always decreases its internal energy.

c) When a system does work on its surroundings, the sign of the work is always positive.

d) Positive work done on a system is always equal to the system's gain in internal energy.

e) If you push on the piston of a gas-filled cylinder, the energy of the gas in the cylinder will increase.

18.11 How much thermal energy is needed to raise the temperature of a 3.0-kg copper block from $25.0\ ^\circ\mathrm{C}$ to $125\ ^\circ\mathrm{C}$?

a) 116 kJ

b) 278 kJ

c) 421 kJ

d) 576 kJ

e) 761 kJ

18.12 How much thermal energy is needed to melt a 3.0-kg copper block that is initially at a temperature of 1359 K?

a) 101 kJ

b) 221 kJ

c) 390 kJ

d) 615 kJ

e) 792 kJ

18.13 Suppose you raise the temperature of 1 kg of water from $-10\ ^\circ\mathrm{C}$ to $+10\ ^\circ\mathrm{C}$, then from $+20\ ^\circ\mathrm{C}$ to $+40\ ^\circ\mathrm{C}$, and finally from $+90\ ^\circ\mathrm{C}$ to $+110\ ^\circ\mathrm{C}$. Which of the three changes in temperature requires the addition of the *least* heat?

a) first change

b) second change

c) third change

d) All of the changes require the same amount of heat.

18.14 The seasonal variations in atmospheric CO_2 concentration shown in Figure 18.28 are caused by

a) the plant growth cycle, in which the plants in the Northern Hemisphere have the greater effect.

b) the plant growth cycle, in which the plants in the Southern Hemisphere have the greater effect.

c) the power usage of humans, which is much higher for the developed countries in the Northern Hemisphere.

d) the power usage of humans, which is much higher for the rapidly developing countries in the Southern Hemisphere.

CONCEPTUAL QUESTIONS

18.15 Estimate the power radiated by an average person. (Approximate the human body as a cylindrical blackbody.)

18.16 Several days after the end of a snowstorm, the roof of one house is still completely covered with snow, and another house's roof has no snow cover. Which house is most likely better insulated?

18.17 Why does tile feel so much colder to your feet after a bath than a bath rug? Why is this effect more striking when your feet are cold?

18.18 Can you think of a way to make a blackbody, a material that absorbs essentially all of the radiant energy falling on it, if you only have a material that reflects half the radiant energy that falls on it?

18.19 In 1883, the volcano on Krakatau Island in the Pacific erupted violently in the largest explosion in Earth's recorded history, destroying much of the island in the process. Global temperature measurements indicate that this explosion reduced the average temperature of Earth by about 1 $^\circ$C during the next two decades. Why?

18.20 Fire walking is practiced in parts of the world for various reasons and is also a tourist attraction at some seaside resorts. How can a person walk across hot coals at a temperature well over 500 $^\circ$F without burning his or her feet?

18.21 Why is a dry, fluffy coat a better insulator than the same coat when it is wet?

18.22 It has been proposed that global warming could be offset by dispersing large quantities of dust in the upper atmosphere. Why would this work, and how?

18.23 A thermos bottle fitted with a piston is filled with a gas. Since the thermos bottle is well insulated, no heat can enter or leave it. The piston is pushed in, compressing the gas.

a) What happens to the pressure of the gas? Does it increase, decrease, or stay the same?

b) What happens to the temperature of the gas? Does it increase, decrease, or stay the same?

c) Do any other properties of the gas change?

18.24 How would the rate of heat transfer between a thermal reservoir at a higher temperature and one at a lower temperature differ if the reservoirs

were in contact with a 10-cm-long glass rod instead of a 10-m-long aluminum rod having an identical cross-sectional area?

18.25 Why might a hiker prefer a plastic bottle to an old-fashioned aluminum canteen for carrying his drinking water?

18.26 A girl has discovered a very old U.S. silver dollar and is holding it tightly in her little hands. Suppose that she put the silver dollar on the wooden (insulating) surface of a table, and then a friend came in from outside and placed on top of the silver dollar an equally old penny that she just found in the snow, where it had been left all night. Estimate the final equilibrium temperature of the system of the two coins in thermal contact.

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Sections 18.2 and 18.3

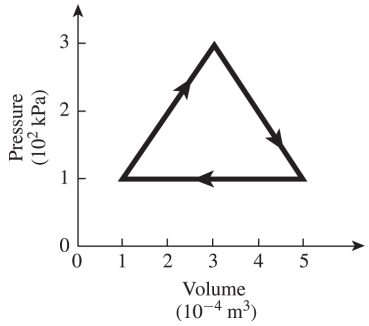
18.27 You are going to lift an elephant $\left(\text{mass} = 5.0 \cdot 10^3 \text{ kg}\right)$ over your head (2.0 m vertical displacement).

a) Calculate the work required to do this. You will lift the elephant slowly (no tossing of the elephant allowed!). If you want, you can use a pulley system. (As you saw in Chapter 5, this does not change the energy required to lift the elephant, but it definitely reduces the force required to do so.)

b) How many doughnuts (250 food calories each) must you metabolize to supply the energy for this feat?

18.28 A gas has an initial volume of 2.00 m^3. It is expanded to three times its original volume through a process for which $P = \alpha V^3$, with $\alpha = 4.00 \text{ N/m}^{11}$. How much work is done by the expanding gas?

18.29 How much work is done per cycle by a gas following the path shown on the pV-diagram?



Sections 18.4 and 18.5

18.30 The internal energy of a gas is 500. J. The gas is compressed adiabatically, and its volume decreases by 100. cm^3. If the pressure applied on the gas during compression is 3.00 atm, what is the internal energy of the gas after the adiabatic compression?

Section 18.6

18.31 You have 1.00 cm^3 of each of the materials listed in Table 18.1 except ice and steam, all at room temperature, 22.0 °C. Which material has the highest temperature after 1.00 J of thermal energy is added to each sample? Which has the lowest temperature? What are these temperatures?

18.32 Suppose you mix 7.00 L of water at $2.00 \cdot 10^1$ °C with 3.00 L of water at 32.0 °C; the water is insulated so that no energy can flow into it or out of it. (You can achieve this, approximately, by mixing the two fluids in a foam cooler of the kind used to keep drinks cool for picnics.) The 10.0 L of water will come to some final temperature. What is this final temperature?

18.33 A 25.0-g piece of aluminum at 85.0 °C is dropped in 1.00 L of water at $1.00 \cdot 10^1$ °C, which is in an insulated beaker. Assuming that there is negligible heat loss to the surroundings, determine the equilibrium temperature of the system.

18.34 A 12.0-g lead bullet is shot with a speed of 250. m/s into a wooden wall. Assuming that 75.0% of the kinetic energy is absorbed by the bullet as heat (and 25.0% by the wall), what is the final temperature of the bullet?

•**18.35** A 1.00-kg block of copper at 80.0 °C is dropped into a container with 2.00 L of water at 10.0 °C. Compare the magnitude of the change in energy of the copper to the magnitude of the change in energy of the water. Which value is larger?

•**18.36** A 1.19-kg aluminum pot contains 2.31 L of water. Both pot and water are initially at 19.7 °C. How much heat must flow into the pot and the water to bring their temperature up to 95.0 °C? Assume that the effect of water evaporation during the heating process can be neglected and that the temperature remains uniform throughout the pot and the water.

•**18.37** A metal brick found in an excavation was sent to a testing lab for nondestructive identification. The lab weighed the brick and found its mass to be 3.00 kg. The brick was heated to a temperature of 300. °C and dropped into an insulated copper calorimeter of mass 1.50 kg containing 2.00 kg of water at 20.0 °C. The final temperature at equilibrium was 31.7 °C. By calculating the specific heat from this data, can you identify the metal of which the brick is made?

•**18.38** A $2.00 \cdot 10^2$ g piece of copper at a temperature of 450. K and a $1.00 \cdot 10^2$ g piece of aluminum at a temperature of $2.00 \cdot 10^2$ K are dropped into an insulated bucket containing $5.00 \cdot 10^2$ g of water at 280. K. What is the equilibrium temperature of the mixture?

•• **18.39** When an immersion glass thermometer is used to measure the temperature of a liquid, the temperature reading will be affected by an

error due to heat transfer between the liquid and the thermometer. Suppose you want to measure the temperature of 6.00 mL of water in a Pyrex glass vial thermally insulated from the environment. The empty vial has a mass of 5.00 g. The thermometer you use is made of Pyrex glass as well and has a mass of 15.0 g, of which 4.00 g is the mercury inside the thermometer. The thermometer is initially at room temperature ($20.0\ ^\circ\mathrm{C}$). You place the thermometer in the water in the vial, and after a while, you read an equilibrium temperature of $29.0\ ^\circ\mathrm{C}$. What was the actual temperature of the water in the vial *before* the temperature was measured? The specific heat of Pyrex glass around room temperature is 800. $\mathrm{J/(kg\ K)}$ and that of liquid mercury at room temperature is 140. $\mathrm{J/(kg\ K)}$.

Section 18.7

•**18.40** Suppose 400. g of water at 30.0 °C is poured over a 60.0-g cube of ice with a temperature of −5.00 °C. If all the ice melts, what is the final temperature of the water? If all of the ice does not melt, how much ice remains when the water-ice mixture reaches equilibrium?

18.41 A person gave off 180. kcal of heat to evaporate water from her skin in a workout session. How much water did the person lose, assuming that the heat given off was used only to evaporate the water?

18.42 A 1.30-kg block of aluminum at 21.0 °C is to be melted and reshaped. How much heat must flow into the block in order to melt it?

18.43 The latent heat of vaporization of liquid nitrogen is about 200. kJ/kg. Suppose you have 1.00 kg of liquid nitrogen boiling at 77.0 K. If you supply heat at a constant rate of 10.0 W via an electric heater immersed in the liquid nitrogen, how long will it take to vaporize all of it? What is the time required to vaporize 1.00 kg of liquid helium, whose heat of vaporization is 20.9 kJ/kg?

•**18.44** Suppose 0.0100 kg of steam (at 100.00 °C) is added to 0.100 kg of water (initially at 19.0 °C). The water is inside an aluminum cup of mass 35.0 g. The cup is inside a perfectly insulated calorimetry container that prevents heat exchange with the outside environment. Find the final temperature of the water after equilibrium is reached.

•**18.45** Suppose $1.00 \cdot 10^2$ g of molten aluminum at 932 K is dropped into 1.00 L of water at room temperature, 22.0 °C.

a) How much water will boil away?

b) How much aluminum will solidify?

c) What will be the final temperature of the water-aluminum system?

d) Suppose the aluminum were initially at 1150 K. Could you still solve this problem using only the information given? What would be the result?

•**18.46** In one of your rigorous workout sessions, you lost 150. g of water through evaporation. Assume that the amount of work done by your body was $1.80 \cdot 10^5$ J and that the heat required to evaporate the water came from your body.

a) Find the loss in internal energy of your body, assuming that the latent heat of vaporization is $2.42 \cdot 10^6$ J/kg.

b) Determine the minimum number of food calories that must be consumed to replace the internal energy lost (1 food calorie = 4186 J).

•• **18.47** Knife blades are often made of hardened carbon steel. In the hardening process, the blade is first heated to a temperature of 1346 $^\circ$F and then cooled down rapidly by immersing it in a bath of water. To achieve the desired hardness, a blade needs to be brought from 1346 $^\circ$F to a temperature below 500. $^\circ$F. If a blade has a mass of 0.500 kg and the water is in an open copper container of mass 2.000 kg and sufficiently large volume, what is the minimum quantity of water that needs to be in the container for this hardening process to be successful? Assume that the water and copper container are initially at a temperature of 20.0 $^\circ$C. Assume that the blade is not in direct mechanical (and thus thermal) contact with the container and that no water boils but all the water reaches 100.0 $^\circ$C. Neglect cooling through radiation into the air. The heat capacity of copper around room temperature is $c_{\text{copper}} = 386\ \text{J}/(\text{kg K})$. Use the data in the table below for the heat capacity of carbon steel.

Temperature Range ($^\circ$C)	**Heat Capacity** (J/kg K)
150 to 200	519
200 to 250	536
250 to 350	553
350 to 450	595
450 to 550	662
550 to 650	754
650 to 750	846

•• **18.48** It has been postulated that ethanol (ethyl alcohol) “snow” falls near the poles of the planets Jupiter, Saturn, Uranus, and Neptune. If the polar regions of Uranus, defined to be north of latitude 75.0°N and south of latitude 75.0°S, experience 1.00 ft of ethanol snow, what is the minimum amount of energy lost to the atmosphere to produce this much snow from ethanol vapor? Assume that solid ethanol has a density of 1.00 g/cm^3 and that ethanol snow—which is fluffy like Earth snow—is about 90.0% empty space. The specific heat capacities are 1.70 J/(g K) for ethanol vapor, 2.44 J/(g K) for ethanol liquid, and 2.42 J/(g K) for solid ethanol. How much power is dissipated if 1.00 ft of ethanol snow falls in one Earth day?

Section 18.8

18.49 A 100. mm by 100. mm by 5.00 mm slab of ice at 0.00 $^\circ$C is placed on one of its larger faces on a 10.0-mm-thick metal disk that covers a pot of boiling water at normal atmospheric pressure. The time needed for the entire ice block to melt is measured to be 0.400 s. The density of ice is 920. kg/m^3. Use the data in Table 18.3 to determine the metal the disk is most likely made of.

18.50 A copper sheet of thickness 2.00 mm is bonded to a steel sheet of thickness 1.00 mm. The outside surface of the copper sheet is held at a temperature of 100.0 $^\circ$C and the steel sheet at 25.0 $^\circ$C.

a) Determine the temperature of the copper-steel interface.

b) How much heat is conducted through 1.00 m^2 of the combined sheets per second?

18.51 The Sun is approximately a sphere of radius $6.963 \cdot 10^5$ km, at a mean distance $a = 1.496 \cdot 10^8$ km from the Earth. The *solar constant*, the intensity of solar radiation at the outer edge of Earth's atmosphere, is 1370. W/m^2. Assuming that the Sun radiates as a blackbody, calculate its surface temperature.

•**18.52** An air-cooled motorcycle engine loses a significant amount of heat through thermal radiation according to the Stefan-Boltzmann equation. Assume that the ambient temperature is $T_0 = 27\ ^\circ\text{C}\ (300\ \text{K})$. Suppose the engine generates 15 hp (11 kW) of power and, because there are several deep surface fins, has a surface area of $A = 0.50\ \text{m}^2$. A shiny engine has an emissivity $e = 0.050$, whereas an engine that is painted black has $e = 0.95$. Determine the equilibrium temperatures for the black engine and the shiny engine. (Assume that radiation is the only mode by which heat is dissipated from the engine.)

•**18.53** One summer day, you decide to make a popsicle. You place a popsicle stick into an 8.00-oz glass of orange juice, which is at room temperature $(71.0\ ^\circ\text{F})$. You then place the glass in the freezer, which is at $-15.0\ ^\circ\text{F}$ and has a cooling power of $4.00 \cdot 10^3$ BTU/h. How long does it take your popsicle to freeze?

•**18.54** An ice cube at 0.00 $^\circ$C measures 10.0 cm on a side. It sits on top of a copper block with a square cross section 10.0 cm on a side and a height of 20.0 cm. The bottom of the copper block is in thermal contact with a large pool of water at 90.0 $^\circ$C. How long does it take the ice cube to melt? Assume that only the part in contact with the copper liquefies; that is, the cube gets shorter as it melts. The density of ice is 0.917 g/cm^3.

•**18.55** A single-pane window is a poor insulator. On a cold day, the temperature of the inside surface of the window is often much less than the room air temperature. Likewise, the outside surface of the window is likely to be much warmer than the outdoor air. The actual surface temperatures are strongly dependent on convection effects. For instance, suppose the air temperatures are $21.5\ ^\circ\mathrm{C}$ inside and $-3.0\ ^\circ\mathrm{C}$ outside, the inner surface of the window is at $8.5\ ^\circ\mathrm{C}$, and the outer surface is at $4.1\ ^\circ\mathrm{C}$. At what rate will heat flow through the window? Take the thickness of the window to be 0.32 cm, the height to be 1.2 m, and the width to be 1.4 m.

•**18.56** A cryogenic storage container holds liquid helium, which boils at 4.22 K. The container's outer shell has an effective area of $0.500\ \mathrm{m}^2$ and is at $3.00 \cdot 10^2$ K. Suppose a student painted the outer shell of the container black, turning it into a pseudo-blackbody.

a) Determine the rate of heat loss due to radiation.

b) What is the rate at which the volume of the liquid helium in the container decreases as a result of boiling off? The latent heat of vaporization of liquid helium is $20.9\ \mathrm{kJ/kg}$. The density of liquid helium is $0.125\ \mathrm{kg/L}$.

•**18.57** Mars is 1.52 times farther away from the Sun than the Earth is and has a diameter 0.532 times that of the Earth.

a) What is the intensity of solar radiation (in $\mathrm{W/m^2}$) on the surface of Mars?

b) Estimate the temperature on the surface of Mars.

•• **18.58** Two thermal reservoirs are connected by a solid copper bar. The bar is 2.00 m long, and the temperatures of the reservoirs are $80.0\ ^\circ\mathrm{C}$ and $20.0\ ^\circ\mathrm{C}$.

a) Suppose the bar has a constant rectangular cross section, 10.0 cm on a side. What is the rate of heat flow through the bar?

b) Suppose the bar has a rectangular cross section that gradually widens from the colder reservoir to the warmer reservoir. The area A is determined by $A = \left(0.0100\ \mathrm{m}^2\right)\left[1.00 + x/\left(2.00\ \mathrm{m}\right)\right]$, where x is the distance along the bar from the colder reservoir to the warmer one. Find the heat flow and the rate of change of temperature with distance at the colder end, at the warmer end, and at the middle of the bar.

•• **8.59** The radiation emitted by a blackbody at temperature T has a frequency distribution given by the Planck spectrum:

$$\varepsilon_T(f) = \frac{2\pi h}{c^2}\left(\frac{f^3}{e^{hf/k_\mathrm{B}T} - 1}\right),$$

where $\varepsilon_T(f)$ is the energy density of the radiation per unit increment of frequency, v (for example, in watts per square meter per hertz), $h = 6.626 \cdot 10^{-34}\ \mathrm{J\ s}$ is Planck's constant, $k_\mathrm{B} = 1.38 \cdot 10^{-23}\ \mathrm{JK^{-1}}$ is the Boltzmann constant, and c is the speed of light in vacuum. (We'll derive this distribution in Chapter 36 as a consequence of the quantum hypothesis of light, but here it can reveal something about radiation. Remarkably, the most accurately and precisely measured example of this energy distribution in nature is the cosmic microwave background radiation.) This distribution goes to zero in the limits $f \to 0$ and $f \to \infty$ with a single peak between those limits. As the temperature is increased, the energy density at each frequency value increases, and the peak shifts to a higher frequency value.

a) Find the frequency corresponding to the peak of the Planck spectrum, as a function of temperature.

b) Evaluate the peak frequency at $T = 6.00 \cdot 10^3\ \mathrm{K}$, approximately the temperature of the photosphere (surface) of the Sun.

c) Evaluate the peak frequency at $T = 2.735\ \mathrm{K}$, the temperature of the cosmic background microwave radiation.

d) Evaluate the peak frequency at $T = 300.\ \mathrm{K}$, which is approximately the surface temperature of Earth.

Additional Exercises

18.60 How much energy is required to warm 0.300 kg of aluminum from 20.0 °C to 100.0 °C?

18.61 The thermal conductivity of fiberglass batting, which is 4.00 in thick, is $8.00 \cdot 10^{-6}$ BTU/ (ft °F s). What is the *R* value (in ft^2 °F h/BTU)?

18.62 Water is an excellent coolant as a result of its very high heat capacity. Calculate the amount of heat that is required to change the temperature of 10.0 kg of water by 10.0 K. Now calculate the kinetic energy of a car with $m = 1.00 \cdot 10^3$ kg moving at a speed of 27.0 m/s (60.4 mph). Compare the two quantities.

18.63 Approximately 95% of the energy developed by the filament in a spherical $1.0 \cdot 10^2$ W light bulb is dissipated through the glass bulb. If the thickness of the glass is 0.50 mm and the bulb's radius is 3.0 cm, calculate the temperature difference between the inner and outer surfaces of the glass. Take the thermal conductivity of the glass to be 0.80 W/ (m K).

18.64 The label on a soft drink states that 12.0 fl. oz (355 g) provides 150. kcal. The drink is cooled to 10.0 °C before it is consumed. It then reaches body temperature of 37.0 °C. Find the net energy content of the drink. (*Hint:* You can treat the soft drink as being identical to water in terms of heat capacity.)

18.65 The human body transports heat from the interior tissues, at the temperature 37.0 °C, to the skin surface, at the temperature 27.0 °C, at a rate of 100. W. If the skin area is 1.50 m^2 and its thickness is 3.00 mm, what is the effective thermal conductivity, *k*, of skin?

•**18.66** It has been said that sometimes lead bullets melt upon impact. Assume that a bullet receives 75.0% of the work done on it by a wall on impact as an increase in internal energy.

a) What is the minimum speed with which a 15.0-g lead bullet would have to hit a surface (assuming that the bullet stops completely and all the kinetic energy is absorbed by it) in order to begin melting

b) What is the minimum impact speed required for the bullet to melt completely

•**18.67** Solar radiation at the Earth's surface has an intensity of about 1.4 kW/m^2. Assuming that Earth and Mars are blackbodies, calculate the intensity of sunlight at the surface of Mars.

•**18.68** You become lost while hiking outside wearing only a bathing suit.

a) Calculate the power radiated from your body, assuming that your body's surface area is about 2.00 m^2 and your skin temperature is about

33.0 °C. Also, assume that your body has an emissivity of 1.00.

b) Calculate the net radiated power from your body when you are inside a shelter at 20.0 °C.

c) Calculate the net radiated power from your body when your skin temperature dropped to 27.0 °C.

•**18.69** A 10.0-g ice cube at −10.0 °C is dropped into 40.0 g of water at 30.0 °C.

a) After enough time has passed to allow the ice cube and water to come to equilibrium, what is the temperature of the water?

b) If a second ice cube is added, what will the temperature be?

•**18.70** Arthur Clarke wrote an interesting short story called "A Slight Case of Sunstroke." Disgruntled football fans came to the stadium one day equipped with mirrors and were ready to barbecue the referee if he favored one team over the other. Imagine the referee to be a cylinder filled with water of mass 60.0 kg at 35.0 °C. Also imagine that this cylinder absorbs all the light reflected on it from 50,000 mirrors. If the heat capacity of water is $4.20 \cdot 10^3$ J/ (kg °C), how long will it take to raise the temperature of the water to 100 °C? Assume that the Sun gives out $1.00 \cdot 10^3$ W/m^2, the dimensions of each mirror are 25.0 cm by 25.0 cm, and the mirrors are held at an angle of 45.0°.

•**18.71** If the average temperature of the North Atlantic is 12.0 °C and the Gulf Stream temperature averages 17.0 °C, estimate the net amount of heat the Gulf Stream radiates to the surrounding ocean. Use the details given in Solved Problem 18.4 (the length is about $8.00 \cdot 10^3$ km), and assume that $e = 0.930$. Don't forget to include the heat absorbed by the Gulf Stream.

•**18.72** For a class demonstration, your physics instructor pours 1.00 kg of steam at 100.0 °C over 4.00 kg of ice at 0.00 °C and waits for the system to reach equilibrium, when he will measure the temperature. While the system reaches equilibrium, you are given the latent heats of ice and steam and the specific heat of water: $L_{\text{ice}} = 3.33 \cdot 10^5$ J/kg, $L_{\text{steam}} = 2.26 \cdot 10^6$ J/kg, $c_{\text{water}} = 4186$ J/ (kg °C). You are asked to calculate the final equilibrium temperature of the system. What value do you find?

•**18.73** Determine the ratio of the heat flow into a six-pack of aluminum soda cans to the heat flow into a 2.00-L plastic bottle of soda when both are taken out of the same refrigerator, that is, have the same initial temperature difference with the air in the room. Assume that each soda can has a diameter of 6.00 cm, a height of 12.0 cm, and a thickness of 0.100 cm.

Use 205 $\mathrm{W/(m\ K)}$ as the thermal conductivity of aluminum. Assume that the 2.00-L bottle of soda has a diameter of 10.0 cm, a height of 25.0 cm, and a thickness of 0.100 cm. Use 0.100 $\mathrm{W/(m\ K)}$ as the thermal conductivity of plastic.

•**18.74** The *R* factor for housing insulation gives the thermal resistance in units of $\mathrm{ft^2\ ^\circ F\ h/BTU}$. A good wall for harsh climates, corresponding to about 10.0 in of fiberglass, has $R = 40.0\ \mathrm{ft^2\ ^\circ F\ h/BTU}$.

a) Determine the thermal resistance in SI units.

b) Find the heat flow per square meter through a wall that has insulation with an *R* factor of 40.0, when the outside temperature is $-22.0\ ^\circ\mathrm{C}$ and the inside temperature is $23.0\ ^\circ\mathrm{C}$.

•**18.75** Suppose you have an attic room that measures 5.0 m by 5.0 m and is maintained at $21\ ^\circ\mathrm{C}$ when the outside temperature is $4.0\ ^\circ\mathrm{C}$.

a) If you used R-19 insulation instead of R-30 insulation, how much more heat would exit this room in 1 day?

b) If electrical energy for heating the room costs 12 cents per kilowatt-hour, how much more would it cost you for heating for a period of 3 months at the same outside temperature with the R-19 insulation?

•• **18.76** A thermal window consists of two panes of glass separated by an air gap. Each pane of glass is 3.00 mm thick, and the air gap is 1.00 cm thick. Window glass has a thermal conductivity of 1.00 $\mathrm{W/(m\ K)}$, and air has a thermal conductivity of 0.0260 $\mathrm{W/(m\ K)}$. Suppose a thermal window separates a room at $20.00\ ^\circ\mathrm{C}$ from the outside at $0.00\ ^\circ\mathrm{C}$.

a) What is the temperature at each of the four air-glass interfaces?

b) At what rate is heat lost from the room, per square meter of window?

c) Suppose the window had no air gap but consisted of a single layer of glass 6.00 mm thick. What would the rate of heat loss per square meter be then, under the same temperature conditions?

d) Heat conduction through the thermal window could be reduced essentially to zero by evacuating the space between the glass panes. Why is this not done?

MULTI-VERSION EXERCISES

18.77 Enhanced geothermal systems (EGS) consist of two or more boreholes that extend several kilometers below ground level into the hot bedrock. Since drilling these holes can cost millions, one concern is that the heat provided by the bedrock cannot pay back the initial investment. How long can 0.669 km^3 of granite deliver an average of 13.9 MW of power, if its initial temperature is 168.3 $^\circ$C and its final temperature is 103.5 $^\circ$C? [The density of granite is 2.75 times that of water, and its specific heat is 0.790 kJ/ (kg $^\circ$C).]

18.78 Enhanced geothermal systems (EGS) consist of two or more boreholes that extend several kilometers below ground level into the hot bedrock. Since drilling these holes can cost millions, one concern is that the heat provided by the bedrock cannot pay back the initial investment. Suppose 0.581 km^3 of granite can deliver an average of 15.7 MW of power for 164.6 yr. If, after that time, the temperature of the granite is 104.5 $^\circ$C, what was its initial temperature (in degrees Celsius)? [The density of granite is 2.75 times that of water, and its specific heat is 0.790 kJ/ (kg $^\circ$C).]

18.79 Enhanced geothermal systems (EGS) consist of two or more boreholes that extend several kilometers below ground level into the hot bedrock. Since drilling these holes can cost millions, one concern is that the heat provided by the bedrock cannot pay back the initial investment. Suppose 0.493 km^3 of granite is to be drawn on for 124.9 yr and in the process will cool from 169.9 $^\circ$C to 105.5 $^\circ$C. What is the average power the granite can deliver during that time? [The density of granite is 2.75 times that of water, and its specific heat is 0.790 kJ/ (kg $^\circ$C).]

18.80 An exterior wall is 5.183 m wide and 3.269 m tall. The wall is insulated with a material that has an *R* factor of 29. The outdoor temperature is 1.073 $^\circ$C, and the indoor temperature is 23.37 $^\circ$C. How much power is carried through the wall?

18.81 An exterior wall is 5.869 m wide and 3.289 m tall, and 69.71 W of power is carried through it. The outdoor temperature is 3.857 $^\circ$C, and the indoor temperature is 24.21 $^\circ$C. What is the *R* factor of the material with which the wall is insulated?

18.82 An exterior wall is 6.555 m wide and 3.311 m tall. The wall is insulated with a material that has an *R* factor of 34. When the outdoor

temperature is 2.641 ˚C, 63.10 W of power is carried through the wall. What is the indoor temperature?

Scuba diving (*scuba* was originally an acronym for "self-contained underwater breathing apparatus") is a popular activity in locations with warm seawater. However, it is also a great application of the physics of gases. The scuba diver shown in Figure 19.1 relies on a tank of compressed air for breathing underwater. The air is typically kept at a pressure of 200 atm ($\sim$3000 psi, or $\sim$20 MPa). Before the diver can breathe this air, its pressure must be modified so that it is about the same as the pressure surrounding the diver's body in the water, which increases by about 1 atm for every 10 m below the surface (see Section 13.4).

Corbis/VCG/Image 100/Getty Images

In this chapter, we study the physics of gases. The results are based on an ideal gas, which doesn't actually exist, but many real gases behave approximately like an ideal gas in many situations. We first examine the properties of gases based on observations, including laws first stated by pioneers of hot-air balloon navigation, who had a very practical interest in the behavior of gases at high altitudes. Then we gain additional insights from the kinetic theory of an ideal gas, which applies mathematical analysis to gas particles under several assumed conditions.

The key properties of gases are the thermodynamic quantities of temperature, pressure, and volume, which is why this chapter is with the others on thermodynamics. However, the physics of gases has applications to many different areas of science, from astronomy to meteorology, from chemistry to biology. Many of these concepts will be important in later chapters.

WHAT WE WILL LEARN

- A gas consists of molecules that have enough spatial separation that the intermolecular bonding characteristic of liquids and solids is absent.
- The physical properties of a gas are pressure, volume, temperature, and number of molecules.
- An ideal gas is one in which the molecules of the gas are treated as point particles that do not interact with one another.
- The Ideal Gas Law gives the relationship among pressure, volume, temperature, and number of molecules of an ideal gas.
- The work done by an ideal gas is proportional to the change in volume of the gas if the pressure is constant.
- Dalton's Law says that the total pressure exerted by a mixture of gases is equal to the sum of the partial pressures exerted by each gas in the mixture.
- The specific heat of a gas can be calculated for both constant-volume and constant-pressure processes, and gases composed of monatomic, diatomic, or polyatomic molecules have different specific heats.
- Kinetic theory, describing the motion of the constituents of an ideal gas, accounts for its macroscopic properties, such as temperature and pressure.
- The temperature of a gas is proportional to the average kinetic energy of its molecules.
- The distribution of speeds of the molecules of a gas is described by the Maxwell speed distribution, and the distribution of kinetic energies of the molecules of a gas is described by the Maxwell kinetic energy distribution.
- The mean free path of a molecule in a gas is the average distance the molecule travels before encountering another molecule.

19.1 Empirical Gas Laws

Chapter 13 presented an overview of the states of matter. It introduced pressure as a physical quantity and stated that a gas is a special case of a fluid. Since the concept of temperature was introduced in Chapter 17, we can now look at how gases respond to changes in temperature, pressure, and volume. The gas laws introduced in this section provide the empirical evidence that will lead to the derivation of the Ideal Gas Law in the next section. We'll see that all of the empirical gas laws are special cases of the Ideal Gas Law.

A **gas** consists of molecules that are spatially separated such that the intermolecular bonding, which is characteristic of liquids and solids, is absent. A gas expands to fill the container in which it is placed. Thus, the volume of a gas is the volume of its container. This chapter uses the term *gas molecules* to refer to the constituents of a gas, although a gas may consist of atoms or molecules or may be a combination of atoms and molecules.

In Chapter 17, the temperature of a substance was defined in terms of its tendency to give off heat to its surroundings or to absorb heat from its surroundings. The pressure of a gas is defined as the force per unit area exerted by the gas molecules on the walls of a container. For many applications, standard temperature and pressure (STP) is defined as $0\ ^\circ\text{C}$ (273.15 K) and 100.000 kPa.

Another characteristic of a gas, in addition to volume, temperature, and pressure, is the number of gas molecules in the volume of gas in a container. This number is expressed in terms of moles: 1 **mole** of a gas is defined to have $6.022 \cdot 10^{23}$ molecules. This number, known as *Avogadro's number*, was introduced in Chapter 13 and will be discussed further in connection with Avogadro's Law later in this section.

Several simple relationships exist among the four properties of a gas—pressure, volume, temperature, and number of molecules. This section covers four simple gas laws that relate these properties. All of these gas laws are named after their discoverers (Boyle, Charles, Gay-Lussac, Avogadro) and are empirical—that is, they were found from performing a series of measurements and not derived from some more fundamental theory. In the next section, we'll combine these

four laws to form the Ideal Gas Law, relating all the macroscopic characteristics of gases. If you understand the Ideal Gas Law, all of the empirical gas laws follow immediately. Why not skip them, then? The answer is that these empirical gas laws form the basis from which the Ideal Gas Law is derived.

Boyle's Law

The first empirical gas law is Boyle's Law, which is also known in Europe as Mariotte's Law. English scientist Robert Boyle published this law in 1662; French scientist Edme Mariotte published a similar result in 1676. **Boyle's Law** states that the product of a gas's pressure, p, and its volume, V, at constant temperature is a constant (Figure 19.2). Mathematically, Boyle's Law is expressed as $pV = \text{constant}$ (at constant temperature).

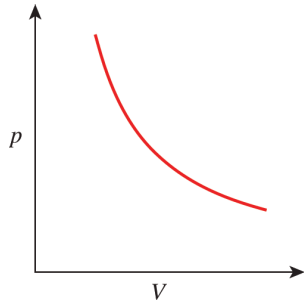

FIGURE 19.2 Relationship between pressure and volume as expressed by Boyle's Law.

Another way to express Boyle's Law is to state that the product of the pressure, p_1, and volume, V_1, of a gas at time t_1 is equal to the product of the pressure, p_2, and the volume, V_2, of the same gas at the same temperature at another time, t_2:

$$p_1V_1 = p_2V_2 \text{ (at constant temperature).} \qquad \textbf{(19.1)}$$

An everyday example of the application of Boyle's Law is breathing. When you take in a breath, your diaphragm expands, and the expansion produces a larger volume in your chest cavity. According to Boyle's Law, the air pressure in your lungs is reduced relative to the normal atmospheric pressure around you. The higher pressure outside your body then forces air into your lungs to equalize the pressure. To breathe out, your diaphragm contracts, reducing the

volume of your chest cavity. This reduction in volume produces a higher pressure, which forces air out of your lungs.

Charles's Law

The second empirical gas law is **Charles's Law,** which states that for a gas kept at constant pressure, the volume of the gas, V, divided by its temperature, T, is constant (Figure 19.3). The French physicist (and pioneering high-altitude balloonist) Jacques Charles proposed this law in 1787. Mathematically, Charles's Law is $V/T = \text{constant}$ (at constant pressure).

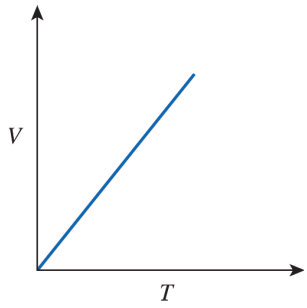

FIGURE 19.3 Relationship between volume and temperature as expressed by Charles's Law.

Another way to state Charles's Law is to state that the ratio of the temperature, T_1, and volume, V_1, of a gas at a given time, t_1, is equal to the ratio of the temperature, T_2, and the volume, V_2, of the same gas at the same pressure at another time, t_2:

$$\frac{V_1}{T_1} = \frac{V_2}{T_2} \Leftrightarrow \frac{V_1}{V_2} = \frac{T_1}{T_2} \quad (\text{at constant pressure}). \textbf{(19.2)}$$

Note that the temperatures must be expressed in kelvins (K).

Because the density, ρ, of a given mass, m, of gas is $\rho = m/V$, Charles's Law can also be written as $\rho T = \text{constant}$ (at constant pressure). As a corollary to equation 19.2, we then have

$$\rho_1 T_1 = \rho_2 T_2 \Leftrightarrow \frac{\rho_1}{\rho_2} = \frac{T_2}{T_1} \quad \text{(at constant pressure).} \tag{19.3}$$

Gay-Lussac's Law

The third empirical gas law is **Gay-Lussac's Law,** which states that the ratio of the pressure, p, of a gas to its temperature, T, at the same volume is constant (Figure 19.4). This law was presented in 1802 by the French chemist Joseph Louis Gay-Lussac (another avid high-altitude balloonist, by the way). Mathematically, Gay-Lussac's Law is expressed as $p/T = \text{constant}$ (at constant volume).

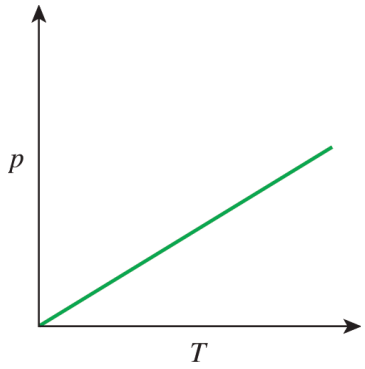

FIGURE 19.4
Relationship between pressure and temperature as expressed by Gay-Lussac's Law.

Another way to express Gay-Lussac's Law is to state that the ratio of the pressure of a gas, p_1, and its temperature, T_1, at a given time, t_1, is equal to the ratio of the pressure, p_2, and the temperature, T_2, of the same gas at the same volume at another time, t_2:

$$\frac{p_1}{T_1} = \frac{p_2}{T_2} \quad \text{(at constant volume)}. \qquad \textbf{(19.4)}$$

Again, the temperatures must be in kelvins (K).

Avogadro’s Law

The fourth empirical gas law deals with the quantity of a gas. **Avogadro’s Law** states that the ratio of the volume of a gas, *V*, to the number of gas molecules, *N*, in that volume is constant if the pressure and temperature are held constant. This law was introduced in 1811 by the Italian physicist Amedeo Avogadro. Mathematically, Avogadro’s Law is expressed as $V/N = \text{constant}$ (at constant pressure and temperature).

Another way to express Avogadro’s Law is to state that the ratio of the volume, V_1, and the number of molecules, N_1, of a gas at a given time, t_1, is equal to the ratio of the volume, V_2, and the number of molecules, N_2, of the same gas at the same pressure and temperature at another time, t_2:

$$\frac{V_1}{N_1} = \frac{V_2}{N_2} \quad (\text{at constant pressure and temperature}). \textbf{(19.5}$$

It has been found that a volume of $22.4\,\text{L}$ $\left(1\,\text{L} = 10^{-3}\,\text{m}^3\right)$ of a gas at standard temperature and pressure contains $6.022 \cdot 10^{23}$ molecules. This number of molecules is called **Avogadro’s number,** N_A. The currently accepted value for Avogadro’s number is

$$N_\text{A} = (6.02214129 \pm 0.00000027) \cdot 10^{23}.$$

(As was pointed out in Chapter 13, Avogadro’s number is defined to be the number of atoms in exactly 12 grams of the most common isotope of carbon, carbon-12.) One mole of any gas will have Avogadro’s number of molecules. The number of moles is usually symbolized by *n*. Thus, the number of molecules, *N*, and the number of moles, *n*, of a gas are related by Avogadro’s number:

$$N = nN_{\mathrm{A}}. \tag{19.6}$$

Therefore, the mass in grams of one mole of a gas is numerically equal to the atomic mass or molecular mass of the constituent particles in atomic mass units. For example, nitrogen gas consists of molecules composed of two nitrogen atoms. Each nitrogen atom has an atomic mass number of 14. Thus, the nitrogen molecule has a molecular mass number of 28, and a 22.4-L volume of nitrogen gas at standard temperature and pressure has a mass of 28 g.

19.2 Ideal Gas Law

We can combine the empirical gas laws described in Section 19.1 to obtain a more general law relating the properties of gases, called the **Ideal Gas Law:**

$$pV = nRT, \tag{19.7}$$

where p, V, and T are the pressure, volume, and temperature, respectively, of n moles of a gas and R is the **universal gas constant.** The value of R is determined experimentally and is given by

$$R = (8.3144621 \pm 0.0000075)\,\mathrm{J}/\,(\mathrm{mol\ K}).$$

The constant R can also be expressed in other units, which changes its numerical value, for example, $R = 0.08205736\ \mathrm{L\ atm}/\,(\mathrm{mol\ K})$.

The Ideal Gas Law was first stated by the French scientist Benoit Paul Émile Clapeyron in 1834. It is the main result of this chapter.

DERIVATION 19.1 Ideal Gas Law

To derive the Ideal Gas Law, we start with one mole of an ideal gas, described by a pressure p_0, a volume V_0, and a temperature T_0, which can be indicated using the shorthand notation $\{p_0, V_0, T_0\}$. (Remember, an ideal gas has no interactions among its molecules.) This particular state of the gas is shown on a plot of temperature versus pressure (a Tp-diagram) in Figure 19.5.

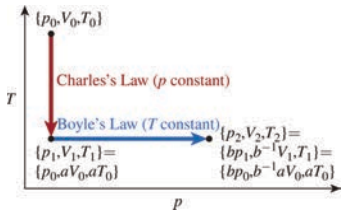

FIGURE 19.5 Path of the state of a gas in a plot of temperature versus pressure (Tp-diagram). The first part of the path takes place at a constant pressure and is described by Charles's Law. The second part of the path takes place at constant temperature and is described by Boyle's Law.

Next, the state of the gas is changed by varying its volume and temperature while holding the pressure constant. In Figure 19.5, the gas's state goes from $\{p_0, V_0, T_0\}$ to $\{p_1, V_1, T_1\}$ on the Tp-

diagram (red arrow). Using Charles's Law (equation 19.2), we can write

$$\frac{V_0}{T_0} = \frac{aV_0}{aT_0} = \frac{V_1}{T_1},$$

where we have multiplied the numerator and denominator of the ratio V_0/T_0 by a constant, a. We can describe the gas in this new state with

$$\{p_1, V_1, T_1\} = \{p_0, aV_0, aT_0\}. \qquad \text{(i)}$$

From this point in the Tp-diagram, the pressure and volume of the gas change while the temperature is held constant. In Figure 19.5, the path goes from $\{p_1, V_1, T_1\}$ to $\{p_2, V_2, T_2\}$, as indicated by the blue arrow. Using Boyle's Law (equation 19.1), we can write

$$p_1V_1 = \frac{b}{b}p_1V_1 = (bp_1)\left(b^{-1}V_1\right) = p_2V_2,$$

where the product p_1V_1 is multiplied and divided by a constant, b. Now we can describe the state of the gas with

$$\{p_2, V_2, T_2\} = \left\{bp_1, b^{-1}V_1, T_1\right\}. \qquad \text{(ii)}$$

Combining equations (i) and (ii) gives us

$$\{p_2, V_2, T_2\} = \left\{bp_0, b^{-1}aV_0, aT_0\right\}.$$

We can now write the ratio

$$\frac{p_2 V_2}{T_2} = \frac{(bp_0)\left(b^{-1}aV_0\right)}{aT_0} = \frac{p_0 V_0}{T_0}.$$

This implies that $p_0 V_0 / T_0$ is a constant, which we can call R, the universal gas constant.

This derivation was done for 1 mole of gas. For n moles of gas, Avogadro's Law says that with constant pressure and temperature, the volume of n moles of gas will be equal to the number of moles times the volume of one mole of gas. We can rearrange $p_0 V_0 / T_0 = R$ and multiply by n to get

$$np_0 V_0 = nRT_0.$$

We now write the Ideal Gas Law as $pV/T = nR$, or, more commonly, as

$$pV = nRT,$$

where $p = p_0, V = nV_0$, and $T = T_0$ are the pressure, volume, and temperature, respectively, of n moles of gas.

The Ideal Gas Law can also be written in terms of the number of gas molecules instead of the number of moles of gas. This is sometimes useful for examining relationships at the molecular level of matter. In this form, the Ideal Gas Law is

$$pV = Nk_\mathrm{B}T, \tag{19.8}$$

where N is the number of atoms or molecules and k_B is the **Boltzmann constant,** given by

$$k_\mathrm{B} = \frac{R}{N_\mathrm{A}}.$$

The currently accepted value of the Boltzmann constant is

$$k_\mathrm{B} = (1.3806488 \pm 0.0000013) \cdot 10^{-23}\ \mathrm{J/K}.$$

The Boltzmann constant is an important fundamental physical constant that often arises in relationships based on atomic or molecular behavior. It will be used again later in this chapter and again in discussions of solid-state electronics and quantum mechanics. You may have noticed by now that the letter *k* is often used in mathematics and physics to denote a constant (the German word for *constant* is *Konstante*, which is where the use of *k* originated). However, the Boltzmann constant is of such basic significance that the subscript B is used to distinguish it from other physical constants denoted by *k*.

Another way to express the Ideal Gas Law for a constant number of moles of gas is

$$\frac{p_1 V_1}{T_1} = \frac{p_2 V_2}{T_2}, \tag{19.9}$$

Concept Check 19.1

The pressure inside a scuba tank is 205 atm at $22.0\ ^\circ\text{C}$. Suppose the tank is left out in the sun and the temperature of the compressed air inside the tank rises to $40.0\ ^\circ\text{C}$. What will the pressure inside the tank be?

a) 205 atm

b) 218 atm

c) 254 atm

d) 321 atm

e) 373 atm

where p_1, V_1, and T_1 are the pressure, volume, and temperature, respectively, at time 1 and p_2, V_2, and T_2 are the pressure, volume,

and temperature, respectively, at time 2. The advantage of this formulation is that you do not have to know the numerical values of the universal gas constant or the Boltzmann constant to relate the pressures, volumes, and temperatures at two different times.

It is straightforward to confirm that Boyle's Law, Charles's Law, and Gay-Lussac's Law are embodied in the Ideal Gas Law. In Figure 19.6, a three-dimensional surface represents the relationship among the pressure, volume, and temperature of an ideal gas. At any fixed value of the pressure, the intersection of this surface with the temperature-volume plane is a line that reflects Charles's Law. The intersection of this surface with the pressure-temperature plane at any fixed value of the volume is a line that reflects Gay-Lussac's Law. And, finally, a line corresponding to Boyle's Law marks the intersection of this surface with the pressure-volume plane at any given temperature.

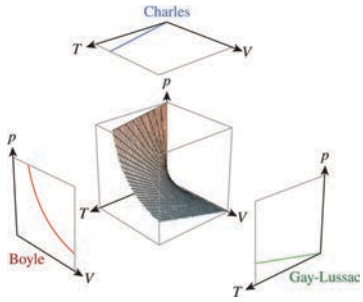

FIGURE 19.6 The relationship among the Ideal Gas Law and its special cases: Charles's Law (constant pressure), Boyle's Law (constant temperature), and Gay-Lussac's Law (constant volume).

Note that the Ideal Gas Law has been obtained in this discussion by combining the empirical gas laws. The next section will analyze the behavior of ideal gas molecules in a container and thereby provide insight into the microscopic physical basis for the Ideal Gas Law. Let's first explore the consequences and predictive powers of the Ideal Gas Law with a few illustrative examples.

EXAMPLE 19.1 Gas in a Cylinder

Consider a gas at a pressure of 24.9 kPa in a cylinder with a volume of $0.100\,\mathrm{m}^3$ and a piston. This pressure and volume corresponds to point 1 in Figure 19.7. The pressure of this gas has to be decreased to allow a manufacturing process to work efficiently. The piston is designed to increase the volume of the cylinder from $0.100\,\mathrm{m}^3$ to $0.900\,\mathrm{m}^3$ while keeping the temperature constant.

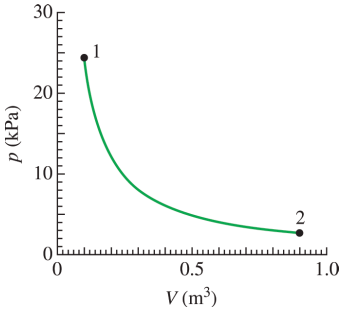

FIGURE 19.7 Plot of pressure versus volume for a gas described by Boyle's Law.

PROBLEM

What is the pressure of the gas at a volume of $0.900\,\mathrm{m}^3$?

SOLUTION

Point 2 in Figure 19.7 represents the pressure of the gas at a volume of $0.900\,\mathrm{m}^3$. You can see that the pressure decreases as the volume increases.

Since the temperature is constant ($T_1 = T_2$) in this situation, the Ideal Gas Law (in the form in equation 19.9), $p_1V_1/T_1 = p_2V_2/T_2$, reduces to $p_1V_1 = p_2V_2$. (Section 19.1 identified this special case of the Ideal Gas Law as Boyle's Law.) We can use this to calculate the new pressure:

$$p_2 = \frac{p_1 V_1}{V_2} = \frac{(24.9\,\text{kPa})\left(0.100\,\text{m}^3\right)}{0.900\,\text{m}^3} = 2.77\,\text{kPa}.$$

There are, of course, many applications where the temperature of a gas changes. Example 19.2 considers one.

EXAMPLE 19.2 Cooling a Balloon

A balloon is blown up at room temperature and then placed in liquid nitrogen (Figure 19.8). The balloon is allowed to cool to liquid-nitrogen temperature and it shrinks dramatically. The cold balloon is then removed from the liquid nitrogen and allowed to warm back to room temperature. The balloon returns to its original volume.

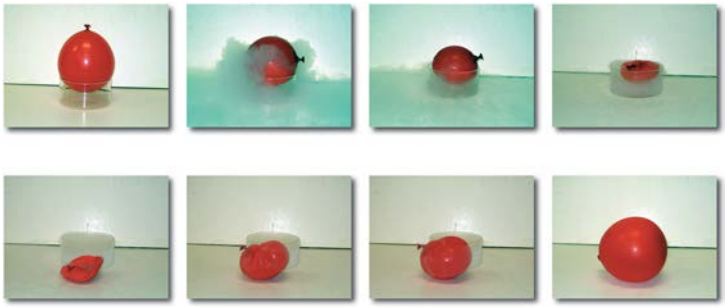

FIGURE 19.8 The top row shows a balloon blown up at room temperature and then placed in liquid nitrogen. In the bottom row, the cold balloon is removed from the liquid nitrogen and allowed to warm to room temperature. The time between subsequent frames in each sequence is 20 s. Note that the liquid nitrogen causes a phase change in the air inside the balloon, causing it to contract more than the Ideal Gas Law alone predicts.

W. Bauer and G. D. Westfall

PROBLEM

By what factor does the volume of the balloon decrease as the temperature of the air inside the balloon goes from room temperature to the temperature of liquid nitrogen?

SOLUTION

To a good approximation, the gas inside the balloon is kept at constant pressure ($p_1 = p_2$), which you can verify from the fact that it is about equally hard to add air to a balloon of any size (for a reasonable range of balloon sizes). The Ideal Gas Law (equation 19.9), $p_1V_1/T_1 = p_2V_2/T_2$, in this case becomes $V_1/T_1 = V_2/T_2$. (In Section 19.1, this special case of the Ideal Gas Law was identified as Charles's Law.) Assume room temperature is 22 °C, or $T_1 = 295\,\text{K}$, and the temperature of liquid nitrogen is $T_2 = 77.2\,\text{K}$. We can calculate the fractional change in volume of the balloon:

$$\frac{V_2}{V_1} = \frac{T_2}{T_1} = \frac{77.2\,\text{K}}{295\,\text{K}} = 0.262.$$

DISCUSSION

The balloon in Figure 19.8 shrank by much more than the factor calculated from Charles's Law. (A ratio of cold volume to warm volume of 25% implies that the radius of the cold balloon should be 63% of the radius of the room-temperature balloon.) There are several reasons for the smaller-than-expected size of the cold balloon. First, the water vapor in the air in the balloon freezes out as ice particles. Second, some of the oxygen and some of the nitrogen in the air inside the balloon condense to liquids, to which the Ideal Gas Law does not apply.

Example 19.3 deals with the relationship of air temperature and air pressure.

EXAMPLE 19.3 Heat on the Golf Course

The 2007 PGA Championship was played in August in Oklahoma at the Southern Hills Country Club, at the highest average temperature of any major golf championship in history, reaching approximately 101 $^\circ$F (38.3 $^\circ$C = 311.5 K). Thus, the air density was lower than at cooler temperatures, causing the golf balls to fly farther. The players had to correct for this effect, just as they have to allow for longer flights when they play at higher elevations.

PROBLEM

The Southern Hills Country Club is at an elevation of 213 m (700 ft) above sea level. At what elevation would the Old Course at St. Andrews, Scotland, shown in Figure 19.9, have to be located, if the air temperature was 48 $^\circ$F (8.9 $^\circ$C = 282.0 K), for the golf balls to have the same increase in flight length as at Southern Hills?

FIGURE 19.9
Teeing off at the Old Course in St. Andrews, Scotland, at sea level and in late winter. At low elevations or low temperatures, the ball does not carry as far.

W. Bauer and G. D. Westfall

SOLUTION

First, we calculate how the temperature influences the air density. We can use the relationship between the density and temperature for constant pressure, $\rho_1/\rho_2 = T_2/T_1$, equation 19.3. Putting in the known values (remember that we need to use kelvins for the air temperature), we obtain

$$\frac{\rho_1}{\rho_2} = \frac{T_2}{T_1} = \frac{282.0\,\mathrm{K}}{311.5\,\mathrm{K}} = 0.9053.$$

In other words, the air at 101 $^\circ$F has only 90.53% of the density of air at 48 $^\circ$F, at the same pressure. Now we have to compute

the altitude that corresponds to the same density ratio. In Section 13.4, we derived a formula that relates the density to the altitude,

$$\rho(h) = \rho_0 e^{-h\rho g/P_0},$$

where h is the height above sea level, ρ_0 is the density of air at sea level, and p_0 is the air pressure at sea level. The constants in the formula relating density to height can be written as

$$\frac{p_0}{\rho_0 g} = \frac{1.01 \cdot 10^5\,\text{Pa}}{(1.229\,\text{kg/m}^3)\left(9.81\,\text{m/s}^2\right)} = 8377\,\text{m}.$$

The elevation at Southern Hills is $h_1 = 213\,\text{m}$, and the air density is

$$\rho(h_1) = \rho_0 e^{-h_1/(8377\,\text{m})}.$$

The air density at the Old Course at an elevation h_2 would be

$$\rho(h_2) = \rho_0 e^{-h_2/(8377\,\text{m})}.$$

Taking the ratio of these two densities gives

$$\frac{\rho(h_2)}{\rho(h_1)} = \frac{\rho_0 e^{-h_2/(8377\,\text{m})}}{\rho_0 e^{-h_1/(8377\,\text{m})}} = e^{-(h_2-h_1)/(8377\,\text{m})}.$$

Setting this ratio equal to the ratio of the densities from the temperature difference gives

$$e^{-(h_2-h_1)/(8377\,\text{m})} = 0.9053.$$

Taking the natural log of both sides of this equation leads to

$$-(h_2 - h_1)/(8377\,\text{m}) = \ln(0.9053),$$

which can be solved for h_2:

$$h_2 = h_1 - (8377\,\text{m})\ln(0.9053) = (213\,\text{m}) - (8377\,\text{m})\ln(0.$$

Thus, at the temperature of 101 ˚F, the course at Southern Hills played as long as the Old Course would at an elevation of 1046 m (3432 ft) and a temperature of 48 ˚F.

DISCUSSION

Our solution neglected the effect of the high humidity at Southern Hills, which reduced the air density by an additional 2% relative to the density of dry air, causing the course to play like one with dry air and a temperature of 48 ˚F at an altitude over 4000 ft above sea level. (The effect of water vapor in the air on the air density is discussed later, in the subsection on Dalton's Law.)

SOLVED PROBLEM 19.1 Pressure of a Planetary Nebula

PROBLEM

A planetary nebula is a cloud of mainly hydrogen gas with a density, ρ, of $1.0 \cdot 10^3$ molecules per cubic centimeter $\left(\text{cm}^3\right)$ and a temperature, T, of $1.0 \cdot 10^4$ K. An example of a planetary nebula, the Ring Nebula, is shown in Figure 19.10. What is the pressure of the gas in the nebula?

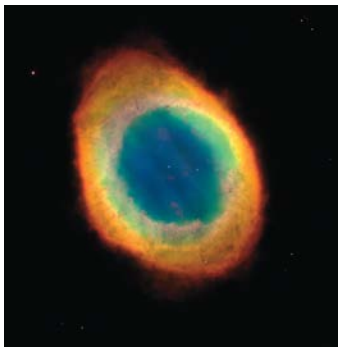

FIGURE 19.10 The Ring Nebula, as seen by the Hubble Space Telescope.

The Hubble Heritage Team (AURA/STScI/NASA)

SOLUTION

THINK

Because of the very low density of the gas in a planetary nebula, it is a very good approximation to treat that gas as an ideal gas and apply the Ideal Gas Law. We know the particle density, which is the number of gas molecules per unit volume, so we can replace the number of molecules in the Ideal Gas Law with the density times the volume of the nebula. The volume then cancels out, and we can solve for the pressure of the gas.

SKETCH

A rough sketch of a planetary nebula is shown in Figure 19.11.

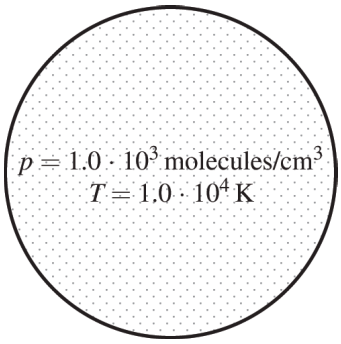

FIGURE 19.11 An idealized planetary nebula.

RESEARCH

The Ideal Gas Law is given by

$$pV = Nk_{\mathrm{B}}T, \qquad \text{(i)}$$

where p is the pressure, V is the volume, N is the number of molecules of gas, k_{B} is the Boltzmann constant, and T is the temperature. The number of molecules, N, is

$$N = \rho V, \qquad \text{(ii)}$$

where ρ is the number of molecules per unit volume in the nebula.

SIMPLIFY

Substituting for N from equation (ii) into (i), we get

$$pV = Nk_{\mathrm{B}}T = \rho V k_{\mathrm{B}}T,$$

which we can simplify to get an expression for the pressure of the gas in the nebula:

$$p = \rho k_{\mathrm{B}} T.$$

CALCULATE

Putting in the numerical values gives us

$$p = \rho k_{\mathrm{B}} T = \left(\frac{1.0 \cdot 10^3 \text{ molecules}}{1 \text{ cm}^3} \right) \left(\frac{1 \text{ cm}^3}{10^{-6} \text{ m}^3} \right) (1.381 \cdot$$
$$= 1.381 \cdot 10^{-10} \text{ Pa}.$$

ROUND

We report our result to two significant figures:

$$p = 1.4 \cdot 10^{-10} \text{ Pa}.$$

DOUBLE-CHECK

We can usually double-check our result by determining whether the unit(s) and the order of magnitude are appropriate. In this case, our answer has a unit of pressure (Pa), but we have no reference point for judging the order of magnitude. Obviously, the pressure of the gas in the nebula must be very low, much lower than the pressure of Earth's atmosphere, because the density of the gas molecules in the nebula is so small. In fact, the pressure we calculated is astonishingly low; as a comparison, the pressure of a good vacuum in a lab on Earth is $p_{\text{lab}} = 10^{-7}$ Pa, which is about 1000 times higher than the pressure in the nebula.

Note that although a gas generally expands to fill its container, in this case there is no container. The gas in a planetary nebula is held together by the gravitational interactions among its molecules.

Work Done by an Ideal Gas at Constant Temperature

Suppose we have an ideal gas at a constant temperature in a closed container whose volume can be changed, such as a cylinder with a piston. This setup allows us to perform an isothermal process, described in Chapter 18. For an isothermal process, the Ideal Gas Law says that the pressure is equal to a constant times the inverse of the volume: $p = nRT/V$. If the volume of the container is changed from an initial volume, $V_{\text{i,}}$ to a final volume, $V_{\text{f,}}$ the work done by the gas (see Chapter 18) is given by

$$W = \int_{V_\text{i}}^{V_\text{f}} p dV.$$

Substituting the expression for the pressure into this integral gives

$$W = \int_{V_\text{i}}^{V_\text{f}} p dV = (nRT) \int_{V_\text{i}}^{V_\text{f}} \frac{dV}{V} = nRT[\ln V]_{V_\text{i}}^{V_\text{f}},$$

which evaluates to

$$W = nRT \ln \left(\frac{V_\text{f}}{V_\text{i}} \right). \qquad \textbf{(19.10)}$$

Equation 19.10 indicates that the work done by the gas is positive if $V_\text{f} > V_\text{i}$ and is negative if $V_\text{f} < V_\text{i}$.

Concept Check 19.2

Suppose an ideal gas has pressure p, volume V, and temperature T. If the volume is doubled at constant pressure, the gas does work $W_p = \text{const}$. If instead the volume is doubled at constant temperature, the gas does work $W_T = \text{const}$. What is the relationship between these two amounts of work done by the gas?

a) $W_{p=\text{const}} < W_{T=\text{const}}$

b) $W_{p=\text{const}} = W_{T=\text{const}}$

c) $W_{p=\text{const}} > W_{T=\text{const}}$

d) The relationship cannot be determined from the information given.

We can compare this result to those found in Chapter 18 for the work done by the gas under other assumptions. For example, if the volume is held constant rather than the temperature, the gas can do no work: $W = 0$. If the pressure is held constant, the work done by the gas is given by (see Chapter 18)

$$W = \int_{V_\text{i}}^{V_\text{f}} p dV = p \int_{V_\text{i}}^{V_\text{f}} dV = p\left(V_\text{f} - V_\text{i}\right) = p\Delta V.$$

Compressed Air Energy Storage

In a dentist's drill, the drill bit needs to rotate at a very high frequency of over 100,000 rpm. Putting an electric motor into the hand piece would add a lot of weight; therefore, the drill is driven by compressed air. Many other tools (including nail guns, air ratchets, and jackhammers) have the same constraints. Air compressors, which supply compressed air at pressures from 500 kPa to 1000 kPa, drive all of them. Citywide distribution systems for compressed air have been in use in cities such as Paris, France, since the end of the 19th century. Locomotives operating on compressed air have even been used in coal mines (where sparks from other types of engines could be fatal!).

Compressed air can be used to store energy temporarily, which is necessary in situations where power production is intermittent, for example, with wind farms and solar power plants. The use of large-scale storage facilities (see Figure 19.12) can smooth the time profile of the produced power. Energy storage and retrieval by these facilities are not as efficient as they are with pump storage facilities that use water, but in geographical locations with very little altitude variation, they may be the only way to accomplish energy storage. The first compressed air storage facility was built in 1978 in Huntorf, Germany, and a 110-MW facility, built in 1991 in McIntosh, Alabama, was the first in the United States.

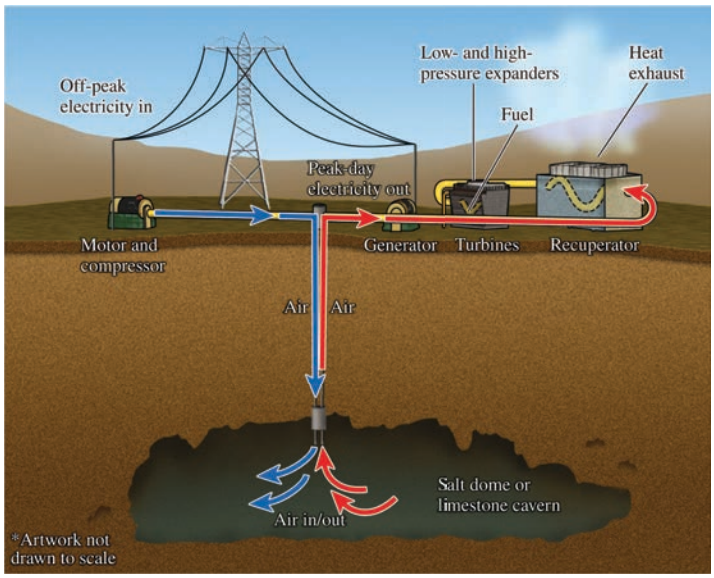

FIGURE 19.12 Schematic diagram of a compressed air energy storage facility.

SOLVED PROBLEM 19.2 Home Energy Storage

Homes located in areas with ample sunshine can harvest energy with solar panels. But in order to avoid buying electricity from the grid (or if a home is located off the grid, for example, in a rural area in a developing country), a homeowner needs some way to store the energy gathered by the solar cells for use during the times when the Sun isn't shining.

PROBLEM

Suppose a home's energy storage device is a 10.0-L tank and its solar panels deliver enough electricity to compress ambient air very slowly from atmospheric pressure to 23.1 MPa. What is the total energy stored in the air in the tank?

SOLUTION

THINK

At first, it might seem that no energy can be stored by increasing the pressure of a gas inside a tank of fixed volume, because a constant volume implies that no work can be done. However, it is the volume of the gas that matters, not the volume of the container in the final state. If the air is compressed very slowly, then the assumption that it stays at constant temperature is fulfilled to a good approximation. Thus, we can use the concept of work done on an ideal gas at constant temperature, that is, work done by isothermal compression. (In Solved Problem 19.4, we will consider a case for which we cannot make the same assumption.)

SKETCH

The pump used in the air compressor acts like a piston that changes the volume of the gas from its initial value to its final value (see Figure 19.13). The final value is the volume of the tank,

and the initial value is the volume that the same amount of air would occupy under normal atmospheric pressure.

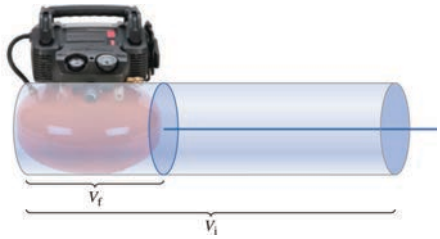

FIGURE 19.13
Compressing ambient air into a tank.

W. Bauer and G. D. Westfall

RESEARCH

Since the process of isothermal compression of a gas applies here, we can use our result for the work done in such a process, $W = nRT\ln(V_f/V_i)$.

We are given the final volume of the air (10.0 L) but not the initial volume and both the final pressure (23.1 MPa) and the initial pressure (atmospheric pressure $= 101\,\text{kPa}$). According to Boyle's Law (the Ideal Gas Law for constant temperature), the initial and final pressures and volumes are related by $p_i V_i = p_f V_f$.

SIMPLIFY

Solving Boyle's Law for the ratio of the volumes yields

$$\frac{V_f}{V_i} = \frac{p_i}{p_f}.$$

Substituting for V_f/V_i from this version of Boyle's Law into our equation for the work done results in

$$W = nRT\ln\left(\frac{p_i}{p_f}\right).$$

Using the Ideal Gas Law, $pV = nRT$, we now substitute for nRT to obtain

$$W = p_\mathrm{f} V_\mathrm{f} \ln\left(\frac{p_\mathrm{i}}{p_\mathrm{f}}\right).$$

(Here we could have used the initial pressure and volume but chose to use the final pressure and volume because their values were given in the problem statement.)

CALCULATE

Now we can insert the numerical values:

$$\begin{aligned} W &= \left(23.1 \cdot 10^6\,\mathrm{Pa}\right)\left(10.0\,\cdot\,10^{-3}\,\mathrm{m}^3\right)\ln\left(0.101/23.1\right) \\ &= -1.254900 \cdot 10^6\,\mathrm{J}. \end{aligned}$$

ROUND

We round our result to three significant figures: $W = -1.25 \cdot 10^6\,\mathrm{J}$. This result means that the energy stored in this compressed gas is $E = +1.25 \cdot 10^6\,\mathrm{J}$.

DOUBLE-CHECK

Does the amount of stored energy we have calculated make sense? Since 1 kWh is 3.6 MJ, our result is approximately equal to $\frac{1}{3}$ kWh. This would be enough to power a couple of 40-W light bulbs for about 5 h, assuming that we could convert all of the stored energy into electricity, which is not possible. Thus, our result has to be taken as an upper limit. However, it seems plausible that a couple of light bulbs could be powered for a few hours with this relatively simple and cheap energy storage system.

Dalton’s Law

How do ideal gas considerations change, if there is more than one type of gas in a given volume, as in the Earth’s atmosphere, for example? **Dalton’s Law** states that the pressure of a gas composed of a homogeneous mixture of different gases is equal to the sum of the partial pressures of the component gases. **Partial pressure** is defined as the pressure each gas would exert if the other gases were not present. Dalton’s Law means that each gas is unaffected by the presence of other gases, as long as there is no interaction between the gas molecules. The law is named for John Dalton, a British chemist, who published it in 1801. Dalton’s Law gives the total pressure, p_{total}, exerted by a mixture of m gases, each with partial pressure p_{i}:

$$p_{\text{total}} = p_1 + p_2 + p_3 + \cdots + p_m = \sum_{i=1}^{m} p_i. \qquad \textbf{(19.11)}$$

The total number of moles of gas, n_{total}, contained in a mixture of m gases is equal to the sum of the numbers of moles of each gas, n_{i}:

$$n_{\text{total}} = n_1 + n_2 + n_3 + \cdots + n_m = \sum_{i=1}^{m} n_i.$$

Then, the **mole fraction**, r_{i}, for each gas in a mixture is the number of moles of that gas divided by the total number of moles of gas:

$$r_i = \frac{n_i}{n_{\text{total}}}. \qquad \textbf{(19.12)}$$

The sum of the mole fractions is equal to 1: $\sum_{i=1}^{m} r_i = 1$. If the number of moles of gas increases, with the temperature and volume constant, the pressure must go up. We can then express each partial pressure as

$$p_i = r_i p_{\text{total}} = n_i \frac{p_{\text{total}}}{n_{\text{total}}}. \qquad \textbf{(19.13)}$$

This means that the partial pressures in a mixture of gases are simply proportional to the mole fractions of the gases present in the mixture.

Concept Check 19.3

What is the mass of 22.4 L of dry air at standard temperature and pressure?

a) 14.20 g

b) 28.00 g

c) 28.95 g

d) 32.22 g

e) 60.00 g

Earth's Atmosphere

The atmosphere of the Earth has a mass of approximately $5.2 \cdot 10^{18}$ kg ($\sim$ 5 quadrillion metric tons; see Solved Problem 13.2). It is a mixture of several gases; see Table 19.1. The table lists only the components of dry air; in addition, air also contains water vapor (H_2O), which makes up approximately 0.25% of the entire atmosphere. (This sounds like a small number but equals approximately 10^{16} kg of water, which is about four times the volume of water in all the Great Lakes!) Near the Earth's surface, the water content of air ranges from less than 1% to over 3%, depending mainly on the air temperature and the availability of liquid water in the vicinity. Water vapor in the air *decreases* the average density of the atmosphere, because the molecular mass of water is 18, which is smaller than the molecular or atomic mass of almost all the other atmospheric gases.

Table 19.1 **Major Gases Making Up the Earth's Atmosphere**

Gas	Percentage by Volume	Chemical Symbol	Molecular Mass
Nitrogen	78.08	N_2	28.0
Oxygen	20.95	O_2	32.0
Argon	0.93	Ar	39.9
Carbon dioxide	0.039	CO_2	44.0
Neon	0.0018	Ne	20.2
Helium	0.0005	He	4.00
Methane	0.0002	CH_4	16.0
Krypton	0.0001	Kr	83.8

Concept Check 19.4

What is the oxygen pressure in the Earth's atmosphere at sea level?

a) 0

b) 0.21 atm

c) 1 atm

d) 4.8 atm

e) 20.9 atm

SOLVED PROBLEM 19.3 Density of Air at STP

PROBLEM

What is the density of air at standard temperature and pressure (STP)?

SOLUTION

THINK

We know that a mole of any gas at STP occupies a volume of 22.4 L. We know the relative fractions of the gases that comprise the atmosphere. We can combine Dalton's Law, Avogadro's Law, and the fractions of gases in air to obtain the mass of air contained in 22.4 L. The density is the mass divided by the volume.

SKETCH

This is one of the rare occasions where a sketch is not helpful

RESEARCH

We consider only the four gases in Table 19.1 that constitute a significant fraction of the atmosphere: nitrogen, oxygen, argon, and carbon dioxide. We know that 1 mole of any gas has a mass M (in grams) in a volume of 22.4 L at STP. From equation 19.12, we know that the mass of each gas in 22.4 L will be the fraction by volume times the molecular mass, so we have

$$m_{\text{air}} = r_{\text{N}_2} M_{\text{N}_2} + r_{\text{O}_2} M_{\text{O}_2} + r_{\text{Ar}} M_{\text{Ar}} + r_{\text{CO}_2} M_{\text{CO}_2}$$

and

$$\rho_{\text{air}} = \frac{m_{\text{air}}}{V_{\text{air}}} = \frac{m_{\text{air}}}{22.4\,\text{L}}.$$

SIMPLIFY

The density of air is then

$$\rho_{\text{air}} = \frac{(0.7808 \cdot 28\ \text{g}) + (0.2095 \cdot 32\ \text{g}) + (0.0093 \cdot 40\ \text{g}) +}{22.4\ \text{L}}$$

CALCULATE

Calculating the numerical result gives us

$$\begin{aligned}\rho_{air} &= \frac{0.0218624\ \text{kg} + 0.006704\ \text{kg} + 0.000372\ \text{kg} + 0.000(}{22.4\ \cdot 10^{-3}\ \text{m}^3} \\ &= 1.29266\ \text{kg/m}^3.\end{aligned}$$

ROUND

We report our result to three significant figures:

$$\rho_{\text{air}} = 1.29\ \text{kg/m}^3.$$

DOUBLE-CHECK

We can double-check our result by calculating the density of nitrogen gas alone at STP, since air is 78.08% nitrogen. The density of nitrogen at STP is

$$\rho_{\text{N}_2} = \frac{28.0\ \text{g}}{22.4\ \text{L}} = 1.25\ \text{g/L} = 1.25\ \text{kg/m}^3.$$

This result is close to and slightly lower than our result for the density of air; so our result is reasonable.

19.3 Equipartition Theorem

We have been discussing the macroscopic properties of gases, including volume, temperature, and pressure. To explain these properties in terms of the constituents of a gas, its molecules (or atoms), requires making several assumptions about the behavior of these molecules in a container. These assumptions, along with the results derived from them, are known as the **kinetic theory of an ideal gas**.

Suppose we have a gas in a container of volume V, and the gas fills this container evenly. We make the following assumptions:

- The number of molecules, N, is large, but the molecules themselves are small, so the average distance between molecules is large compared to their size. All molecules are identical, and each has mass m.

- The molecules are in constant random motion on straight-line trajectories. They do not interact with one another and can be considered point particles.
- The molecules have elastic collisions with the walls of the container.
- The volume, V, of the container is large compared to the size of the molecules. The container walls are rigid and stationary.

The kinetic theory explains how the microscopic properties of the gas molecules give rise to the macroscopic observables of pressure, volume, and temperature as related by the Ideal Gas Law. For now, we are mainly interested in what the average kinetic energy of the gas molecules is and how it relates to the temperature of the gas. This connection is called the **equipartition theorem.** In the next section, we use this theorem to derive expressions for the specific heats of gases. We'll then see that the equipartition theorem is

intimately connected to the idea of degrees of freedom of the motion of the gas molecules. Finally, in Section 19.6, we'll return to the kinetic theory, considering the distribution of kinetic energies of the molecules (instead of just the average kinetic energy), and discuss the limitations of the concept of an ideal gas.

First, we obtain the average kinetic energy of the ideal gas by simply averaging the kinetic energies of the individual gas molecules:

$$K_{\text{ave}} = \frac{1}{N}\sum_{i=1}^{N} K_i = \frac{1}{N}\sum_{i=1}^{N} \tfrac{1}{2}mv_i^2 = \tfrac{1}{2}m\left(\frac{1}{N}\sum_{i=1}^{N} v_i^2\right) =$$

Thus, the **root-mean-square speed** of the gas molecules, v_{rms}, is defined as

$$v_{\text{rms}} = \sqrt{\frac{1}{N}\sum_{i=1}^{N} v_i^2}. \qquad \textbf{(19.15)}$$

Note that the root-mean-square speed is *not the same* as the average speed of the gas molecules. But it can be considered a suitable average, because it immediately relates to the average kinetic energy, as seen in equation 19.14.

Derivation 19.2 shows how the average kinetic energy of the molecules in an ideal gas relates to the temperature of the gas. We'll see that the temperature of the gas is simply proportional to the average kinetic energy, with a proportionality constant $\frac{3}{2}$ times the Boltzmann constant:

$$K_{\text{ave}} = \tfrac{3}{2}k_{\text{B}}T. \qquad \textbf{(19.16)}$$

This is the equipartition theorem, which states that gas molecules in thermal equilibrium have the same average kinetic energy, equal to $\frac{1}{2}k_{\text{B}}T$, associated with each of their three independent degrees of

freedom. Thus, when we measure the temperature of a gas, we are determining the average kinetic energy of the molecules of the gas. This relationship is one of the key insights of kinetic theory and will be very useful in the rest of this chapter and in later chapters.

Let's see how to derive the equipartition theorem starting from Newtonian mechanics and using the ideal gas law.

DERIVATION 19.2 Average Kinetic Energy of Gas Molecules

The pressure of a gas in a container is determined by the interaction of the gas molecules with the walls of the container, that is, by the change in their momentum over a given time, which is a force. The pressure of the gas is a consequence of elastic collisions of the gas molecules with the walls of the container. When a gas molecule hits a wall, it bounces back with the same kinetic energy it had before the collision. We assume that the wall is stationary, and thus the component of the momentum of the gas molecule perpendicular to the surface of the wall is reversed in the collision (see Section 7.5).

Consider a gas molecule with mass m and an x-component of velocity, $v_{x,}$ traveling perpendicular to the wall of a container (Figure 19.14). The gas molecule bounces off the wall and moves in the opposite direction with velocity $-v_x$. (Remember, we assumed elastic collisions between molecules and walls.) The change in the x-component of the momentum, Δp_x, of the gas molecule during the collision with the wall is

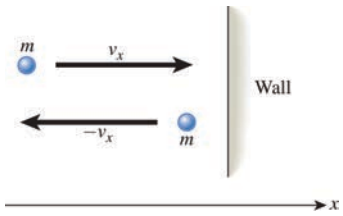

FIGURE 19.14 Gas molecule with mass m and velocity V_X bouncing off the wall of a container.

$$\Delta p_x = p_{\mathrm{f},x} - p_{\mathrm{i},x} = (m)(-v_x) - (m)(v_x) = -2mv_x.$$

To calculate the time-averaged force exerted by the gas on the wall of the container, we need to know not only how much the momentum changes during the collision but also how often a collision of a gas molecule with a wall occurs. To get an expression for the time between collisions, we assume the container is a cube with side length L (Figure 19.15). Then a collision with a particular wall, like that shown in Figure 19.14, occurs every time the gas molecule makes a complete trip from one side of the cube to the other and back again. This round trip covers a distance $2L$. We can express the time interval, Δt, between collisions with the wall as

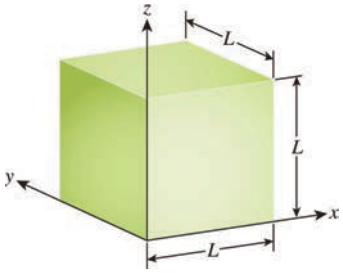

FIGURE 19.15 A cubical container with side length *L*. Three of the faces of the cube are in the *xy*-, *xz*-, and *yz*-planes.

$$\Delta t = \frac{2L}{v_x}.$$

We know from Newton's Second Law that the x-component of the force exerted by the wall on the gas molecule, $F_{\text{wall},x}$, is given by

$$F_{\text{wall},x} = \frac{\Delta p_x}{\Delta t} = \frac{-2mv_x}{(2L/v_x)} = -\frac{mv_x^2}{L},$$

where we have used $\Delta p_x = -2mv_x$ and $\Delta t = 2L/v_x$.

The x-component of the force exerted by the gas molecule on the wall, F_x, has the same magnitude as $F_{\text{wall},x}$ but is in the opposite direction; that is, $F_x = -F_{\text{wall},x}$, which is a direct consequence of Newton's Third Law (see Chapter 4). If there are N gas molecules, we can express the total force due to these gas molecules on the wall as

$$F_{\text{tot},x} = \sum_{i=1}^{N} \frac{mv_{x,i}^2}{L} = \frac{m}{L} \sum_{i=1}^{N} v_{x,i}^2. \qquad \text{(i)}$$

This result for the force on the wall located at $x = L$ is independent of the y- and z-components of the velocity vectors of the gas molecules. Since the molecules are in random motion, the average square of the x-components of the velocity is the same as the average square of the y-components or the z-components: $\sum_{i=1}^{N} v_{x,i}^2 = \sum_{i=1}^{N} v_{y,i}^2 = \sum_{i=1}^{N} v_{z,i}^2$. Since $v_i^2 = v_{x,i}^2 + v_{y,i}^2 + v_{z,i}^2$, we have $\sum_{i=1}^{N} v_{x,i}^2 = \frac{1}{3} \sum_{i=1}^{N} v_i^2$, or the average square of the x-components of the velocity is $\frac{1}{3}$ of the average square of the velocity. This is the reason for the name of the equipartition theorem: Each Cartesian velocity component has an equal part, $\frac{1}{3}$, of the overall kinetic energy. We can use this fact to rewrite equation (i) for the x-component of the force of the gas on the wall:

$$F_{\text{tot},x} = \frac{m}{3L} \sum_{i=1}^{N} v_i^2.$$

Repeating this force analysis for the other five walls, or faces of the cube, we find that each experiences a force of the same magnitude, given by $F_{\text{tot}} = \frac{m}{3L} \sum_{i=1}^{N} v_i^2$. To find the pressure

exerted by the gas molecules, we divide this force by the area of the wall, $A = L^2$:

$$p = \frac{F_{\text{tot}}}{A} = \frac{\frac{m}{3L}\sum_{i=1}^{N} v_i^2}{L^2} = \frac{m\sum_{i=1}^{N} v_i^2}{3L^3} = \frac{m}{3V}\sum_{i=1}^{N} v_i^2,$$

where we have used the cube's volume, $V = L^3$, in the last step. Using equation 19.15 for the root-mean-square speed of the gas molecules, we can express the pressure as

$$p = \frac{Nmv_{\text{rms}}^2}{3V}. \qquad \text{(ii)}$$

Page 602

This result holds for each face of the cube, and it can be applied to a volume of any shape. Multiplying both sides of equation (ii) by the volume leads to $pV = \frac{1}{3}Nmv_{\text{rms}}^2$, and since the Ideal Gas Law (equation 19.8) states that $pV = Nk_{\text{B}}T$, we have $Nk_{\text{B}}T = \frac{1}{3}Nmv_{\text{rms}}^2$. Canceling out the factor of N on both sides leads to

$$3k_{\text{B}}T = mv_{\text{rms}}^2. \qquad \text{(iii)}$$

Since $\frac{1}{2}mv_{\text{rms}}^2 = K_{\text{ave}}$, the average kinetic energy of a gas molecule, we have arrived at the desired result, equation 19.16:

$$K_{\text{ave}} = \tfrac{3}{2}k_{\text{B}}T.$$

Note that we can solve $3k_{\text{B}}T = mv_{\text{rms}}^2$, equation (iii) of Derivation 19.2, for the root-mean-square speed of the gas

molecules:

$$v_{\text{rms}} = \sqrt{\frac{3k_{\text{B}}T}{m}}. \tag{19.17}$$

EXAMPLE 19.4 Average Kinetic Energy of Air Molecules

Suppose a roomful of air is at a temperature of $22.0\,^{\circ}\text{C}$.

PROBLEM

What is the average kinetic energy of the molecules (and atoms) in the air?

SOLUTION

The average kinetic energy of the air molecules is given by equation 19.16:

$$K_{\text{ave}} = \tfrac{3}{2}k_{\text{B}}T = \tfrac{3}{2}\left(1.381{\cdot}10^{-23}\,\text{J/K}\right)\left(273.15\,\text{K} + 22.0\,\text{K}\right)$$

Often, the average kinetic energy of air molecules is given in electron-volts (eV) rather than joules:

$$K_{\text{ave}} = \left(6.11{\cdot}10^{-21}\ \text{J}\right)\frac{1\,\text{eV}}{1.602{\cdot}10^{-19}\,\text{J}} = 0.0382\ \text{eV}.$$

A useful approximation to remember is that the average kinetic energy of air molecules at sea level and room temperature is about 0.04 eV.

Concept Check 19.5

The average kinetic energy of molecules of an ideal gas doubles if the _____ doubles.

a) temperature

b) pressure

c) mass of the gas molecules

d) volume of the container

e) none of the above

19.4 Specific Heat of an Ideal Gas

Chapter 18 addressed the specific heat of materials, which we now consider for gases. Gases can consist of atoms or molecules, and the internal energy of gases can be expressed in terms of their atomic and molecular properties. These relationships lead to the molar specific heats of ideal gases.

Let's begin with **monatomic gases**, which are gases in which atoms are not bound to other atoms. Monatomic gases include helium, neon, argon, krypton, and xenon (the noble gases). We assume that all the internal energy of a monatomic gas is in the form of translational kinetic energy. The average translational kinetic energy depends only on the temperature, as stated in equation 19.16.

The internal energy of a monatomic gas is the number of atoms, *N*, times the average translational kinetic energy of one atom in the gas:

$$E_{\text{int}} = NK_{\text{ave}} = N\left(\tfrac{3}{2}k_{\text{B}}T\right).$$

The number of atoms of the gas is the number of moles, n, times Avogadro's number, $N_{\text{A:}}$ $N = nN_{\text{A}}$. Since $N_{\text{A}}k_{\text{B}} = R$, we can express the internal energy as

$$E_{\text{int}} = \tfrac{3}{2}nRT. \qquad \textbf{(19.18)}$$

Equation 19.18 shows that the internal energy of a monatomic gas depends only on the temperature of the gas.

Specific Heat at Constant Volume

Suppose an ideal monatomic gas at temperature T is held at constant volume. If heat, Q, is added to the gas, it has been shown empirically (see Chapter 18) that the temperature of the gas changes according to

$$Q = nC_V\Delta T \quad (\text{at constant volume}),$$

where C_V is the molar specific heat at constant volume. Because the volume of the gas is constant, it can do no work. Thus, we can use the First Law of Thermodynamics (see Chapter 18) to write

$$\Delta E_{\text{int}} = Q - W = nC_V\Delta T \quad (\text{at constant volume}). \textbf{(19.19)}$$

Remembering that the internal energy of a monatomic gas depends only on its temperature, we use equation 19.18 and obtain

$$\Delta E_{\text{int}} = \tfrac{3}{2}nR\Delta T.$$

Combining this result with $Q = nC_{\text{V}}\Delta T$ gives $nC_{\text{V}}\Delta T = \frac{3}{2}nR\Delta T$. Canceling the terms n and ΔT, which appear on both sides, we get an expression for the molar specific heat of an ideal monatomic gas at constant volume:

$$C_V = \tfrac{3}{2}R = 12.5\ \text{J}/\left(\text{mol K}\right). \qquad \textbf{(19.20)}$$

This value for the molar specific heat of an ideal monatomic gas agrees well with measured values for monatomic gases at standard temperature and pressure. These gases are primarily the noble gases. The molar specific heats for **diatomic gases** (gas molecules with two atoms) and **polyatomic gases** (gas molecules with more than two atoms) are higher than the molar specific heats for monatomic gases, as shown in Table 19.2. We'll discuss this difference later in this section.

Table 19.2	Some Typical Molar Specific Heats Obtained for Different Types of Gases		
Gas	C_V [J/(mol K)]	C_p [J/(mol K)]	$\gamma = C_p/C_V$
Helium (He)	12.5	20.8	1.66
Neon (Ne)	12.5	20.8	1.66
Argon (Ar)	12.5	20.8	1.66
Krypton (Kr)	12.5	20.8	1.66
Hydrogen (H_2)	20.4	28.8	1.41
Nitrogen (N_2)	20.7	29.1	1.41
Oxygen (O_2)	21.0	29.4	1.41
Carbon dioxide (CO_2)	28.2	36.6	1.29
Methane (CH_4)	27.5	35.9	1.30

We can substitute from equation 19.20 for $\frac{3}{2}R$ in equation 19.18 and obtain

$$E_{\text{int}} = nC_V T, \tag{19.21}$$

which means that the internal energy of an ideal gas depends only on n, C_V, and T.

The equation $\Delta E_{\text{int}} = nC_V \Delta T$ applies to all gases as long as the appropriate molar specific heat is used. According to this equation, the change in internal energy of an ideal gas depends only on n, C_V, and the change in temperature, ΔT. The change in internal energy does not depend on any corresponding pressure or volume change.

Specific Heat at Constant Pressure

Now let's consider the situation in which the temperature of an ideal gas is increased while the pressure of the gas is held constant. The added heat, Q, has been shown empirically to be related to the change in temperature as follows:

$$Q = nC_p\Delta T \text{ (for constant pressure)}, \qquad \textbf{(19.22)}$$

where C_p is the molar specific heat at constant pressure. The molar specific heat at constant pressure is greater than the molar specific heat at constant volume because energy must be supplied to do work as well as to increase the temperature.

To relate the molar specific heat at constant volume to the molar specific heat at constant pressure, we start with the First Law of Thermodynamics: $\Delta E_{\text{int}} = Q - W$. In the previous section, we showed that $\Delta E_{\text{int}} = nC_V\Delta T$ applies for any pressure or volume change, including constant pressure. We substitute from equation 19.22 for Q. In Chapter 18, the work, W, done when the pressure remains constant was expressed as $W = p\Delta V$. With these substitutions into $\Delta E_{\text{int}} = Q - W$, we obtain

$$nC_V\Delta T = nC_p\Delta T - p\Delta V.$$

The Ideal Gas Law (equation 19.7) relates the change in volume to the change in temperature if the pressure is held constant: $p\Delta V = nR\Delta T$. Substituting this expression for the work, we finally have

$$nC_V\Delta T = nC_p\Delta T - nR\Delta T.$$

Every term in this equation contains the common factor $n\Delta T$. Dividing it out gives the very simple relation between the specific heats at constant volume and at constant pressure:

$$C_p = C_V + R. \qquad \textbf{(19.23)}$$

Self-Test Opportunity 19.1

Using the data in Table 19.2, verify the relationship given in equation 19.23 between the molar specific heat at constant pressure and the molar specific heat at constant volume for an ideal gas.

Degrees of Freedom

As you can see in Table 19.2, the relationship $C_V = \frac{3}{2}R$ holds for monatomic gases but not for diatomic and polyatomic gases. This failure can be explained in terms of the possible degrees of freedom of motion for various types of molecules.

In general, a **degree of freedom** is a direction in which something can move. For a point particle in three-dimensional space, there are three orthogonal directions, which are independent of each other. For a collection of *N* point particles, there are 3*N* degrees of freedom for translational motion in three-dimensional space. But if the point particles are arranged in a solid object, they cannot move independently of each other, and the number of degrees of freedom is reduced to the translational degrees of freedom of the center of mass of the object (three), plus independent rotations of the object around the center of mass. In general, there are three possible independent rotations, giving a total of six degrees of freedom, three translational and three rotational.

Let's consider three different kinds of gases (Figure 19.16). The first is a monatomic gas, such as helium (He). The second is a diatomic gas, represented by nitrogen (N_2). The third is a polyatomic molecule, for example, methane (CH_4). The molecule of the polyatomic gas can rotate around all three coordinate axes and thus has three rotational degrees of freedom. The diatomic molecule shown in Figure 19.16 is aligned with the *x*-axis, and rotation about this axis will not yield a different configuration. Therefore, this molecule has only two rotational degrees of freedom, shown in the figure as being associated with rotations about the *y*- and *z*-axes. The monatomic gas consists of spherically symmetrical atoms, which have no rotational degrees of freedom. (Note that the argument presented here for rotational degrees of freedom does not really make sense for objects that obey classical Newtonian mechanics but does for those that follow the laws of quantum mechanics. We will discuss quantum physics in Chapters 36 through 40. For now, it is interesting to note that quantum mechanics has observable consequences in the macroscopic world, determining, for example, the specific heats of different gases.)

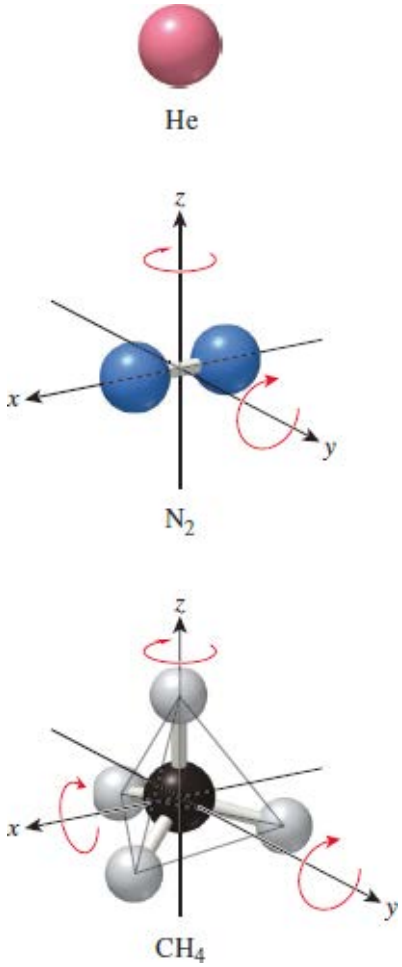

FIGURE 19.16 Rotational degrees of freedom for a helium atom (He), a nitrogen molecule (N_2), and a methane molecule (CH_4).

The various ways in which the internal energy of an ideal gas can be allocated are specified by the principle of **equipartition of energy,** which states that gas molecules in thermal equilibrium have the same average energy associated with each independent degree of freedom of their motion. The average energy per degree of freedom is given by $\frac{1}{2}k_BT$ for each gas molecule.

The equipartition theorem (equation 19.16) for gas molecules' average kinetic energy associated with temperature, $K_{\text{ave}} = \frac{3}{2}k_BT$,

is consistent with the equipartition of the molecules' translational kinetic energy among three directions (or three degrees of freedom), *x*, *y*, and *z*. The translational kinetic energy has three degrees of freedom, the average kinetic energy per translational degree of freedom is $\frac{1}{2}k_{\mathrm{B}}T$, and the average kinetic energy of the gas molecules is given by $3\left(\frac{1}{2}k_{\mathrm{B}}T\right) = \frac{3}{2}k_{\mathrm{B}}T$.

Thus, the molar specific heat at constant volume predicted by the kinetic theory for monatomic gases by assuming three degrees of freedom for the translational motion is consistent with reality. However, the observed molar specific heats at constant volume are higher for diatomic gases than for monatomic gases. For polyatomic gases, the observed molar specific heats are even higher.

Specific Heat at Constant Volume for a Diatomic Gas

The nitrogen molecule in Figure 19.16 is lined up along the *x*-axis. If we look along the *x*-axis at the molecule, we see a point and thus are not able to discern any rotation around the *x*-axis. However, if we look along the *y*-axis or the *z*-axis, we can see that the nitrogen molecule can have appreciable rotational motion about either of those axes. Therefore, there are two degrees of freedom for rotational kinetic energy of the nitrogen molecule and, by extension, all diatomic molecules. Therefore, the average kinetic energy per diatomic molecule is $(3+2)\left(\frac{1}{2}k_{\mathrm{B}}T\right) = \frac{5}{2}k_{\mathrm{B}}T$.

This result implies that calculation of the molar specific heat at constant volume for a diatomic gas should be similar to that for a monatomic gas, but with two additional degrees of freedom for the average energy. Thus, we modify equation 19.20 to obtain the molar specific heat at constant volume for a diatomic gas:

$$C_V = \frac{3+2}{2}R = \tfrac{5}{2}R = \tfrac{5}{2}[8.31\ \mathrm{J/\left(mol\ K\right)}] = 20.8\ \mathrm{J/\left(mol\ K\right)}$$

Comparing this value to the actual measured molar specific heats at constant volume given in Table 19.2 for the diatomic gases hydrogen, nitrogen, and oxygen, we see that this prediction from the kinetic theory of ideal gases agrees reasonably well with those measurements.

Specific Heat at Constant Volume for a Polyatomic Gas

Now let's consider the polyatomic gas, methane $(\mathrm{CH_4})$, shown in Figure 19.16. The methane molecule is composed of four hydrogen atoms arranged in a tetrahedron, bonded to a carbon atom at the center. Looking along any of the three axes, we can discern rotation of this molecule. Thus, this particular molecule and all polyatomic molecules have three degrees of freedom related to rotational kinetic energy.

Thus, calculation of the molar specific heat at constant volume for a polyatomic gas should be similar to that for a monatomic gas, but with three additional degrees of freedom for the average energy. We modify equation 19.20 to obtain the molar specific heat at constant volume for a polyatomic gas:

$$C_V = \frac{3+3}{2}R = \tfrac{6}{2}R = 3\,[8.31\ \mathrm{J/\,(mol\ K)}] = 24.9\ \mathrm{J/\,(mol\ K)}.$$

Comparing this value to the actual measured molar specific heat at constant volume given in Table 19.2 for the polyatomic gas methane, we see that the value predicted by the kinetic theory of ideal gases is close to, but somewhat lower than, the measured value.

What accounts for the differences between predicted and actual values of the molar specific heats for diatomic and polyatomic molecules is the fact that these molecules can have internal degrees of freedom, in addition to translational and rotational degrees of freedom. The atoms of these molecules can oscillate with respect to one another. For example, imagine that the two oxygen atoms and one carbon atom of a carbon dioxide molecule are connected by springs. The three atoms could oscillate back and forth with respect to each other, which corresponds to extra degrees of freedom. The molar specific heat at constant volume is thus larger than the $24.9\ \mathrm{J/\,(mol\ K)}$ predicted for a polyatomic gas.

A certain minimum energy is required to excite the motion of internal oscillation in molecules. This fact cannot be understood from the viewpoint of classical mechanics; Chapters 36 through 38 will provide this understanding. For now, all you need to know is that a threshold effect is observed for vibrational degrees of freedom. In

fact, the rotational degrees of freedom of diatomic and polyatomic gas molecules also exhibit this threshold effect. At low temperatures, the internal energy of the gas may be too low to enable the molecules to rotate. However, at standard temperature and pressure, most diatomic and polyatomic gases have a molar specific heat at constant volume that is consistent with their molecules' translational and rotational degrees of freedom.

Ratio of Specific Heats

Finally, it is convenient to take the ratio of the specific heat at constant pressure to that at constant volume. This ratio is conventionally denoted by the Greek letter γ:

$$\gamma \equiv \frac{C_p}{C_V}. \qquad \textbf{(19.24)}$$

Inserting the predicted values for the specific heats of ideal gases with different degrees of freedom gives $\gamma = C_p/C_V = \frac{5}{2}R/\frac{3}{2}R = \frac{5}{3}$ for monatomic gases, $\gamma = C_p/C_V = \frac{7}{2}R/\frac{5}{2}R = \frac{7}{5}$ for diatomic gases, and $\gamma = C_p/C_V = \frac{8}{2}R/\frac{6}{2}R = \frac{4}{3}$ for polyatomic gases.

Table 19.2 also lists values for γ obtained from empirical data. Despite the fact that the empirical values of the specific heats for the gases other than the noble gases are not very close to the calculated values for an ideal gas, the values of the ratio γ are in very good agreement with our theoretical expectations.

Concept Check 19.6

The ratio of specific heat at constant pressure to specific heat at constant volume, C_p/C_V, for an ideal gas

a) is always equal to 1.

b) is always smaller than 1.

c) is always larger than 1.

d) can be smaller or larger than 1, depending on the degrees of freedom of the gas molecules.

19.5 Adiabatic Processes for an Ideal Gas

As we saw in Chapter 18, an adiabatic process is one in which the state of a system changes and no exchange of heat with the surroundings takes place during the change. An adiabatic process can occur when the system change occurs quickly. Thus, $Q = 0$ for an adiabatic process. From the First Law of Thermodynamics, we then have $\Delta E_{\text{int}} = -W$, as shown in Chapter 18.

Let's explore how the change in volume is related to the change in pressure for an ideal gas undergoing an adiabatic process, that is, a process in the absence of heat transfer. The relationship is given by

$$pV^{\gamma} = \text{constant} \quad (\text{for an adiabatic process}), \quad \textbf{(19.25)}$$

where $\gamma = C_p/C_V$ is the ratio of the specific heat at constant pressure and the specific heat at constant volume for the ideal gas.

DERIVATION 19.3 Pressure and Volume in an Adiabatic Process

In order to derive the relationship between pressure and volume for an adiabatic process, let's consider small differential changes in the internal energy during such a process: $dE_{\text{int}} = -dW$. In Chapter 18, we saw that $dW = p\,dV$, and therefore for the adiabatic process, we have

$$dE_{\text{int}} = -p\,dV. \qquad \text{(i)}$$

However, equation 19.21 says that the internal energy is related in general to the temperature: $E_{\text{int}} = nC_V T$. Since we want to calculate dE_{int}, we take the derivative of this equation with respect to the temperature:

$$dE_{\text{int}} = nC_V\,dT. \qquad \text{(ii)}$$

Combining equations (i) and (ii) for dE_{int} then yields

$$-pdV = nC_V\,dT. \qquad \text{(iii)}$$

We can take the derivative of the Ideal Gas Law (equation 19.7), $pV = nRT$ (with n and R constant):

$$pdV + V\,dp = nRdT. \qquad \text{(iv)}$$

Solving equation (iii) for dT and substituting that expression into equation (iv) gives us

$$pdV + V\,dp = nR\left(-\frac{pdV}{nC_V}\right).$$

Now we can collect the terms proportional to dV on the left-hand side, giving

$$\left(1 + \frac{R}{C_V}\right)pdV + V\,dp = 0. \qquad \text{(v)}$$

Since $R = C_p - C_V$ from equation 19.23, we see that $1 + R/C_V = 1 + (C_p - C_V)/C_V = C_p/C_V$. Equation 19.24 represents this ratio of the two specific heats as γ. With this, equation (v) becomes $\gamma p\,dV + V\,dp = 0$. Dividing both sides by pV lets us finally write

$$\frac{dp}{p} + \gamma\frac{dV}{V} = 0.$$

Integration then yields

$$\ln p + \gamma \ln V = \text{constant}. \qquad \text{(vi)}$$

Using the rules of logarithms, equation (vi) can also be written as $\ln\,(pV^\gamma) = \text{constant}$. We can exponentiate both sides of this equation to get the desired result:

$$pV^\gamma = \text{constant}.$$

Another way of stating the relationship between pressure and volume for an adiabatic process involving an ideal gas is

$$p_\text{f}V_\text{f}^\gamma = p_\text{i}V_\text{i}^\gamma \quad \text{(for an adiabatic process)}, \qquad \textbf{(19.26)}$$

where p_i and V_i are the initial pressure and volume, respectively, and p_f and V_f are the final pressure and volume, respectively.

Figure 19.17 plots the behavior of a gas during three different processes as a function of pressure and volume. The red curve represents an adiabatic process, in which pV^γ is constant, for a monatomic gas with $\gamma = \frac{5}{3}$. The other two curves represent isothermal (constant T) processes. One isothermal process occurs at $T = 300\,\text{K}$, and the other occurs at $T = 400\,\text{K}$. The adiabatic process shows a steeper decrease in pressure as a function of volume than the isothermal processes.

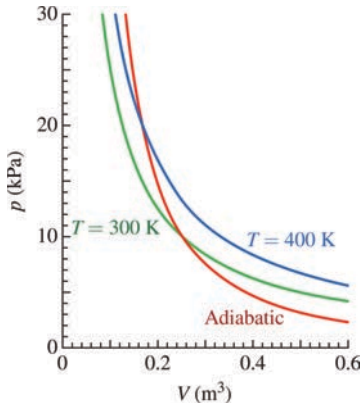

FIGURE 19.17 Plot of the behavior of a monatomic gas during three different processes on a *pV*-diagram. One process is adiabatic (red). The second process is isothermal with $T = 300\,\text{K}$ (green) The third process is also isothermal with $T = 400\,\text{K}$ (blue).

We can write an equation relating the temperature and volume of a gas in an adiabatic process by combining equation 19.25 and the Ideal Gas Law (equation 19.7):

$$pV^{\gamma} = \left(\frac{nRT}{V}\right)V^{\gamma} = (nR)TV^{\gamma-1} = \text{constant}.$$

Assuming that the gas is in a closed container, n is constant, and we can rewrite this relationship as $TV^{\gamma-1} = \text{constant}$ (for an adiabatic process), or

$$T_{\text{f}}V_{\text{f}}^{\gamma-1} = T_{\text{i}}V_{\text{i}}^{\gamma-1} \quad \text{(for an adiabatic process)}, \textbf{(19.27)}$$

where T_{i} and V_{i} are the initial temperature and volume, respectively, and T_{f} and V_{f} are the final temperature and volume, respectively.

An adiabatic expansion as described by equation 19.27 occurs when you open a container that holds a cold, carbonated beverage. The carbon dioxide from the carbonation and the water vapor make up a gas with a pressure above atmospheric pressure. When this gas expands and some comes out of the container's opening, the system must do work. Because the process happens very quickly, no heat can be transferred to the gas; thus, the process is adiabatic, and the product of the temperature and the volume raised to the power $\gamma - 1$ remains constant. The volume of the gas increases, and the temperature must decrease. Thus, condensation occurs around the opening of the container.

Concept Check 19.7

A monatomic ideal gas occupies a volume V_{i}, which is then decreased to $\frac{1}{2}V_{\text{i}}$ via an adiabatic process. Which relationship is correct for the pressures of this gas?

a) $p_{\text{f}} = 2p_{\text{i}}$

b) $p_{\text{f}} = \frac{1}{2}p_{\text{i}}$

c) $p_{\text{f}} = 2^{5/3}p_{\text{i}}$

d) $p_{\text{f}} = \left(\frac{1}{2}\right)^{5/3}p_{\text{i}}$

Concept Check 19.8

A monatomic ideal gas occupies a volume V_i, which is then decreased to $\frac{1}{2}V_i$ via an adiabatic process. Which relationship is correct for the temperatures of this gas?

a) $T_f = 2^{2/3}T_i$

b) $T_f = 2^{5/3}T_i$

c) $T_f = \left(\frac{1}{2}\right)^{2/3}T_i$

d) $T_f = \left(\frac{1}{2}\right)^{5/3}T_i$

Self-Test Opportunity 19.2

In Solved Problem 19.4, we assumed that the volume of the tire can be approximated as a cylindrical ring of thickness *t*. This implies a square cross section for the tire. Describe how our result would change if we approximated the cross section of the tire more realistically as a circle of diameter *t*.

SOLVED PROBLEM 19.4 Bicycle Tire Pump

A hand-operated tire pump (Figure 19.18a) is used to inflate a bicycle tire. The tire pump consists of a cylinder with a piston. The tire pump is connected to the tire with a small hose. There is a valve between the pump and the tire that allows air to enter the tire, but not to exit. In addition, there is a valve that allows air to enter the pump after the compression stroke is complete and the piston is retracted to its original position. Figure 19.18b shows the pump and tire before the compression stroke. Figure 19.18c shows the pump and tire after the compression stroke.

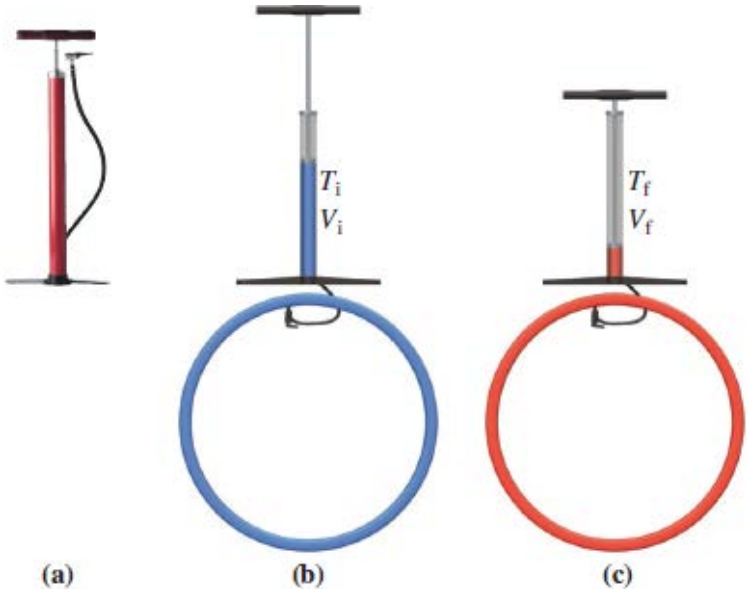

FIGURE 19.18 (a) A hand-operated tire pump used to inflate a bicycle tire. (b) The pump and tire before the compression stroke. (c) The pump and tire after the compression stroke.

The inner radius of the cylinder of the pump is $r_p = 1.00\,\text{cm}$, the height of the active volume before the compression stroke is $h_i = 60.0\,\text{cm}$, and the height of the active volume after the compression stroke is $h_f = 10.0\,\text{cm}$. The tire can be considered to be a cylindrical ring with inner radius $r_1 = 66.0\,\text{cm}$, outer

radius $r_2 = 67.5\,\text{cm}$, and thickness $t = 1.50\,\text{cm}$. The temperature of the air in the pump and tire before the compression stroke is $T_\text{i} = 295\,\text{K}$.

PROBLEM

What is the temperature, $T_\text{f,}$ of the air after one compression stroke?

SOLUTION

THINK

The volume and temperature of the air before the compression stroke are V_i and T_i, respectively, and the volume and temperature of the air after the compression stroke are V_f and $T_\text{f,}$ respectively. The compression stroke takes place quickly, so no heat can be transferred into or out of the system, and this process can be treated as an adiabatic process. The volume of air in the pump decreases when the pump handle is pushed down while the volume of air in the tire remains constant.

SKETCH

The dimensions of the tire pump and the tire are shown in Figure 19.19.

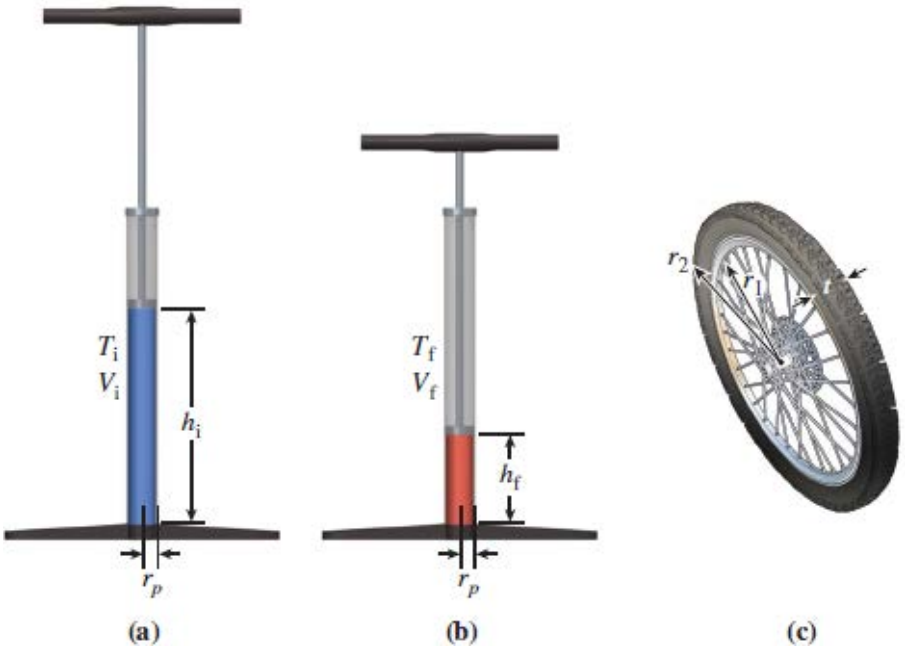

FIGURE 19.19 (a) Dimensions of the tire pump before the compression stroke. (b) Dimensions of the tire pump after the compression stroke. (c) Dimensions of the bicycle tire.

RESEARCH

The volume of air in the tire is

$$V_{\text{tire}} = t\left(\pi r_2^2 - \pi r_1^2\right).$$

The volume of air in the pump before the compression stroke is

$$V_{\text{pump,i}} = \pi r_{\text{p}}^2 h_{\text{i}}.$$

The volume of air in the pump after the compression stroke is

$$V_{\text{pump,f}} = \pi r_{\text{p}}^2 h_{\text{f}}.$$

The initial volume of air in the pump-tire system is $V_{\text{i}} = V_{\text{pump,i}} + V_{\text{tire}}$, and the final volume of air in the pump-tire

system is $V_\mathrm{f} = V_\mathrm{pump,f} + V_\mathrm{tire}$. We ignore the volume of air in the hose between the pump and the tire.

This process is adiabatic, so we can use equation 19.27 to describe the system before and after the compression stroke:

$$T_\mathrm{f} V_\mathrm{f}^{\gamma-1} = T_\mathrm{i} V_\mathrm{i}^{\gamma-1}. \qquad \text{(i)}$$

SIMPLIFY

We can solve equation (i) for the final temperature:

$$T_\mathrm{f} = T_\mathrm{i} \frac{V_\mathrm{i}^{\gamma-1}}{V_\mathrm{f}^{\gamma-1}} = T_\mathrm{i} \left(\frac{V_\mathrm{i}}{V_\mathrm{f}} \right)^{\gamma-1}.$$

We can then insert the expressions for the initial volume and the final volume:

$$T_\mathrm{f} = T_\mathrm{i} \left(\frac{\pi r_\mathrm{p}^2 h_\mathrm{i} + t\left(\pi r_2^2 - \pi r_1^2\right)}{\pi r_\mathrm{p}^2 h_\mathrm{f} + t\left(\pi r_2^2 - \pi r_1^2\right)} \right)^{\gamma-1} = T_i \left(\frac{r_\mathrm{p}^2 h_\mathrm{i} + t\left(r_2^2 -}{r_\mathrm{p}^2 h_\mathrm{f} + t\left(r_2^2 -} \right.$$

CALCULATE

Air is mostly diatomic gases (78% $\mathrm{N_2}$ and 21% $\mathrm{O_2}$, see Table 19.1), so we use $\gamma = \frac{7}{5}$, from Section 19.4. Putting in the numerical values then gives us

$$T_\mathrm{f} = (295\ \mathrm{K}) \left(\frac{(0.0100\ \mathrm{m})^2 (0.600\ \mathrm{m}) + (0.0150\ \mathrm{m}) \left((0.67\right.}{(0.0100\ \mathrm{m})^2 (0.100\ \mathrm{m}) + (0.0150\ \mathrm{m}) \left((0.67\right.}$$
$$= 313.162\ \mathrm{K}.$$

ROUND

We report our result to three significant figures:

$$T_\mathrm{f} = 313\,\mathrm{K}.$$

DOUBLE-CHECK

The ratio of the initial volume of air in the pump-tire system to the final volume is

$$\frac{V_\mathrm{i}}{V_\mathrm{f}} = 1.16.$$

During the compression stroke, the temperature of the air increases from 295 K to 313 K, so the ratio of final temperature to initial temperature is

$$\frac{T_\mathrm{f}}{T_\mathrm{i}} = \frac{313\,\mathrm{K}}{295\,\mathrm{K}} = 1.06,$$

which seems reasonable because the final temperature should be equal to the initial temperature times the ratio of the initial and final volume raised to the power $\gamma - 1$: $(1.16)^{\gamma-1} = 1.16^{0.4} = 1.06$. If you depress the piston many times in a short period of time, each compression stroke will increase the temperature of the air in the tire by about 6%. Thus, the air in the tire and in the pump gets warmer as the tire is inflated.

Work Done by an Ideal Gas in an Adiabatic Process

We can also find the work done by a gas undergoing an adiabatic process from an initial state to a final state. In general, the work is given by

$$W = \int_{\mathrm{i}}^{\mathrm{f}} p dV.$$

For an adiabatic process, we can use equation 19.25 to write $p = cV^{-\gamma}$ (where c is a constant), and the integral determining the work becomes

$$W = \int_{V_\mathrm{i}}^{V_\mathrm{f}} cV^{-\gamma} dV = c \int_{V_\mathrm{i}}^{V_\mathrm{f}} V^{-\gamma} dV = c\left[\frac{V^{1-\gamma}}{1-\gamma}\right]_{V_\mathrm{i}}^{V_\mathrm{f}} = \frac{c}{1-\gamma}\left(V_\mathrm{f}^{1-}\right.$$

The constant c has the value $c = pV^{\gamma}$. Using the Ideal Gas Law in the form $p = nRT/V$, we have

$$c = \left(\frac{nRT}{V}\right) V^{\gamma} = nRTV^{\gamma-1}.$$

Now we insert this constant into the expression for the work and use equation 19.27. We finally find the work done by a gas undergoing an adiabatic process:

$$W = \frac{nR}{1-\gamma}(T_\mathrm{f} - T_\mathrm{i}). \qquad \textbf{(19.28)}$$

19.6 Kinetic Theory of Gases

As promised earlier, this section examines some important results from the kinetic theory of gases beyond the equipartition theorem of Section 19.3.

Self-Test Opportunity 19.3

Show explicitly that integrating the Maxwell speed distribution from $v = 0$ to $v = \infty$ yields 1, as required for a probability distribution.

Maxwell Speed Distribution

Equation 19.17 gives the root-mean-square speed of gas molecules at a given temperature. This is close to the average speed, but what is the distribution of speeds? That is, what is the probability that a gas molecule has some given speed between v and $v + dv$? The speed distribution, called the **Maxwell speed distribution,** or sometimes the *Maxwell-Boltzmann speed distribution*, is given by

$$f(v) = 4\pi\left(\frac{m}{2\pi k_{\mathrm{B}}T}\right)^{3/2} v^2 e^{-mv^2/2k_{\mathrm{B}}T}. \qquad \textbf{(19.29)}$$

The units of the Maxwell speed distribution are $(\mathrm{m/s})^{-1}$. As required for a probability distribution, integration of this distribution with respect to dv yields 1: $\int_0^\infty f(v)dv = 1$.

A very important feature of probability distributions for observable quantities, including the one in equation 19.29 for the molecular speed, is that all kinds of physically meaningful averages can be calculated from them by simply multiplying the quantity to be averaged by the probability distribution and integrating over the entire range. For example, we can obtain the average speed for the Maxwell speed distribution by multiplying the speed, v, by the probability distribution, $f(v)$, and integrating this product, $vf(v)$, over all possible values of the speed from zero to infinity. The average speed is then given by

$$v_{\mathrm{ave}} = \int_0^\infty vf(v)dv = \sqrt{\frac{8k_{\mathrm{B}}T}{\pi m}},$$

where we used the definite integral $\int_0^\infty x^3 e^{-x^2/a}dx = a^2/2$ in performing the integration.

To find the root-mean-square speed for the Maxwell speed distribution, we first find the average speed squared:

$$\left(v^2\right)_{\text{ave}} = \int_0^\infty v^2 f\left(v\right) dv = \frac{3k_{\text{B}}T}{m},$$

where we employed the definite integral $\int_0^\infty x^4 e^{-x^2/a} dx = \frac{3}{8} a^{5/2} \sqrt{\pi}$. We then take the square root:

$$v_{\text{rms}} = \sqrt{\left(v^2\right)_{\text{ave}}} = \sqrt{\frac{3k_{\text{B}}T}{m}}.$$

As required, this agrees with equation 19.17 for the speed of gas molecules in an ideal gas.

The most probable speed for the Maxwell speed distribution—that is, the value at which $f(v)$ has a maximum—is calculated by taking the derivative of $f(v)$ with respect to v, setting that derivative equal to zero, and solving for v, which gives

$$v_{\text{mp}} = \sqrt{\frac{2k_{\text{B}}T}{m}}.$$

Page 611

Figure 19.20 shows the Maxwell speed distribution for nitrogen (N_2) molecules in air at a temperature of $295\,\text{K}\,(22\,^\circ\text{C})$, with the most probable speed, the average speed, and the root-mean-square speed. You can see in Figure 19.20 that the speeds of the nitrogen molecules are distributed around the average speed, v_{ave}. However, the distribution is not symmetrical around v_{rms}. A tail in the distribution extends to high velocities. You can also see that the most probable speed corresponds to the maximum of the distribution.

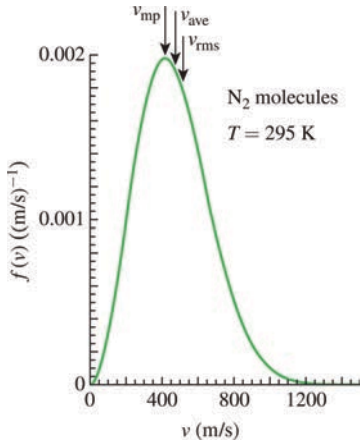

FIGURE 19.20 Maxwell speed distribution for nitrogen molecules with a temperature of 295 K plotted on a linear scale.

Figure 19.21 shows the Maxwell speed distribution for nitrogen molecules at four different temperatures. As the temperature is increased, the Maxwell speed distribution gets wider. Consequently, the maximum value of $f(v)$ has to get lower with increasing temperature, because the total area under the curve always equals 1, as required for a probability distribution.

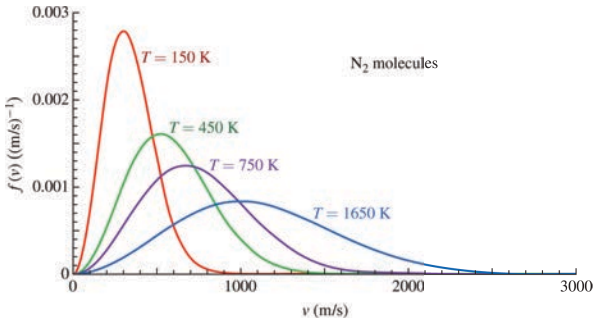

FIGURE 19.21 Maxwell speed distribution for N_2 molecules at four different temperatures.

In addition, at a given temperature, the Maxwell speed distribution for lighter atoms or molecules is wider and has more of a high-speed tail than the distribution for heavier atoms or molecules (Figure 19.22). Figure 19.22a shows the Maxwell speed distributions

for hydrogen and nitrogen molecules plotted on a logarithmic scale at a temperature of 22 °C, which is characteristic of temperatures found at the surface of the Earth. How far the high-speed tails of these distributions extend is important to the composition of Earth's atmosphere. As we saw in Chapter 12, the escape speed, $v_{e,}$ for any object near the surface of the Earth is 11.2 km/s. Thus, any air molecule that has at least this escape speed can leave Earth's atmosphere. No gas atoms or molecules are near the escape speed at this temperature. However, hydrogen gas is light compared to the other gases in the Earth's atmosphere and tends to move upward. The temperature of Earth's atmosphere depends on the altitude. At an altitude of 100 km above the surface, the Earth's atmosphere starts to become very warm and can reach temperatures of 1500 °C. This layer of the atmosphere is called the *thermosphere*.

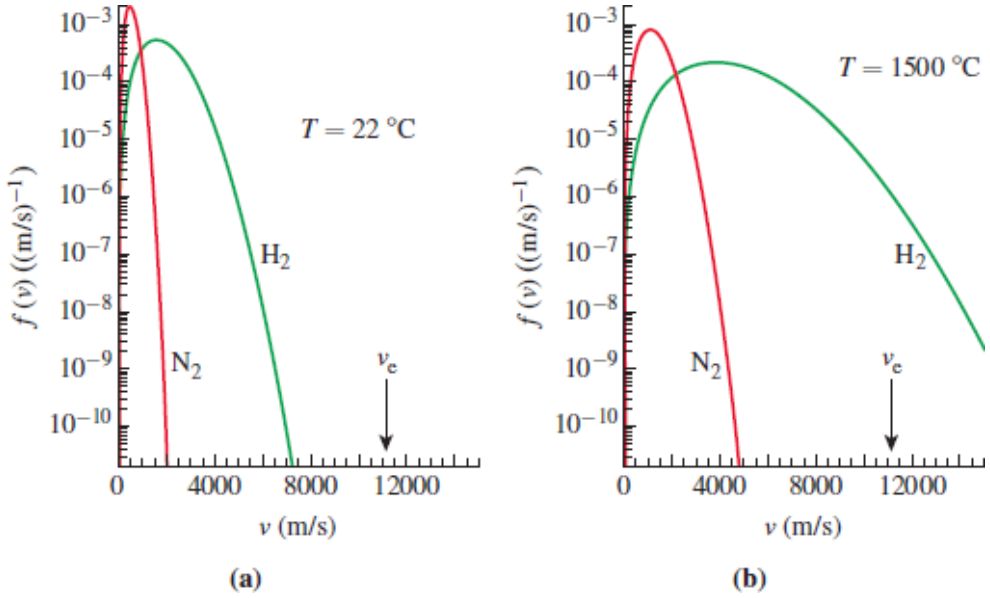

FIGURE 19.22 Maxwell speed distributions for hydrogen molecules and nitrogen molecules in the Earth's atmosphere, plotted on a logarithmic scale: (a) at a temperature of 22 °C; (b) at a temperature of 1500 °C.

Figure 19.22b shows the Maxwell speed distributions for hydrogen and nitrogen molecules plotted on a logarithmic scale at a temperature of 1500 °C. We can calculate the fraction of hydrogen molecules that will have a speed higher than the escape speed by

evaluating the integral for the Maxwell speed distribution from the escape speed to infinity:

$$\text{Fraction of } H_2 \text{ escaping} = \int_{v=11.2\,\text{km/s}}^{\infty} f(v)dv = 7 \cdot 10^{-4} = 0.07$$

Only a small fraction of the hydrogen molecules in the thermosphere have speeds above the escape speed. The hydrogen molecules with speeds above the escape speed will go out into space. The hydrogen molecules remaining behind have the same temperature as the rest of the thermosphere, and the speed distribution will reflect this temperature. Thus, over time on the geologic scale, most hydrogen molecules in the Earth's atmosphere rise to the thermosphere and eventually leave the Earth.

Page 612

What about the rest of the atmosphere, which consists mainly of nitrogen and oxygen? Essentially no nitrogen molecules have speeds above the escape speed. The ratio of the value of the Maxwell speed distribution at the escape speed for nitrogen relative to that for hydrogen is $f_{\text{N}}(11.2\,\text{km/s})/f_{\text{H}}(11.2\,\text{km/s}) = 3 \cdot 10^{-48}$. Since the entire atmosphere has a mass of $5 \cdot 10^{18}\,\text{kg}$ and contains approximately 10^{44} nitrogen molecules, you can see that virtually no nitrogen molecule has a speed above the escape speed. Thus, there is very little hydrogen in Earth's atmosphere, while nitrogen and heavier gases (oxygen, argon, carbon dioxide, neon, and so on) remain in the atmosphere permanently.

Maxwell Kinetic Energy Distribution

Just as gas molecules have a distribution of speeds, they also have a distribution of kinetic energies. The **Maxwell kinetic energy distribution** (sometimes called the *Maxwell-Boltzmann kinetic energy distribution*) describes the energy spectra of gas molecules and is given by

$$g(K) = \frac{2}{\sqrt{\pi}} \left(\frac{1}{k_{\mathrm{B}} T} \right)^{3/2} \sqrt{K} e^{-K/k_{\mathrm{B}} T}. \qquad \textbf{(19.30)}$$

The Maxwell kinetic energy distribution times dK gives the probability of observing a gas molecule with a kinetic energy between K and $K + dK$. Integration of this distribution with respect to dK yields 1, $\int_0^\infty g(K) dK = 1$, as required for any probability distribution. The unit for the Maxwell kinetic energy distribution is J^{-1}.

Figure 19.23 shows the Maxwell kinetic energy distribution for nitrogen molecules at a temperature of 295 K. The kinetic energies of the nitrogen molecules are distributed around the average kinetic energy. Like the Maxwell speed distribution, the Maxwell kinetic energy distribution is not symmetrical around $K_{\mathrm{ave},}$ but has a significant tail at high kinetic energies. This high-kinetic-energy tail can carry information about the temperature of the gas.

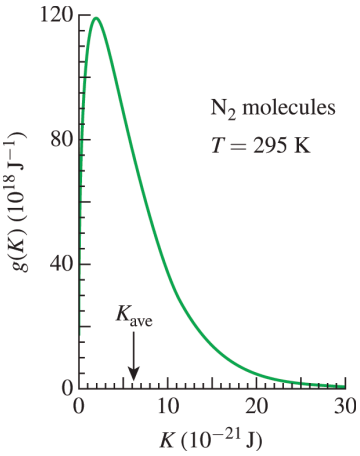

FIGURE 19.23
Maxwell kinetic energy distribution for nitrogen molecules at a temperature of 295 K, plotted on a linear scale.

Figure 19.24 shows the Maxwell kinetic energy distribution for nitrogen molecules at two temperatures, $T = 295\,\mathrm{K}$ and $T = 1500\,\mathrm{K}$. The kinetic energy distribution at $T = 1500\,\mathrm{K}$ is much flatter and extends to much higher kinetic energies than the kinetic energy distribution at $T = 295\,\mathrm{K}$. The high-kinetic-energy tails for the distributions in Figure 19.24 approach a simple exponential distribution of kinetic energy with a slope of $-1/k_{\mathrm{B}}T$, as illustrated by the dashed lines for the two temperatures.

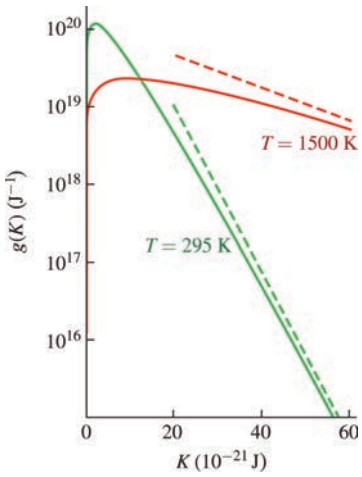

FIGURE 19.24
Maxwell kinetic energy distributions for nitrogen molecules at $T = 295\,\mathrm{K}$ and $T = 1500\,\mathrm{K}$, plotted on a logarithmic scale.

Note that the formulations given here for the Maxwell speed distribution and the Maxwell kinetic energy distribution do not take the effects of relativity into account. For example, the speed distribution extends up to infinite velocities, and no object can travel faster than the speed of light (to be discussed in detail in Chapter 35 on relativity). However, the relevant velocities for ideal gases are small compared with the speed of light. The highest speed shown in Figure 19.22 is $v = 1.5 \cdot 10^4\,\mathrm{m/s}$ (for hydrogen molecules at $T = 1500\,\mathrm{K}$), which is only 0.005% of the speed of light. The Maxwell speed and kinetic energy distributions are also based on the assumption that the molecules of the gas do not interact. If the gas molecules interact, then these distributions do not apply. For gas molecules moving in the Earth's atmosphere, the assumption of no interactions is justified, so many of the properties of the Earth's atmosphere can be described using the Maxwell speed distribution and the Maxwell kinetic energy distribution.

EXAMPLE 19.5 Temperature of the Quark-Gluon Plasma

Measuring the kinetic energy distribution of the constituents of a gas can reveal the temperature of the gas. This technique is used in many applications, including the study of gases consisting of elementary particles and nuclei. For example, Figure 19.25 shows the kinetic energy distributions of antiprotons and pions produced in relativistic heavy ion collisions of gold nuclei. (Antiprotons and pions will be discussed extensively in Chapter 39.) The data were produced by the STAR collaboration and are shown as red dots. Data points for low kinetic energies are missing, because the experimental apparatus cannot detect those energies. The blue lines represent fits to the data, using equation 19.30 with the best-fit value for the temperature, T. Values of $k_{\mathrm{B}}T = 6.71 \cdot 10^{-11}\,\mathrm{J} = 419\,\mathrm{MeV}$ for the antiprotons and $k_{\mathrm{B}}T = 3.83 \cdot 10^{-11}\,\mathrm{J} = 239\,\mathrm{MeV}$ for the pions were extracted, meaning that the temperatures of the antiprotons and pions are $4.86 \cdot 10^{12}\,\mathrm{K}$ and $2.77 \cdot 10^{12}\,\mathrm{K}$, respectively. (These temperatures are several hundred million times higher than the temperature at the surface of the Sun!) These observations and others enable researchers to infer that a quark-gluon plasma with a temperature of $2 \cdot 10^{12}\,\mathrm{K}$ is created for a very short time of approximately $10^{-22}\,\mathrm{s}$ in these collisions.

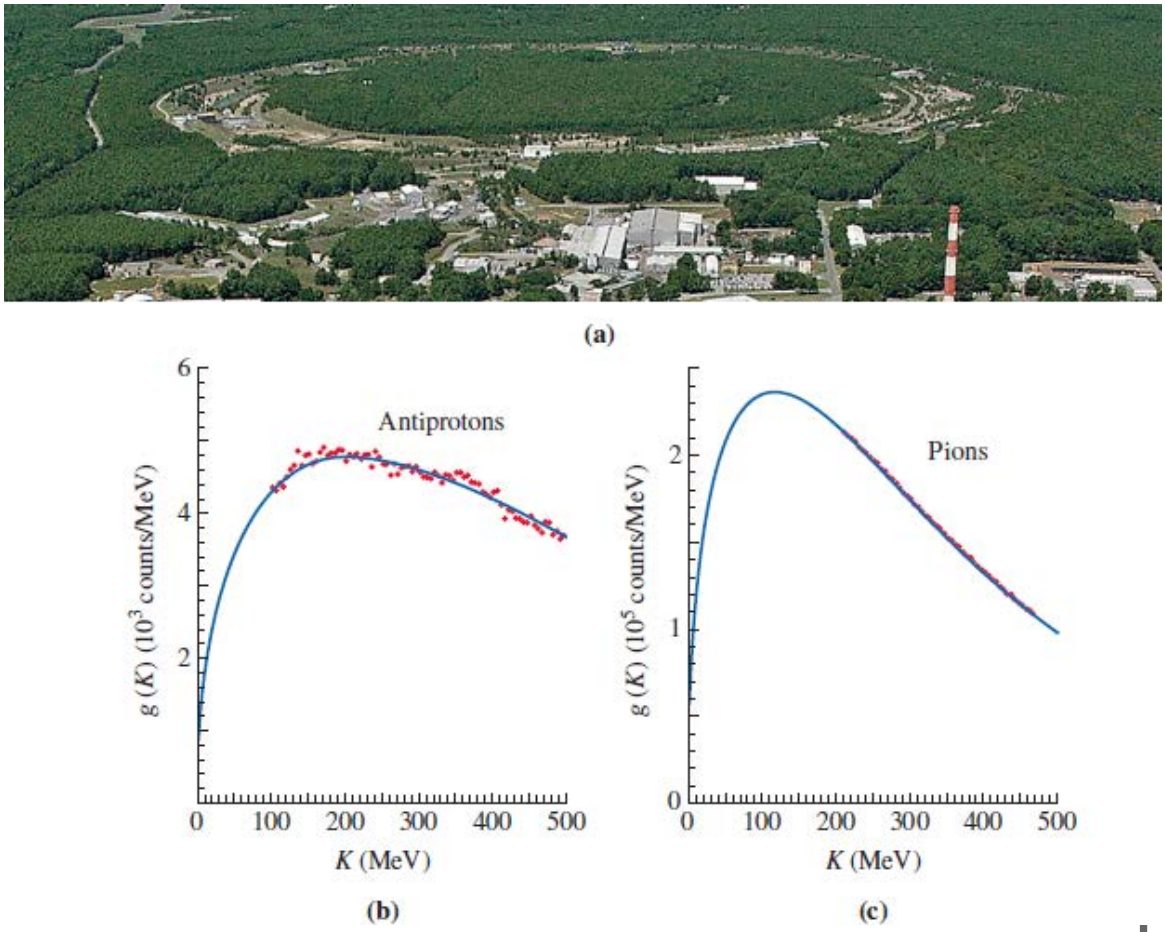

FIGURE 19.25 (a) The 3.83-km-circumference ring of the Relativistic Heavy Ion Collider at Brookhaven National Laboratory. Experimental data on the kinetic energy distribution of (b) antiprotons and (c) pions produced in collisions of gold nuclei. These collisions become by far the hottest place in the Solar System for the short times they exist and produce a state of matter, the quark-gluon plasma, which existed for a fraction of a second after the Big Bang. The blue lines represent fits to the kinetic energy distributions using equation 19.30.

a: Courtesy of Brookhaven National Laboratory

Note: The connection between the temperature of the quark-gluon plasma and the temperature values extracted from the particle energy distributions is not entirely straightforward, because the collisions of the gold nuclei are explosive events. Also, an ideal gas is not the correct model. In addition, the kinetic

energies in Figure 19.25 were determined with the relativistically correct formulation, which will be introduced in Chapter 35. Nevertheless, the degree to which the observed kinetic energy distributions follow the Maxwell distribution is astounding.

To end this subsection, let's consider nuclear fusion in the center of the Sun. This nuclear fusion is the source of energy that causes all of the Sun's radiation and thus makes life on Earth possible. The temperature at the center of the Sun is approximately $1.5 \cdot 10^7\,\mathrm{K}$. According to equation 19.16, the average kinetic energy of the hydrogen ions in the Sun's center is $\frac{3}{2} k_\mathrm{B} T = 3.1 \cdot 10^{-16}\,\mathrm{J} = 1.9\,\mathrm{keV}$. However, for two hydrogen atoms to undergo nuclear fusion, they have to come close enough to each other to overcome their mutual electrostatic repulsion. (These topics will be discussed in detail in Chapters 21 on electrostatics and 40 on nuclear physics.) The minimum energy required to overcome the electrostatic repulsion is on the order of 1 MeV, or a few hundred times higher than the average kinetic energy of the hydrogen ions in the Sun's center. Thus, only hydrogen ions on the extreme tail of the Maxwell distribution have sufficient energy to participate in fusion reactions.

Mean Free Path

One of the assumptions about an ideal gas is that the gas molecules are point particles and do not interact with each other. But real gas molecules do have (very small, but nonzero) sizes and so have a chance of colliding with each other. Collisions of gas molecules with each other produce a scattering effect that causes the motion to be random and the distribution of their speeds to become the Maxwell distribution speed very quickly, independently of any initial speed distribution given to them.

How far do real gas molecules travel before they encounter another molecule? This distance is the **mean free path**, $\boldsymbol{\lambda}$**,** of molecules in a gas. The mean free path is proportional to the temperature and inversely proportional to the pressure of the gas and the cross-sectional area of the molecule:

$$\lambda = \frac{k_{\mathrm{B}}T}{\sqrt{2}\,(4\pi r^2)p}. \qquad \textbf{(19.31)}$$

DERIVATION 19.4 Mean Free Path

To estimate the mean free path, we start with the geometric definition of the **cross section for scattering.** We assume that all the molecules in the gas are spheres with radius r. If two molecules touch, they will have an elastic collision, in which total momentum and total kinetic energy are conserved (see Chapter 7). Let's imagine that a moving gas molecule encounters another gas molecule at rest, as shown in Figure 19.26a.

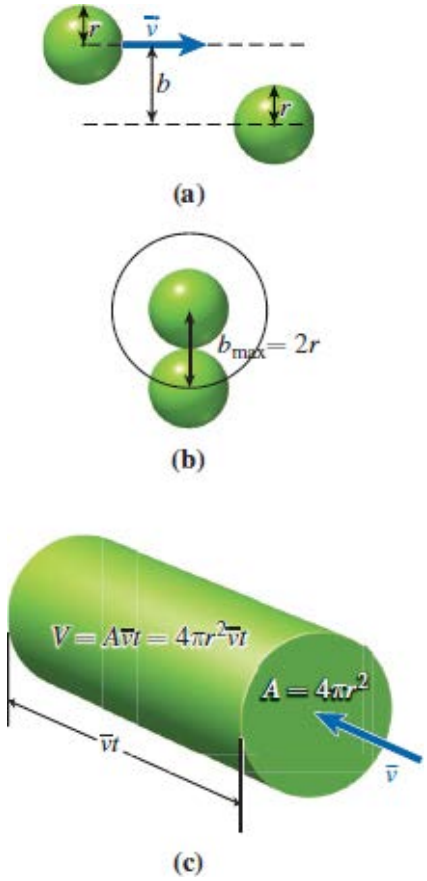

FIGURE 19.26 (a) A moving gas molecule approaches a stationary gas molecule with impact parameter b. (b) The cross section for scattering is represented by a circle with radius $2r$. (c) The volume swept out by molecules inside the cross-sectional area A in a time t when the molecules are traveling at speed $\overline{v}$.

The impact parameter b, as shown in Figure 19.26a, is the perpendicular distance between two lines connecting the centers of the two molecules and oriented parallel to the direction of the velocity of the moving molecule. The moving molecule will collide with the stationary molecule if $b \leq 2r$. Thus, the cross section for scattering is given by a circle with area

$$A = \pi(2r)^2 = 4\pi r^2,$$

as illustrated in Figure 19.26b. In a time period t, molecules with the average speed $\overline{v}$ will sweep out a volume

$$V = A\left(\overline{v}t\right) = \left(4\pi r^2\right)\left(\overline{v}t\right) = 4\pi r^2 \overline{v}t,$$

as shown in Figure 19.26c. Thus, the mean free path, λ, is the distance the molecule travels divided by the number of molecules it will collide with in that distance. The number of molecules that the molecule will encounter is just the volume swept out times the number of molecules per unit volume, n_V. The mean free path is then

$$\lambda = \frac{\overline{v}t}{Vn_V} = \frac{\overline{v}t}{(4\pi r^2 \overline{v}t)n_V} = \frac{1}{(4\pi r^2)n_V}.$$

This result needs to be modified because we assumed that one moving molecule was incident on a stationary molecule. In an ideal gas, all the molecules are moving, so we must use the average relative velocity, $v_{\text{rel},}$ between the molecules rather than the average velocity of the molecules.

It can be shown that $v_{\text{rel}} = \overline{v}\sqrt{2}$; so the volume swept out by the molecules changes to $V = 4\pi r^2 v_{\text{rel}} t = 4\pi r^2 \overline{v}\sqrt{2}t$. Thus, the expression for the mean free path becomes

$$\lambda = \frac{1}{\sqrt{2}\,(4\pi r^2)n_V}.$$

For diffuse gases, we can replace the number of molecules per unit volume with the ideal gas value, using equation 19.8:

$$n_V = \frac{N}{V} = \frac{p}{k_{\text{B}}T}.$$

The mean free path for a molecule in a real diffuse gas is then

$$\lambda = \frac{1}{\sqrt{2}\,(4\pi r^2)\left(\frac{p}{k_{\text{B}}T}\right)} = \frac{k_{\text{B}}T}{\sqrt{2}\,(4\pi r^2)p}.$$

Concept Check 19.9

The mean free path of a gas molecule doubles if the _____.

a) density of molecules goes down by a factor of 2
b) density of molecules doubles
c) diameter of the gas molecules doubles
d) diameter of the gas molecules goes down by a factor of 2
e) none of the above

Now that we have derived the formula for the mean free path, it is instructive to study a real case. Let's look at the most important gas, the Earth's atmosphere. An ideal gas has an "infinitely" long mean free path relative to the spacing between molecules in the gas. How closely a real gas approaches the ideal gas is determined by the ratio of the mean free path to the intermolecular spacing in the gas. Let's see how close Earth's atmosphere is to being an ideal gas.

EXAMPLE 19.6 Mean Free Path of Air Molecules

PROBLEM

What is the mean free path of a gas molecule in air at normal atmospheric pressure of 101.3 kPa and a temperature of 22.0 °C? Since air is 78.1% nitrogen, we'll assume for the sake of simplicity that air is 100% nitrogen. The radius of a nitrogen molecule is about 0.150 nm. Compare the mean free path to the radius of a nitrogen molecule and to the average spacing between the nitrogen molecules.

SOLUTION

We can use equation 19.31 to calculate the mean free path:

$$\lambda = \frac{\left(1.381 \cdot 10^{-23}\ \mathrm{J/K}\right)\left(293.15\ \mathrm{K}\right)}{\sqrt{2}\,(4\pi)\left(0.150 \cdot 10^{-9}\ \mathrm{m}\right)^2\left(101.3 \cdot 10^{3}\ \mathrm{Pa}\right)} = 9.99 \cdot 10$$

The ratio of the mean free path to the molecular radius is then

$$\frac{\lambda}{r} = \frac{9.99 \cdot 10^{-8}\ \mathrm{m}}{0.150 \cdot 10^{-9}\ \mathrm{m}} = 666.$$

The volume per particle in an ideal gas can be obtained using equation 19.8:

$$\frac{V}{N} = \frac{k_\mathrm{B}T}{p}.$$

The average spacing between molecules is then the average volume to the $\frac{1}{3}$ power:

$$\left(\frac{V}{N}\right)^{1/3} = \left(\frac{k_\mathrm{B}T}{p}\right)^{1/3} = \left(\frac{\left(1.381 \cdot 10^{-23}\ \mathrm{J/K}\right)\left(293.15\ \mathrm{K}\right)}{\left(101.3 \cdot 10^{3}\ \mathrm{Pa}\right)}\right.$$

Thus, the ratio between the mean free path and the average spacing between molecules is

$$\frac{9.99 \cdot 10^{-8}\ \text{m}}{3.42 \cdot 10^{-9}\ \text{m}} = 29.2.$$

The value of this ratio demonstrates that treating air as an ideal gas is a good approximation. Figure 19.27 compares the diameter of nitrogen molecules, the average distance between molecules, and the mean free path.

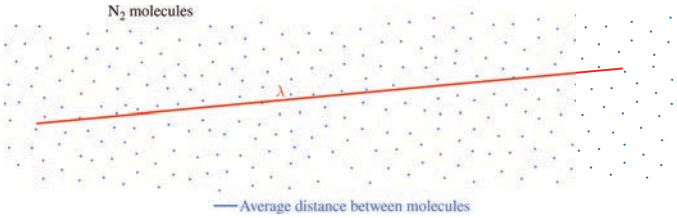

FIGURE 19.27 Scale drawing showing the size of nitrogen molecules, the mean free path of the molecules in the gas, and the average distance between molecules.

19.7 Real Gases

For an ideal gas, we assume that the molecules are point particles and have no interaction with each other. For real gases, we cannot make either of these assumptions. In Section 19.6, we saw that gas molecules can collide with one another because of their finite size. Since the molecules have a finite size, the volume that each molecule occupies is not available for other molecules and has to be excluded from the overall volume, V, of the container. In addition, the molecules can attract one another; since this attraction is a pairwise interaction, we expect it to be proportional to the square of the particle density, or inversely proportional to the square of the volume. Thus, the ideal gas equation of state, $pV = nRT$, has to be modified as follows:

$$\left(p + a\frac{n^2}{V^2}\right)(V - nb) = nRT, \qquad \textbf{(19.32)}$$

where a is a parameter that measures the strength of the intermolecular attraction and b is the volume of 1 mole of the gas. Equation 19.32, called the *van der Waals equation*, is a more realistic equation of state.

Figure 19.28a is a plot of the ideal gas equation of state for 1 mole of an ideal gas, showing the pressure as a function of volume and temperature. This is basically the same plot presented in Figure 19.6, just from a different angle and over a smaller range of temperatures. Figure 19.28b shows how this plot changes as a result of the van der Waals corrections of equation 19.32. You can see that the pressure is lower, which is due to the attractive interactions between the molecules. But you can also see that the plot has a “dip” along all isotherms at lower temperatures. The reason for this dip is that at small volumes the molecules can form a liquid, whereas at

large volumes they form a gas. The oscillations for a given isotherm indicate the region where liquid and gas coexist.

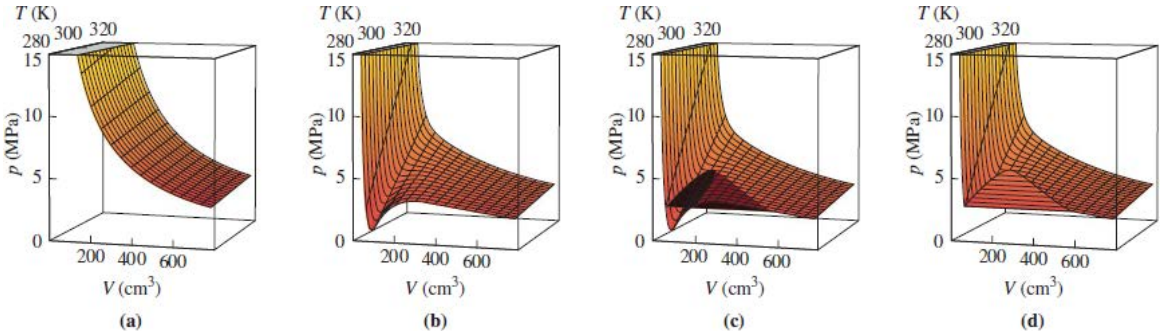

FIGURE 19.28 Pressure as a function of temperature and volume for 1 mole of ethane. (a) Ideal gas equation of state, (b) van der Waals equation, (c) Maxwell construction, (d) real equation of state for ethane.

The oscillations in the coexistence region are remedied with Maxwell's construction (see Figure 19.28c). Removing the unphysical oscillations and connecting the isotherms in straight lines, as shown in Figure 19.28d, finally reveals the coexistence region between liquid and gas and the physical equation of state. The upper end point of the coexistence region is called the *critical point*. To the left of the coexistence region is the liquid phase, and to the right is the gas phase. Note how much more sharply the pressure rises along a given isotherm if the volume is reduced in the liquid region than in the gas region. This indicates how much more incompressible liquids are than gases.

The particular equation of state plotted in Figure 19.28 is for ethane, C_2H_6. For other gases, the plots are very similarly shaped, but different values of the parameters a and b in equation 19.32 lead to the coexistence region being located in a different part of the temperature-volume plane.

Self-Test Opportunity 19.4

Show that the ideal gas equation of state is a special case of the van der Waals equation in the limit of an infinitely large volume.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- The Ideal Gas Law relates the pressure p, the volume V, the number of moles n, and the temperature T, of an ideal gas: $pV = nRT$, where $R = 8.314\,\mathrm{J/(mol\,K)}$ is the universal gas constant. (Boyle's, Charles's, Gay-Lussac's, and Avogadro's Laws are all special cases of the Ideal Gas Law.)
- The Ideal Gas Law can also be expressed as $pV = Nk_\mathrm{B}T$, where N is the number of molecules of gas and $k_\mathrm{B} = 1.381 \cdot 10^{-23}\,\mathrm{J/K}$ is the Boltzmann constant.
- Dalton's Law states that the total pressure exerted by a mixture of gases is equal to the sum of the partial pressures of the gases in the mixture:

$$p_\mathrm{total} = p_1 + p_2 + p_3 + \cdots + p_n.$$

- The work done by an ideal gas at constant temperature in changing from an initial volume V_i to a final volume V_f is given by $W = nRT \ln{(V_\mathrm{f}/V_\mathrm{i})}$.
- The equipartition theorem states that gas molecules in thermal equilibrium have the same average kinetic energy associated with each independent degree of freedom of their motion. The average kinetic energy per degree of freedom is $\frac{1}{2}k_\mathrm{B}T$.
- The root-mean-square speed of the molecules of a gas is $v_\mathrm{rms} = \sqrt{3k_\mathrm{B}T/m}$, where m is the mass of each molecule.
- The molar specific heat of a gas at constant volume, C_V, is defined by $Q = nC_V\Delta T$, where Q is the heat, n is the number of moles of gas, and ΔT is the change in temperature of the gas.

- The molar specific heat of a gas at constant pressure, C_p, is defined by $Q = nC_p\Delta T$, where Q is the heat, n is the

number of moles of gas, and ΔT is the change in temperature of the gas.

- The molar specific heat of a gas at constant pressure is related to the molar specific heat of a gas at constant volume by $C_p = C_V + R$.
- The molar specific heat at constant volume is $C_V = \frac{3}{2}R = 12.5\ \mathrm{J/(mol\ K)}$ for a monatomic gas and $C_V = \frac{5}{2}R = 20.8\ \mathrm{J/(mol\ K)}$ for a diatomic gas.
- For a gas undergoing an adiabatic process, $Q = 0$, and the following relationships hold: $pV^\gamma = \text{constant}$ and $TV^{\gamma-1} = \text{constant}$, where $\gamma = C_p/C_V$. For monatomic gases, $\gamma = \frac{5}{3}$; for diatomic gases, $\gamma = \frac{7}{5}$.
- The Maxwell speed distribution is given by $f(v) = 4\pi\left(\frac{m}{2\pi k_\mathrm{B}T}\right)^{3/2} v^2 e^{-mv^2/2k_\mathrm{B}T}$, and $f(v)\,dv$ describes the probability that a molecule has a speed between v and $v + dv$.
- The Maxwell kinetic energy distribution is given by $g(K) = \frac{2}{\sqrt{\pi}}\left(\frac{1}{k_\mathrm{B}T}\right)^{3/2} \sqrt{K} e^{-K/k_\mathrm{B}T}$, and $g(K)\,dK$ describes the probability that a molecule has a kinetic energy between K and $K + dK$.
- The mean free path, λ, of a molecule in an ideal gas is given by $\lambda = \frac{k_\mathrm{B}T}{\sqrt{2}\,(4\pi r^2)p}$, where r is the radius of the molecule.

ANSWERS TO SELF-TEST OPPORTUNITIES

19.1 Compare C_p to $(C_V + R)$

Gas	$\boldsymbol{C_V}$ [J/ (mol K)]	$\boldsymbol{C_p}$ [J/ (mol K)]	$(\boldsymbol{C_V + R})$ [J/ (m
Helium (He)	12.5	20.8	20.8
Neon (Ne)	12.5	20.8	20.8
Argon (Ar)	12.5	20.8	20.8
Krypton (Kr)	12.5	20.8	20.8
Hydrogen (H_2)	20.4	28.8	28.7
Nitrogen (N_2)	20.7	29.1	29.0
Oxygen (O_2)	21.0	29.4	29.1
Carbon dioxide (CO_2)	28.2	36.6	36.5
Methane (CH_4)	27.5	35.9	35.8

19.2 Approximate the tire's cross section as a circle of area $\pi(t/2)^2$. With this area, the volume of the tire is approximately $\pi(t/2)^2 2\pi\,(r_1 + r_2)/2 = \pi^2 t^2\,(r_1 + r_2)/4$. This volume is $\pi/4 \approx 78.5\%$ of the volume used in Solved Problem 19.2. Thus, the

change in the pump volume relative to the tire volume will be larger than in the solved problem, and so the final temperature should be slightly higher than that result. Following the same steps as in the solved problem gives a final temperature of 318 K.

19.3 Use the definite integral $\int_0^\infty x^2 e^{-x^2/a} dx = \frac{1}{4} a^{3/2} \sqrt{\pi}$.

19.4 For $V \to \infty$, we can neglect the excluded volume, nb, which is constant; thus, $\lim_{V \to \infty} (V - nb) = V$. Also, $\lim_{V \to \infty} \left(an^2/V^2 \right) = 0$, because b and n are constant. Putting these together gives $\lim_{V \to \infty} \left(\left(p + an^2/V^2 \right) (V - nb) \right) = pV$, and pV is the left-hand side of the ideal gas equation of state.

PROBLEM-SOLVING GUIDELINES

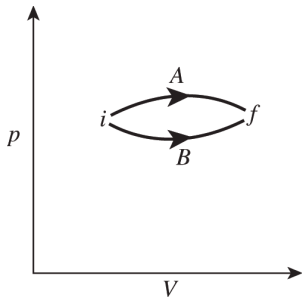
1. It is often useful to list all the known and unknown quantities when applying the Ideal Gas Law, to clarify what you have and what you're looking for. This step includes identifying an initial state and a final state and listing the quantities for each state.

2. If you're dealing with moles of a gas, you need the form of the Ideal Gas Law that involves R. If you're dealing with numbers of molecules, you need the form involving k_B.

3. Pay close attention to units, which may be given in different systems. For temperatures, unit conversion does not just involve multiplicative constants; the different temperature scales are also offset by additive constants. To be on the safe side, temperatures should always be converted to kelvins. Also, be sure that the value of R or k_B you use is consistent with the units you're working with. In addition, remember that molar masses are usually given as grams; you might need to convert the masses to kilograms.

MULTIPLE-CHOICE QUESTIONS

19.1 A system can go from state i to state f as shown in the figure. Which relationship is true?



a) $Q_A > Q_B$

b) $Q_A = Q_B$

c) $Q_A < Q_B$

d) It is impossible to decide from the information given.

19.2 A tire on a car is inflated to a gauge pressure of 32 lb/in^2 at a temperature of 27 $^\circ$C. After the car is driven for 30 mi, the pressure has increased to 34 lb/in^2. What is the temperature of the air inside the tire at this point?

a) 40. $^\circ$C

b) 23 $^\circ$C

c) 32 $^\circ$C

d) 54 $^\circ$C

19.3 Molar specific heat at constant pressure, C_p, is larger than molar specific heat at constant volume, C_V, for

a) a monoatomic ideal gas.

b) a diatomic atomic gas.

c) all of the above.

d) none of the above.

19.4 An ideal gas may expand from an initial pressure, p_{i}, and volume, V_{i}, to a final volume, V_{f}, isothermally, adiabatically, or isobarically. For which type of process is the heat that is added to the gas the largest? (Assume that p_{i}, V_{i}, and V_{f} are the same for each process.)

a) isothermal process

b) adiabatic process

c) isobaric process

d) All the processes have the same heat flow.

19.5 Which of the following gases has the highest root-mean-square speed?

a) nitrogen at 1 atm and 30 $^{\circ}$C

b) argon at 1 atm and 30 $^{\circ}$C

c) argon at 2 atm and 30 $^{\circ}$C

d) oxygen at 2 atm and 30 $^{\circ}$C

e) nitrogen at 2 atm and 15 $^{\circ}$C

19.6 Two identical containers hold equal masses of gas, oxygen in one and nitrogen in the other. The gases are held at the same temperature. How does the pressure of the oxygen compare to that of the nitrogen?

a) $p_{\mathrm{O}} > p_{\mathrm{N}}$

b) $p_{\mathrm{O}} = p_{\mathrm{N}}$

c) $p_{\mathrm{O}} < p_{\mathrm{N}}$

d) cannot be determined from the information given

19.7 One mole of an ideal gas, at a temperature of 0 $^{\circ}$C, is confined to a volume of 1.0 L. The pressure of this gas is

a) 1.0 atm.

b) 22.4 atm.

c) $1/22.4$ atm.

d) 11.2 atm.

19.8 One hundred milliliters of liquid nitrogen with a mass of 80.7 g is sealed inside a 2-L container. After the liquid nitrogen heats up and turns into a gas, what is the pressure inside the container?

a) 0.05 atm

b) 0.08 atm

c) 0.09 atm

d) 9.1 atm

e) 18 atm

19.9 Consider a box filled with an ideal gas. The box undergoes a sudden free expansion from V_1 to V_2. Which of the following correctly describes this process?

a) Work done by the gas during the expansion is equal to $nRT \ln (V_2/V_1)$.

b) Heat is added to the box.

c) Final temperature equals initial temperature times (V_2/V_1).

d) The internal energy of the gas remains constant.

19.10 Compare the average kinetic energy at room temperature of a nitrogen molecule to that of an oxygen molecule. Which has the larger kinetic energy?

a) oxygen molecule

b) nitrogen molecule

c) They have the same kinetic energy.

d) It depends on the pressure.

19.11 Ten students take a 100-point exam. Their grades are 25, 97, 95, 100, 35, 32, 92, 75, 78, and 34 points. The average grade and the rms grade are, respectively,

a) 50.0 and 25.0.

b) 66.7 and 33.3.

c) 77.1 and 19.3.

d) 37.8 and 76.2.

e) 66.3 and 72.6.

19.12 A polyatomic ideal gas occupies an initial volume $V_{\mathrm{i},}$ which is decreased to $\frac{1}{8}V_{\mathrm{i}}$ via an adiabatic process. Which equation expresses the relationship between the initial and final pressures of this gas?

a) $p_{\mathrm{f}} = 2p_{\mathrm{i}}$

b) $p_{\mathrm{f}} = 4p_{\mathrm{i}}$

c) $p_{\mathrm{f}} = 16p_{\mathrm{i}}$

d) $p_{\mathrm{f}} = \frac{17}{5}p_{\mathrm{i}}$

e) $p_{\mathrm{f}} = \frac{23}{7}p_{\mathrm{i}}$

19.13 A polyatomic ideal gas occupies an initial volume $V_{\mathrm{i},}$ which is decreased to $\frac{1}{8}V_{\mathrm{i}}$ via an adiabatic process. Which equation expresses the relationship between the initial and final temperatures of this gas?

a) $T_{\mathrm{f}} = \frac{2}{3}T_{\mathrm{i}}$

b) $T_{\mathrm{f}} = 2T_{\mathrm{i}}$

c) $T_{\mathrm{f}} = 16T_{\mathrm{i}}$

d) $T_{\mathrm{f}} = \frac{9}{5}T_{\mathrm{i}}$

e) $T_{\mathrm{f}} = 8T_{\mathrm{i}}$

19.14 The reason there is almost no hydrogen in the Earth's atmosphere is that

a) hydrogen reacts with oxygen to form water.

b) sunlight destroys hydrogen.

c) the ozone layer absorbs hydrogen.

d) plants do not emit hydrogen.

e) hydrogen molecules in the thermosphere can have speeds that exceed Earth's escape velocity.

CONCEPTUAL QUESTIONS

19.15 Hot air is less dense than cold air and therefore experiences a net buoyant force and rises. Since hot air rises, the higher the elevation, the warmer the air should be. Therefore, the top of Mount Everest should be very warm. Explain why Mount Everest is colder than Death Valley.

19.16 The Maxwell speed distribution assumes that the gas is in equilibrium. Thus, if a gas, all of whose molecules were moving at the same speed, were given enough time, they would eventually come to satisfy the speed distribution. But the derivations of the kinetic theory presented in the text assumed that when a gas molecule hits the wall of a container, it bounces back with the same energy it had before the collision and that gas molecules exert no forces on each other. If gas molecules exchange energy neither with the walls of their container nor with each other, how can they ever come to equilibrium? Is it not true that if they all had the same speed initially, some would have to slow down and others speed up, according to the Maxwell speed distribution?

19.17 When you blow hard on your hand, it feels cool, but when you breathe softly, it feels warm. Why?

19.18 Explain why the average velocity of air molecules in a closed auditorium is zero but their root-mean-square speed or average speed is not zero.

19.19 In a diesel engine, the fuel-air mixture is compressed rapidly. As a result, the temperature rises to the spontaneous combustion temperature for the fuel, causing the fuel to ignite. How is the rise in temperature possible, given the fact that the compression occurs so rapidly that there is not enough time for a significant amount of heat to flow into or out of the fuel-air mixture?

19.20 A cylinder with a sliding piston contains an ideal gas. The cylinder (with the gas inside) is heated by transferring the same

amount of heat to the system in two different ways:

(1) The piston is blocked to prevent it from moving.

(2) The piston is allowed to slide frictionlessly to the end of the cylinder.

How does the final temperature of the gas under condition 1 compare to the final temperature of the gas under condition 2? Is it possible for the temperatures to be equal?

19.21 Show that the adiabatic bulk modulus, defined as $B = -V\,(dp/dV)$, for an ideal gas is equal to γp.

19.22 A monatomic ideal gas expands isothermally from $\{p_1, V_1, T_1\}$ to $\{p_2, V_2, T_1\}$. Then it undergoes an isochoric process, which takes it from $\{p_2, V_2, T_1\}$ to $\{p_1, V_2, T_2\}$. Finally the gas undergoes an isobaric compression, which takes it back to $\{p_1, V_1, T_1\}$.

a) Use the First Law of Thermodynamics to find Q for each of these processes.

b) Write an expression for total Q in terms of p_1, p_2, V_1, and V_2.

19.23 Two atomic gases will react to form a diatomic gas: $\mathrm{A} + B \rightarrow \mathrm{AB}$. Suppose you perform this reaction with 1 mole each of A and B in a thermally isolated chamber, so no heat is exchanged with the environment. Will the temperature of the system increase or decrease?

19.24 A relationship that gives the pressure, p, of a substance as a function of its density, ρ, and temperature, T, is called an *equation of state*. For a gas with molar mass M, write the Ideal Gas Law as an equation of state.

19.25 The compression and rarefaction associated with a sound wave propagating in a gas are so much faster than the flow of heat in the gas that they can be treated as adiabatic processes.

a) Find the speed of sound, v_s, in an ideal gas of molar mass M.

b) In accord with Einstein's refinement of Newtonian mechanics, v_s cannot exceed the speed of light in vacuum, c. This fact implies a maximum temperature for an ideal gas. Find this temperature.

c) Evaluate the maximum temperature of part (b) for *monatomic* hydrogen gas (H).

d) What happens to the hydrogen at this maximum temperature?

19.26 The kinetic theory of an ideal gas takes into account not only translational motion of atoms or molecules but also, for diatomic and polyatomic gases, vibration and rotation. Will the temperature increase from a given amount of energy being supplied to a monatomic gas differ from the temperature increase due to the same amount of energy being supplied to a diatomic gas? Explain.

19.27 In the thermosphere, the layer of Earth's atmosphere extending from an altitude 100 km up to 700 km, the temperature can reach about 1500 °C. How would air in that layer feel to one's bare skin?

19.28 A glass of water at room temperature is left on the kitchen counter overnight. In the morning, the amount of water in the glass is smaller due to evaporation. The water in the glass is below the boiling point, so how is it possible for some of the liquid water to have turned into a gas?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 19.1

19.29 A tire has a gauge pressure of 300. kPa at 15.0 °C. What is the gauge pressure at 45.0 °C? Assume that the change in volume of the tire is negligible.

19.30 A tank of compressed helium for inflating balloons is advertised as containing helium at a pressure of 2400. psi, which, when allowed to expand at atmospheric pressure, will occupy a volume of 244 ft^3. Assuming no temperature change takes place during the expansion, what is the volume of the tank in cubic feet?

• **19.31** Before embarking on a car trip from Michigan to Florida to escape the winter cold, you inflate the tires of your car to a manufacturer-suggested pressure of 33.0 psi while the outside temperature is 25.0 °F and then make sure your valve caps are airtight. You arrive in Florida two days later, and the temperature outside is a pleasant 72.0 °F.

a) What is the new pressure in your tires, in SI units?

b) If you let air out of the tires to bring the pressure back to the recommended 33.0 psi, what percentage of the original mass of air in the tires will you release?

•**19.32** A 1.00-L volume of a gas undergoes an isochoric process in which its pressure doubles, followed by an isothermal process until the original pressure is reached. Determine the final volume of the gas.

•**19.33** Suppose you have a pot filled with steam at 100.0 °C and at a pressure of 1.00 atm. The pot has a diameter of 15.0 cm and is 10.0 cm high. The mass of the lid is 0.500 kg. How hot do you need to heat the steam to lift the lid off the pot?

Section 19.2

•**19.34** A quantity of liquid water comes into equilibrium with the air in a closed container, without completely evaporating, at a temperature of 25.0 °C. How many grams of water vapor does a liter of the air contain in this situation? The vapor pressure of water at 25.0 °C is 3.1690 kPa.

•**19.35** Use the equation $\rho T = \text{constant}$ and information from Chapter 16 to estimate the speed of sound in air at 40.0 °C, given that the speed at 0.00 °C is 331 m/s.

19.36 Suppose 2.00 moles of an ideal gas is enclosed in a container of volume $1.00 \cdot 10^{-4}\ \text{m}^3$. The container is then placed in a furnace and raised to a temperature of 400. K. What is the final pressure of the gas?

19.37 Suppose 1.00 mole of an ideal gas is held at a constant volume of 2.00 L. Find the change in pressure if the temperature increases by 100. °C.

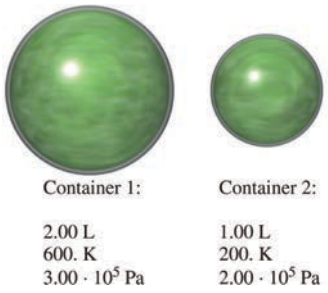
19.38 How much heat is added to the system when 2.00 kJ of work is performed by an ideal gas in an isothermal process? Give a reason for your answer.

•**19.39** Liquid nitrogen, which is used in many physics research labs, can present a safety hazard if a large quantity evaporates in a confined space. The resulting nitrogen gas reduces the oxygen concentration, creating the risk of asphyxiation. Suppose 1.00 L of liquid nitrogen $\left(\rho = 808\ \text{kg/m}^3\right)$ evaporates and comes into equilibrium with the air at 21.0 °C and 101 kPa. How much volume will it occupy?

•**19.40** Liquid bromine (Br_2) is spilled in a laboratory accident and evaporates. Assuming that the vapor behaves as an ideal gas, with a temperature of 20.0 °C and a pressure of 101.0 kPa, find its density.

•19.41 Two containers contain the same gas at different temperatures and pressures, as indicated in the figure. The small container has a volume of 1.00 L, and the large container has a volume of 2.00 L. The two containers are then connected to each other using a thin tube, and the pressure and temperature in both containers are allowed to equalize. If the final temperature is 300. K,

what is the final pressure? Assume that the connecting tube has negligible volume and mass.



•**19.42** A sample of gas for which $p = 1000.\ \text{Pa}$, $V = 1.00\ \text{L}$, and $T = 300.\ \text{K}$ is confined in a cylinder.

a) Find the new pressure if the volume is reduced to half of the original volume at the same temperature.

b) If the temperature is raised to 400. K in the process of part (a), what is the new pressure?

c) If the gas is then heated to 600. K from the initial value and the pressure of the gas becomes 3000. Pa, what is the new volume?

•**19.43** A cylinder of cross-sectional area $12.0\ \text{cm}^2$ is fitted with a piston, which is connected to a spring with a spring constant of $1000.\ \text{N/m}$, as shown in the figure. The cylinder holds 0.005000 mole of an ideal gas at room temperature $(23.0\ ^\circ\text{C})$. How far is the spring compressed if the temperature of the gas is raised to $150.\ ^\circ\text{C}$?

••**19.44** Air at 1.00 atm is inside a cylinder 20.0 cm in radius and 20.0 cm in length that sits on a table. The top of the cylinder is sealed

with a movable piston. A 20.0-kg block is dropped onto the piston. From what height above the piston must the block be dropped to compress the piston by 1.00 mm? 2.00 mm? 1.00 cm?

Section 19.3

19.45 Interstellar space far from any stars is usually filled with atomic hydrogen (H) at a density of 1.00 atom/cm^3 and a very low temperature of 2.73 K.

a) Determine the pressure in interstellar space.

b) What is the root-mean-square speed of the atoms?

c) What would be the edge length of a cube that would contain atoms with a total of 1.00 J of energy?

19.46 a) What is the root-mean-square speed for a collection of helium-4 atoms at 300. K?

b) What is the root-mean-square speed for a collection of helium-3 atoms at 300. K?

19.47 Two isotopes of uranium, ^{235}U and ^{238}U, are separated by a gas diffusion process that involves combining them with fluorine to make the compound UF_6. Determine the ratio of the root-mean-square speeds of UF_6 molecules for the two isotopes. The masses of $^{235}UF_6$ and $^{238}UF_6$ are 349.03 amu and 352.04 amu, respectively.

19.48 The electrons that produce electric currents in a metal behave approximately like molecules of an ideal gas. The mass of an electron is $m_e = 9.109 \cdot 10^{-31}$ kg. If the temperature of the metal is 300.0 K, what is the root-mean-square speed of the electrons?

•**19.49** In a period of 6.00 s, $9.00 \cdot 10^{23}$ nitrogen molecules strike a section of a wall with an area of 2.00 cm^2. If the molecules move with a speed of 400.0 m/s and strike the wall head on in elastic collisions, what is the pressure exerted on the wall? (The mass of one N_2 molecule is $4.65 \cdot 10^{-26}$kg.)

•**19.50** Assuming that the pressure remains constant, at what temperature is the root-mean-square speed of a helium atom equal to the root-mean-square speed of an air molecule at STP?

Section 19.4

19.51 Two copper cylinders, immersed in a water tank at 50.0 °C, contain helium and nitrogen, respectively. The helium-filled cylinder has a volume twice as large as the nitrogen-filled cylinder.

a) Calculate the average kinetic energy of a helium molecule and the average kinetic energy of a nitrogen molecule.

b) Determine the molar specific heat at constant volume (C_V) and at constant pressure (C_p) for the two gases.

c) Find γ for the two gases.

19.52 At room temperature, identical gas cylinders contain 10 moles of nitrogen gas and argon gas, respectively. Determine the ratio of energies stored in the two systems. Assume ideal gas behavior.

19.53 Calculate the change in internal energy of 1.00 mole of a diatomic ideal gas that starts at room temperature (293 K) when its temperature is increased by 2.00 K.

19.54 Treating air as an ideal gas of diatomic molecules, calculate how much heat is required to raise the temperature of the air in an 8.00 m by 10.0 m by 3.00 m room from 20.0 °C to 22.0 °C at 101 kPa. Neglect the change in the number of moles of air in the room.

•**19.55** What is the approximate energy required to raise the temperature of 1.00 L of air by 100. °C? The volume is held constant.

•**19.56** You are designing an experiment that requires a gas with $\gamma = 1.60$. However, from your physics lectures, you remember that no gas has such a γ value. However, you also remember that mixing monatomic and diatomic gases can yield a gas with such a γ value. Determine the fraction of diatomic molecules in a mixture of gases that has this value.

Section 19.5

19.57 Suppose 15.0 L of an ideal monatomic gas at a pressure of $1.50 \cdot 10^5$ kPa is expanded adiabatically (no heat transfer) until the volume is doubled.

a) What is the pressure of the gas at the new volume?

b) If the initial temperature of the gas was 300. K, what is its final temperature after the expansion?

19.58 A diesel engine works at a high compression ratio to compress air until it reaches a temperature high enough to ignite the diesel fuel. Suppose the compression ratio (ratio of volumes) of a specific diesel engine is 20.0 to 1.00. If air enters a cylinder at 1.00 atm and is compressed adiabatically, the compressed air reaches a pressure of 66.0 atm. Assuming that the air enters the engine at room temperature ($25.0\ ^\circ\text{C}$) and that the air can be treated as an ideal gas, find the temperature of the compressed air.

19.59 Air in a diesel engine cylinder is quickly compressed from an initial temperature of $20.0\ ^\circ\text{C}$, an initial pressure of 1.00 atm, and an initial volume of 600. cm^3 to a final volume of 45.0 cm^3. Assuming the air to be an ideal diatomic gas, find the final temperature and pressure.

•**19.60** Suppose 6 L of a monatomic ideal gas, originally at 400. K and a pressure of 3.00 atm (called state 1), undergoes the following processes:

$1 \rightarrow 2$ isothermal expansion to $V_2 = 4V_1$

$2 \rightarrow 3$ isobaric compression

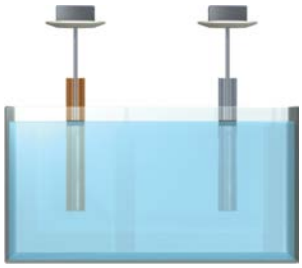
$3 \rightarrow 1$ adiabatic compression to its original state

Find the pressure, volume, and temperature of the gas in states 2 and 3. How many moles of the gas are there?

••How much work is done by the gas during each of the three processes in Problem 19.60 and how much heat flows into the gas in each process?

••**19.62** Consider two geometrically identical cylinders of inner diameter 5.00 cm, one made of copper and the other of Teflon, each closed on the bottom and open on top. The two cylinders are

immersed in a large-volume water tank at room temperature ($20.0\ ^\circ\text{C}$), as shown in the figure. Note that the copper cylinder is an excellent conductor of heat and the Teflon cylinder is a good insulator. A frictionless piston with a rod and platter attached is placed in each cylinder. The mass of the piston-rod-platter assembly is 0.500 kg, and the cylinders are filled with helium gas so that initially both pistons are at equilibrium at 20.0 cm from the bottom of their respective cylinders.



a) A 5.00-kg lead block is *slowly* placed on each platter, and the piston is *slowly* lowered until it reaches its final equilibrium state. Calculate the final height of each piston (as measured from the bottom of its cylinder).

b) If the two lead blocks are *dropped suddenly* on the platters, how will the final heights of the two pistons compare immediately after the lead blocks are dropped?

••**19.63** Chapter 13 examined the variation of pressure with altitude in the Earth's atmosphere, assuming constant temperature—a model known as the *isothermal atmosphere*. A better approximation is to treat the pressure variations with altitude as adiabatic. Assume that air can be treated as a diatomic ideal gas with effective molar mass $M_{\text{air}} = 28.97\ \text{g/mol}$. Note that in reality many complexities of the Earth's atmosphere cannot be modeled as an adiabatic ideal gas, for example, the thermosphere.

a) Find the air pressure and temperature of the atmosphere as functions of altitude. Let the pressure at sea level be $p_0 = 101.0\ \text{kPa}$ and the temperature at sea level be $20.0\ ^\circ\text{C}$.

b) Determine the altitude at which the air pressure is half its sea level value and the temperature at this altitude. Also determine the altitude at which the air density is half its sea level value and the temperature at that altitude.

c) Compare these results with the isothermal model of Chapter 13.

Section 19.6

19.64 Consider nitrogen gas, N_2, at 20.0 °C. What is the root-mean-square speed of the nitrogen molecules? What is the most probable speed? What percentage of nitrogen molecules have a speed within 1.00 m/s of the most probable speed? (*Hint:* Assume that the probability of nitrogen atoms having speeds between 200.00 m/s and 202.00 m/s is constant.)

19.65 As noted in the text, the speed distribution of molecules in the Earth's atmosphere has a significant impact on its composition.

a) What is the average speed of a nitrogen molecule in the atmosphere, at a temperature of 18.0 °C and a (partial) pressure of 78.8 kPa?

b) What is the average speed of a hydrogen molecule at the same temperature and pressure?

19.66 A sealed container contains 1.00 mole of neon gas at STP. Estimate the number of neon atoms having speeds in the range from 200.00 m/s to 202.00 m/s. (*Hint:* Assume that the probability of neon atoms having speeds between 200.00 m/s and 202.00 m/s is constant.)

•**19.67** For a room at 0.00 °C and 1.00 atm, write an expression for the fraction of air molecules having speeds greater than the speed of sound, according to the Maxwell speed distribution. What is the average speed of each molecule? What is the root-mean-square speed? Assume that the air consists of uniform particles with a mass of 15.0 amu.

••**19.68** If a space shuttle is struck by a meteor, producing a circular hole 1.00 cm in diameter in the window, how long does it take before the pressure inside the cabin is reduced to half of its original value? Assume that the cabin of the shuttle is a cube with edges measuring 5.00 m and that the air inside is at a constant temperature of 21.0 °C at 1.00 atm and consists of uniform diatomic molecules each with a mass of 15 amu. (*Hint:* What fraction of the molecules are moving in the correct direction to exit through the hole, and what is their average speed? Derive an expression for the rate at which molecules exit the hole as a function of pressure, and thus of dp/dt.)

Additional Exercises

19.69 Suppose 1.00 mole of molecular nitrogen gas expands in volume very quickly, so no heat is exchanged with the environment during the process. If the volume increases from 1.00 L to 1.50 L, determine the work done on the environment if the gas's temperature drops from 22.0 °C to 18.0 °C. Assume ideal gas behavior.

19.70 Calculate the root-mean-square speed of air molecules at room temperature (20.0 °C) from the kinetic theory of an ideal gas.

19.71 At Party City, you purchase a helium-filled balloon with a diameter of 40.0 cm at 20.0 °C and at 1.00 atm.

a) How many helium atoms are inside the balloon?

b) What is the average kinetic energy of the atoms?

c) What is the root-mean-square speed of the atoms?

19.72 What is the total mass of all the oxygen molecules in a cubic meter of air at a temperature of 25.0 °C and a pressure of $1.01 \cdot 10^5$ Pa? Note that air is 20.9% (by volume) oxygen (molecular O_2), with the remainder being primarily nitrogen (molecular N_2).

19.73 The tires of a $3.00 \cdot 10^3$-lb car are filled to a gauge pressure (pressure added to atmospheric pressure) of 32.0 lb/in^2 while the car is on a lift at a repair shop. The car is then lowered to the ground.

a) Assuming that the internal volume of the tires does not change appreciably as a result of contact with the ground, give the absolute pressure in the tires in pascals when the car is on the ground.

b) What is the total contact area between the tires and the ground?

19.74 A gas expands at constant pressure from 3.00 L at 15.0 °C until the volume is 4.00 L. What is the final temperature of the gas?

19.75 An ideal gas has a density of 0.0899 g/L at 20.00 °C and 101.325 kPa. Identify the gas.

19.76 A tank of a gas consisting of 30.0% O_2 and 70.0% Ar has a volume of 1.00 m^3. It is moved from storage at 20.0 °C to the outside on a sunny day. Initially, the pressure gauge reads 1000. psi. After

several hours, the pressure reading is 1500. psi. What is the temperature of the gas in the tank at this time?

19.77 Suppose 5.00 moles of an ideal monatomic gas expands at a constant temperature of 22.0 °C from an initial volume of 2.00 m^3 to 8.00 m^3.

a) How much work is done by the gas?

b) What is the final pressure of the gas?

•**19.78** A cylindrical chamber with a radius of 3.50 cm contains 0.120 mole of an ideal gas. It is fitted with a 450.-g piston that rests on top, enclosing a space of height 7.50 cm. As the cylinder is cooled by 15.0 °C, how far below the initial position does the piston end up?

•**19.79** Find the *most probable* kinetic energy for a molecule of a gas at temperature $T = 300.$ K. In what way does this value depend on the identity of the gas?

•**19.80** A closed auditorium of volume $2.50 \cdot 10^4$ m^3 is filled with 2000 people at the beginning of a show, and the air in the space is at a temperature of 293 K and a pressure of $1.013 \cdot 10^5$ Pa. If there were no ventilation, by how much would the temperature of the air rise during the 2.00-h show if each person metabolizes at a rate of 70.0 W?

•**19.81** At a temperature of 295. K, the vapor pressure of pentane (C_5H_{12}) is 60.7 kPa. Suppose 1.000 g of gaseous pentane is contained in a cylinder with diathermal (thermally conducting) walls and a piston to vary the volume. The initial volume is 1.000 L, and the piston is moved in slowly, keeping the temperature at 295 K. At what volume will the first drop of liquid pentane appear?

•**19.82** Helium gas at 22.0 °C and at 1.00 atm is contained in a well-insulated cylinder fitted with a piston. The piston is moved very slowly (adiabatic expansion) so that the volume increases to four times its original value.

a) What is the final pressure?

b) What is the final temperature of the gas?

MULTI-VERSION EXERCISES

19.83 Suppose 0.05839 mole of an ideal monatomic gas has a pressure of 1.000 atm at 273.15 K and is then cooled at constant pressure until its volume is reduced by 47.11%. What is the amount of work done by the gas?

19.84 Suppose an ideal monatomic gas has a pressure of 1.000 atm at 273.15 K and is then cooled at constant pressure until its volume is reduced by 47.53%. The amount of work done by the gas is $-7.540 \cdot 10^{1}$ J. How many moles of gas are there?

19.85 Suppose 0.03127 mole of an ideal monatomic gas with a pressure of 1.000 atm at 273.15 K is cooled at constant pressure and reduced in volume. The amount of work done by the gas is $-3.404 \cdot 10^{1}$ J. By what percentage was the volume of the gas reduced?

19.86 A 2.869-L bottle contains air plus 1.393 mole of sodium bicarbonate and 1.393 mole of acetic acid. These compounds react to produce 1.393 mole of carbon dioxide gas, along with water and sodium acetate. If the bottle is tightly sealed at atmospheric pressure $\left(1.013 \cdot 10^{5}\ \text{Pa}\right)$ before the reaction occurs, what is the pressure inside the bottle when the reaction is complete? Assume that the bottle is kept in a water bath that keeps the temperature in the bottle constant.

19.87 A bottle contains air plus 1.413 mole of sodium bicarbonate and 1.413 mole of acetic acid. These compounds react to produce 1.413 mole of carbon dioxide gas, along with water and sodium acetate. The bottle is tightly sealed at atmospheric pressure $\left(1.013 \cdot 10^{5}\ \text{Pa}\right)$ before the reaction occurs. The pressure inside the bottle when the reaction is complete is $1.064 \cdot 10^{6}$ Pa. What is the volume of the bottle? Assume that the bottle is kept in a water bath that keeps the temperature in the bottle constant.

19.88 A 3.787-L bottle contains air plus n moles of sodium bicarbonate and n moles of acetic acid. These compounds react to produce n moles of carbon dioxide gas, along with water and sodium acetate. The bottle is tightly sealed at atmospheric pressure $\left(1.013 \cdot 10^5 \text{ Pa}\right)$ before the reaction occurs. The pressure inside the bottle when the reaction is complete is $9.599 \cdot 10^5$ Pa. How many moles, n, of carbon dioxide gas are in the bottle? Assume that the bottle is kept in a water bath that keeps the temperature in the bottle constant.

The early studies of thermodynamics were motivated by the desire of scientists and engineers to discover the governing principles of engines and machines so that they could design more efficient and powerful ones. The steam engine could be used to power early locomotives and ships; however, over-heated steam boilers could explode and cause damage and fatalities. Today, steam locomotives and ships are used primarily on scenic routes for tourists.

The principles that affect the efficiency of heat engines apply to all engines, from steam locomotives (Figure 20.1a) to jet engines. The Thrust SSC (supersonic car) shown in Figure 20.1b, used two powerful jet engines to set a land speed record of 763 mph in October 1997, a record that still stands in 2022. However, for all its speed and power, it still produces more waste heat than usable energy, which is true of most engines.

FIGURE 20.1 (a) A steam locomotive. (b) The Thrust SSC.

In this chapter, we examine heat engines in theory and in practice. Their operation is governed by the Second Law of Thermodynamics—one of the most far-reaching and powerful statements in all of science. There are several different ways to express this law, including one involving a concept called *entropy*. The ideas discussed in this chapter have applications to practically all areas of science, including information processing, biology, and astronomy.

WHAT WE WILL LEARN

- Reversible thermodynamic processes are idealized processes in which a system can move from one thermodynamic state to another and back again, while remaining close to thermodynamic equilibrium.
- Most processes are irreversible; for example, the pieces of a broken coffee cup lying on the floor cannot spontaneously reassemble back into the cup. Practically all real-world thermodynamic processes are irreversible.
- Mechanical energy can be converted to thermal energy, and thermal energy can be converted to mechanical energy.
- A heat engine is a device that converts thermal energy into mechanical energy. This engine operates in a thermodynamic cycle, returning to its original state periodically.
- No heat engine can have an efficiency of 100%. The Second Law of Thermodynamics places fundamental limitations on the efficiency of a heat engine.
- Refrigerators and air conditioners are heat engines that operate in reverse.
- The Second Law of Thermodynamics says that the entropy of an isolated system can never decrease.
- The entropy of a system can be related to the microscopic states of the constituents of the system.

20.1 Reversible and Irreversible Processes

As noted in Chapter 18, if you pour hot water into a glass and place that glass on a table, the water will slowly cool until it reaches the temperature of its surroundings. The air in the room will also warm, although imperceptibly. You would be astonished if, instead, the water got warmer and the air in the room cooled down slightly, while conserving energy. In fact, the First Law of Thermodynamics is satisfied for *both* of these scenarios. However, it is always the case that the water cools until it reaches the temperature of its surroundings. Thus, other physical principles are required to explain why the temperature changes one way and not the other.

Practically all real-life thermodynamic processes are irreversible. For example, if a disk of ice at a temperature of $0\ ^\circ\mathrm{C}$ is placed in a metal can having a temperature of $40\ ^\circ\mathrm{C}$, heat flows irreversibly from the can to the ice, as shown in Figure 20.2a. The ice will melt to water; the water will then warm and the can will cool, until the water and the can are at the same temperature ($10\ ^\circ\mathrm{C}$ in this case). It is not possible to make small changes in any thermodynamic variable and return the system to the state corresponding to a warm can and frozen water.

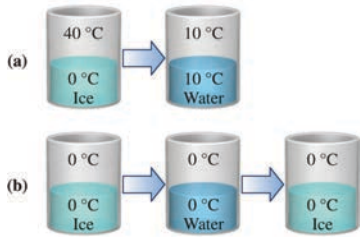

FIGURE 20.2 Two thermodynamic processes: (a) An irreversible process in which a disk of ice at a temperature of $0\ ^\circ\mathrm{C}$ is placed inside a metal can at a temperature of $40\ ^\circ\mathrm{C}$. (b) A reversible process in which a disk of ice at a temperature of $0\ ^\circ\mathrm{C}$ is placed inside a metal can at a temperature of $0\ ^\circ\mathrm{C}$.

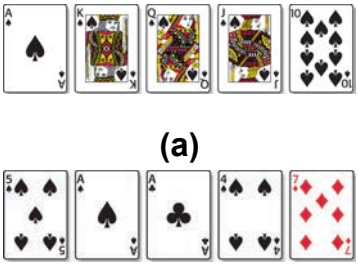
However, we can imagine a class of idealized *reversible* processes. With a **reversible process,** a system is always close to being in thermodynamic equilibrium. In this case, making a small change in the state of the system can reverse any change in the thermodynamic variables of the system. For example, in Figure 20.2b, a disk of ice at a temperature of $0\ ^\circ\mathrm{C}$ is placed in a metal can that is also at a temperature of $0\ ^\circ\mathrm{C}$. Raising the temperature of the can slightly will melt the ice to water. Then, lowering the temperature of the metal can will refreeze the water to ice, thus returning the system to its original state. (Technically speaking, the crystal structure of the ice would be different and thus the final state would be different from the initial state, but not in a way that concerns us here.)

We can think of reversible processes as equilibrium processes in which the system always stays in thermal equilibrium or close to

thermal equilibrium. If a system were actually in thermal equilibrium, no heat would flow and no work would be done by the system. Thus, a reversible process is an idealization. However, for a nearly reversible process, small temperature and pressure adjustments can keep a system close to thermal equilibrium.

On the other hand, if a process involves heat flow with a finite temperature difference, free expansion of a gas, or conversion of mechanical work to thermal energy, it is an **irreversible process.** It is not possible to make small changes to the temperature or pressure of the system and cause the process to proceed in the opposite direction. In addition, while an irreversible process is taking place, the system is not in thermal equilibrium.

The irreversibility of a process is related to the randomness or disorder of the system. For example, suppose you order a deck of cards by rank and suit and then take the first five cards, as illustrated in Figure 20.3a. You will observe a well-ordered system of cards, for example, all spades, starting with the ace and going down to the ten. Next, you put those five cards back in the deck, toss the deck of cards in the air, and let the cards fall on the floor. You pick up the cards one by one without looking at their rank or suit and then take the first five cards off the top of the deck. It is highly improbable that these five cards will be ordered by rank and suit. It is much more likely that you will see a result like the one shown in Figure 20.3b, that is, with cards in random order. The process of tossing and picking up the cards is irreversible.



(a)

(b)

FIGURE 20.3 (a) The first five cards of a card deck ordered by rank and suit. (b) The first five cards of a deck that has been tossed in the air and picked up randomly.

Another example of an irreversible process is the free expansion of a gas, which we touched on in Chapter 18 and will discuss in greater detail in Section 20.7.

Poincaré Recurrence Time

The common experience of déjà vu (French for “already seen”) is the feeling of having experienced a certain situation sometime before. But do events really repeat? If processes leading from one event to another are truly irreversible, then an event cannot repeat exactly.

The French mathematician and physicist Henry Poincaré made an important contribution to this discussion in 1890, by famously stating his recurrence theorem. In it he postulates that certain isolated dynamical systems will return to a state arbitrarily close to their initial state after a sufficiently long time. This time is known as the *Poincaré recurrence time,* or simply the *Poincaré time,* of the system. This time can be calculated fairly straightforwardly for many systems that have only a finite number of different states, as the following example illustrates.

EXAMPLE 20.1 Deck of Cards

Suppose you repeat the tossing and gathering of a deck of cards performed for Figure 20.3 again and again. Eventually, there is a chance that one of the random orders in which you pick up the cards will yield the sequence ace through ten of spades for the first five cards in the deck.

PROBLEM

If it takes 1 min on average to toss the cards into the air and then collect them into a stack again, how long can you expect it to take, on average, before you will find the sequence of ace through ten of spades as the first five cards in the deck?

SOLUTION

There are 52 cards in the deck. Each of them has the same $\frac{1}{52}$ probability of being on top. So the probability that the ace of spades ends up on top is $\frac{1}{52}$. If the ace is the top card, then there are 51 cards left. The probability that the king of spades is in the top position of the remaining 51 cards is $\frac{1}{51}$. Thus, the combined probability that the ace and king of spades are the top two cards in that order is $1/(52 \cdot 51) = 1/2652$. In the same way, the probability of the ordered sequence of ace through ten of spades occurring is $1/(52 \cdot 51 \cdot 50 \cdot 49 \cdot 48) = 1/311,875,200$.

So the average number of tries needed to obtain the desired sequence is 311,875,200. Since each of them takes 1 min, successful completion of this exercise would take approximately 593 yr.

DISCUSSION

We can almost immediately state the average number of tries it would take to get all 52 cards in the ordered sequence ace through two, for all four suits. It is $52 \cdot 51 \cdot 50 \cdot \cdots \cdot 3 \cdot 2 \cdot 1 = 52!$ If each of these attempts took a minute, it would require an average of $1.534 \cdot 10^{62}$ yr to obtain

the desired order. But even after this time, there would be no guarantee that the ordered sequence had to appear. However, since there are 52! possible different sequences of the cards in the deck, at least one of the sequences would have appeared at least twice.

20.2 Engines and Refrigerators

The preceding discussion of the reversibility of thermodynamic processes might have seemed a bit abstract. However, now we are going to discuss engines, particularly those that operate in cycles, and the fine distinctions between reversible and irreversible processes are key to the operation of these engines.

A **heat engine** is a device that turns thermal energy into useful work. For example, an internal combustion engine or a jet engine extracts mechanical work from the thermal energy generated by burning a gasoline-air mixture (Figure 20.4a). For a heat engine to do work repeatedly, it must operate in a cycle. For example, work would be done if you put a firecracker under a soup can and exploded the firecracker. The thermal energy from the explosion would be turned into mechanical motion of the soup can. (However, the applications of this firecracker/soup-can engine are limited.)

An engine that operates in a cycle passes through various thermodynamic states and eventually returns to its original state. The cyclic processes that heat engines utilize always involve some kind of temperature change. We can think of the most basic heat engine as operating between two thermal reservoirs (Figure 20.4b). One thermal reservoir is at a high temperature, T_{H}, and the other thermal reservoir is at a low temperature, T_{L}. The engine takes heat, Q_{H}, from the high-temperature reservoir, turns some of that heat into mechanical work, *W,* and exhausts the remaining heat, Q_{L} (where $Q_{\mathrm{L}} > 0$), to the low-temperature reservoir. According to the First Law of Thermodynamics (equivalent to the conservation of energy), $Q_{\mathrm{H}} = W + Q_{\mathrm{L}}$. Thus, to make an engine operate, it must be supplied energy in the form of Q_{H}, and then it will return useful work, *W*. The **efficiency, ϵ**, of an engine is defined as

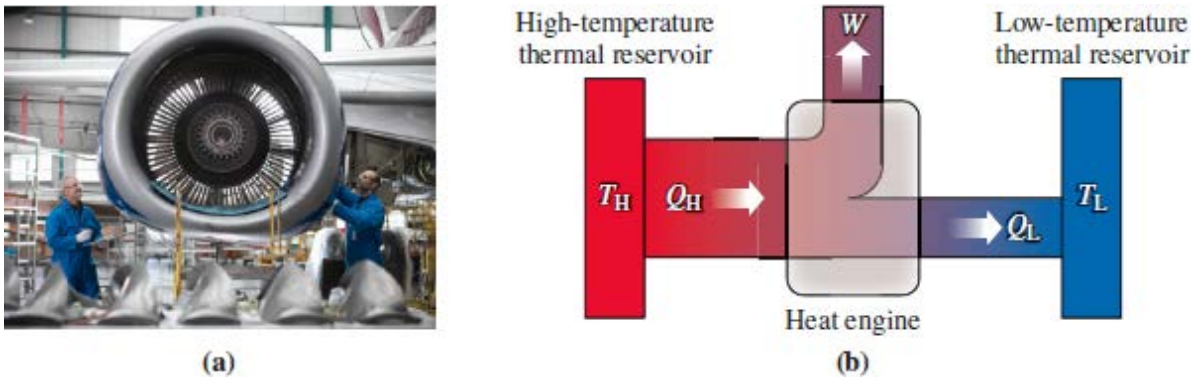


FIGURE 20.4 (a) A jet engine turns thermal energy into mechanical work. (b) Flow diagram of a heat engine operating between two thermal reservoirs. The engine takes heat from the high-temperature thermal reservoir, does some useful work, *W*, and exhausts the remaining heat to the low-temperature thermal reservoir.

a: Monty Rakusen/Getty Images

$$\epsilon = \frac{W}{Q_H}. \qquad \textbf{(20.1)}$$

A **refrigerator,** like the one shown in Figure 20.5a, is a heat engine that operates in reverse. Instead of converting heat into work, the refrigerator uses work to move heat from a low-temperature thermal reservoir to a high-temperature thermal reservoir (Figure 20.5b). In a real refrigerator, an electric motor drives a compressor, which transfers thermal energy from the interior of the refrigerator to the air in the room. An air conditioner is also a refrigerator; it transfers thermal energy from the air in a room to the air outdoors.

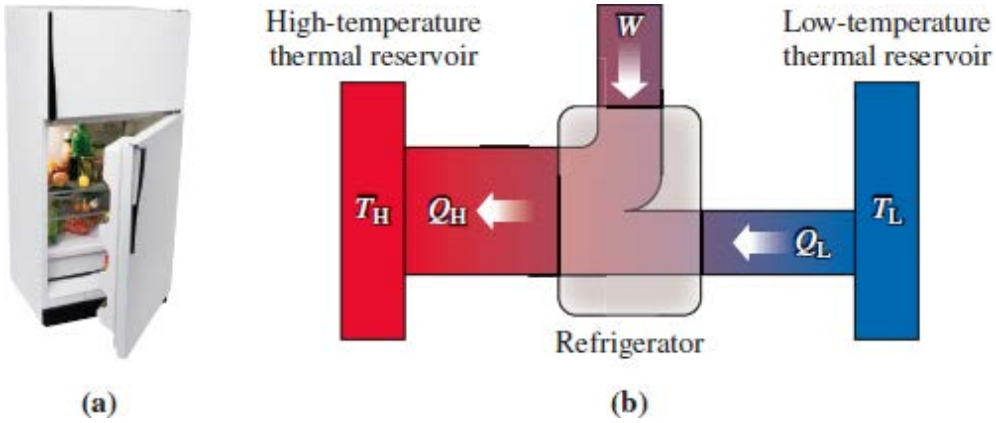

FIGURE 20.5 (a) A household refrigerator. (b) Flow diagram of a refrigerator operating between two thermal reservoirs.

a: C Squared Studios/Photodisc/Getty Images

For a refrigerator, the First Law of Thermodynamics requires that $Q_L + W = Q_H$. It is desired that a refrigerator remove as much heat as possible from the cooler reservoir, Q_L, given the work, W, put into the refrigerator. The **coefficient of performance,** K, of a refrigerator is defined as

$$K = \frac{Q_L}{W}. \qquad \textbf{(20.2)}$$

In the United States, refrigerators are usually rated by their annual energy usage, without quoting their actual efficiency. An efficient refrigerator is one whose energy use is comparable to the lowest energy use in its capacity class.

Air conditioners are often rated in terms of an energy efficiency rating (EER), defined as the heat removal capacity, H, in BTU/hour divided by the power P used in watts. The relationship between K and EER is

$$K = \frac{|Q_{\mathrm{L}}|}{|W|} = \frac{Ht}{Pt} = \frac{H}{P} = \frac{\mathrm{EER}}{3.41},$$

where t is a time interval. The factor $1/3.41$ arises from the definition of a BTU per hour:

$$\frac{1\mathrm{BTU/h}}{1\ \mathrm{watt}} = \frac{(1055\ \mathrm{J})/(3600\ \mathrm{s})}{1\ \mathrm{J/s}} = \frac{1}{3.41}.$$

Typical EER values for a room air conditioner range from 8 to 11, meaning that values of K range from 2.3 to 3.2. Thus, a typical room air conditioner can remove about three units of heat for every unit of energy used. Central air conditioners are often rated by a seasonally adjusted energy efficiency rating (SEER) that takes into account how long the air conditioner operates during a year.

A **heat pump** is a variation of a refrigerator that can be used to warm buildings. The heat pump warms the building by cooling the outside air. Just as for a refrigerator, $Q_{\mathrm{L}} + W = Q_{\mathrm{H}}$. However, for a heat pump, the quantity of interest is the heat put into the warmer reservoir, Q_{H}, rather than the heat removed from the cooler reservoir. Thus, the coefficient of performance of a heat pump is

$$K_{\text{heat pump}} = \frac{Q_{\mathrm{H}}}{W}, \qquad \textbf{(20.3)}$$

where W is the work required to move the heat from the low-temperature reservoir to the high-temperature reservoir. The typical coefficient of performance of a commercial heat pump ranges from 3 to 4. Heat pumps do not work well when the outside temperature sinks below $-18\ ^\circ\mathrm{C}(0\ ^\circ\mathrm{F})$.

EXAMPLE 20.2 Warming a House with a Heat Pump

A heat pump with a coefficient of performance of 3.500 is used to warm a house that loses 75,000. BTU/h of heat on a cold day. Assume that the cost of electricity is 10.00 cents per kilowatt-hour.

PROBLEM

How much does it cost to warm the house for the day?

SOLUTION

The coefficient of performance of a heat pump is given by equation 20.3:

$$K_{\text{heat pump}} = \frac{Q_{\text{H}}}{W},$$

The work required to warm the house is then

$$W = \frac{Q_{\text{H}}}{K_{\text{heat pump}}}.$$

Page 628

The house is losing 75,000 BTU/h, which we convert to SI units:

$$\frac{75,000\,\text{BTU}}{1\,\text{h}} \cdot \frac{1055\,\text{J}}{1\,\text{BTU}} \cdot \frac{1\,\text{h}}{3600\,\text{s}} = 21.98\,\text{kW}.$$

Therefore, the power required to warm the house is

$$P = \frac{W}{t} = \frac{Q_{H/t}}{K_{\text{heat pump}}} = \frac{21.98\,\text{kw}}{3.500} = 6.280\,\text{kW}.$$

The cost to warm the house for 24 h is then

$$\text{Cost} = (6.280\,\text{kW})(24\,\text{h})\frac{\$0.1000}{1\,\text{kWh}} = \$15.07.$$

20.3 Ideal Engines

An **ideal engine** is one that utilizes only reversible processes. Thus, the engine incorporates no "energy-wasting" effects, such as friction or viscosity. Remember, as defined in Section 20.2, a heat engine is a device that turns thermal energy into useful work. You might think that an *ideal* engine would be 100% efficient—would turn all the thermal energy supplied to it into useful mechanical work. However, we'll see that even the most efficient ideal engine cannot accomplish this. This fundamental inability to convert thermal energy totally into useful mechanical work lies at the very heart of the Second Law of Thermodynamics and of entropy, the two main topics of this chapter.

Carnot Cycle

An example of an ideal engine is the **Carnot engine,** which is the most efficient engine that operates between two temperature reservoirs and the only one to do so reversibly. The cycle of thermodynamic processes used by the Carnot engine is called the **Carnot cycle.**

In order to be reversible, a Carnot cycle consists of two isothermal processes and two adiabatic processes, as shown in Figure 20.6 in a pV-diagram (pressure-volume diagram). We can pick an arbitrary starting point for the cycle; let's say that it begins at point 1. The system first undergoes an isothermal process, during which the system expands and absorbs heat from a thermal reservoir at fixed temperature T_{H} (in Figure 20.6, $T_{\mathrm{H}} = 400\ \mathrm{K}$). At point 2, the system begins an adiabatic expansion in which no heat is gained or lost. At point 3, the system begins another isothermal process, this time giving up heat to a second thermal reservoir at a lower temperature, T_{L} (in Figure 20.6, $T_{\mathrm{L}} = 300\ \mathrm{K}$), while the system compresses. At point 4, the system begins a second adiabatic process in which no heat is gained or lost. The Carnot cycle is complete when the system returns to point 1.

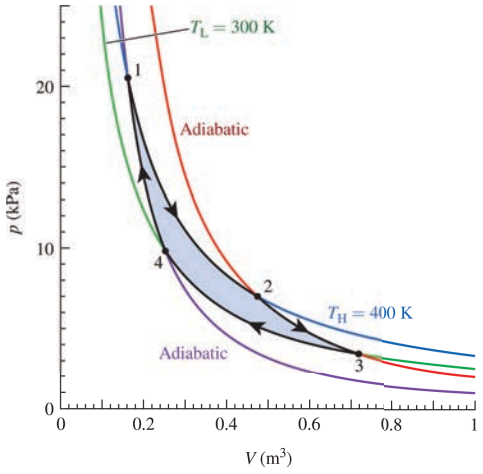

FIGURE 20.6 The Carnot cycle, consisting of two isothermal processes and two adiabatic processes.

The efficiency of the Carnot engine is not 100% but instead is given by

$$\epsilon = 1 - \frac{T_{\mathrm{L}}}{T_{\mathrm{H}}}. \tag{20.4}$$

Remarkably, the efficiency of a Carnot engine depends only on the temperature ratio of the two thermal reservoirs. For the engine shown in Figure 20.6, for example, the efficiency is $\epsilon = 1 - (300\,\mathrm{K})/(400\,\mathrm{K}) = 0.25$.

DERIVATION 20.1 Efficiency of Carnot Engine

We can determine the work and heat gained and lost in a Carnot cycle. To do this, we assume that the system consists of an ideal gas in a container whose volume can change. This system is placed in contact with a thermal reservoir and originally has pressure p_1 and volume V_1, corresponding to point 1 in Figure 20.6. The thermal reservoir holds the temperature of the system constant at T_{H}. The volume of the system is then allowed to increase until the system reaches point 2 in Figure 20.6. At point 2, the pressure is p_2 and the volume is V_2. During this isothermal process, work, W_{12}, is done by the system, and heat, Q_{H}, is transferred to the system. Because this process is isothermal, the internal energy of the system does not change. Thus, the amount of work done by the system and the thermal energy transferred to the system are equal, given by (see the discussion in Section 19.2):

$$W_{12} = Q_{\mathrm{H}} = nRT_{\mathrm{H}} \ln\left(\frac{V_2}{V_1}\right). \qquad \text{(i)}$$

The system is then removed from contact with the thermal reservoir whose temperature is T_{H}. The system continues to expand adiabatically to point 3 in Figure 20.6. At point 3, the expansion is stopped, and the system is put in contact with a second thermal reservoir that has temperature T_{L}. An adiabatic expansion means that $Q = 0$. In Chapter 19, we saw that the work done by an ideal gas undergoing an adiabatic process is $W = nR(T_{\mathrm{f}} - T_{\mathrm{i}})/(1 - \gamma)$, where $\gamma = C_p/C_V$ and C_p is the specific heat of the gas at constant pressure and C_V is the specific heat of the gas at constant volume. Thus, the work done by the system in going from point 2 to point 3 is

$$W_{23} = \frac{nR}{1-\gamma}(T_{\mathrm{L}} - T_{\mathrm{H}}).$$

Remaining in contact with the thermal reservoir whose temperature is T_{L}, the system is compressed isothermally from point 3 to point 4. The work done by the system and the heat absorbed by the system are

$$W_{34} = -Q_{\mathrm{L}} = nRT_{\mathrm{L}} \ln\left(\frac{V_4}{V_3}\right). \qquad \text{(ii)}$$

(In Chapter 18, this would have been written $W_{34} = Q_{\mathrm{L}}$ because Q_{L} would be the heat added to the system and therefore $Q_{\mathrm{L}} < 0$. However, in this chapter, we define Q_{L} as the heat delivered to the low-temperature reservoir, at $T = T_{\mathrm{L}}$, and hence $Q_{\mathrm{L}} > 0$.)

Finally, the system is removed from contact with the second thermal reservoir and compressed adiabatically from point 4 back to the original point, point 1. For this adiabatic process, $Q = 0$, and the work done by the system is

$$W_{41} = \frac{nR}{1-\gamma}(T_{\mathrm{H}} - T_{\mathrm{L}}).$$

Note that $W_{41} = -W_{23}$, since the work done in the adiabatic processes depends only on the initial and final temperatures. Therefore, $W_{41} + W_{23} = 0$, and for the complete cycle, the total work done by the system is

$$W = W_{12} + W_{23} + W_{34} + W_{41} = W_{12} + W_{34}.$$

Substituting the expressions for W_{12} and W_{34} from equations (i) and (ii) into the right side of the preceding equation, we have

$$W = nRT_{\mathrm{H}} \ln\left(\frac{V_2}{V_1}\right) + nRT_{\mathrm{L}} \ln\left(\frac{V_4}{V_3}\right).$$

We can now find the efficiency of the Carnot engine. The efficiency is defined in equation 20.1 as the ratio of the work done by the system, *W,* to the amount of heat supplied to the system, Q_{H}:

$$\epsilon = \frac{W}{Q_{\mathrm{H}}} = \frac{nRT_{\mathrm{H}} \ln\left(\frac{V_2}{V_1}\right) + nRT_{\mathrm{L}} \ln\left(\frac{V_4}{V_3}\right)}{nRT_{\mathrm{H}} \ln\left(\frac{V_2}{V_1}\right)} = 1 +$$

Page 630

This expression for the efficiency of a Carnot engine contains the volumes at points 1, 2, 3, and 4. However, we can eliminate the volumes from this expression using the relation for adiabatic expansion of an ideal gas from Chapter 19, $TV^{\gamma-1} = \text{constant}$.

For the adiabatic process from point 2 to point 3, we then have

$$T_{\mathrm{H}} V_2^{\gamma-1} = T_{\mathrm{L}} V_3^{\gamma-1}. \qquad \text{(iv)}$$

Similarly, for the adiabatic process from point 4 to point 1, we have

$$T_{\mathrm{L}} V_4^{\gamma-1} = T_{\mathrm{H}} V_1^{\gamma-1}. \qquad \text{(v)}$$

Forming ratios of both sides of equations (iv) and (v):

$$\frac{T_{\mathrm{H}} V_2^{\gamma-1}}{T_{\mathrm{H}} V_1^{\gamma-1}} = \frac{T_{\mathrm{L}} V_3^{\gamma-1}}{T_{\mathrm{L}} V_4^{\gamma-1}} \Rightarrow \frac{V_2}{V_1} = \frac{V_3}{V_4}.$$

Using this relationship between the volumes, we can now rewrite equation (iii) for the efficiency as

$$\epsilon = 1 + \frac{-T_{\mathrm{L}} \ln\left(\dfrac{V_3}{V_4}\right)}{T_{\mathrm{H}} \ln\left(\dfrac{V_2}{V_1}\right)} = 1 - \frac{T_{\mathrm{L}}}{T_{\mathrm{H}}},$$

which matches equation 20.4.

Can the efficiency of the Carnot engine reach 100%? To obtain 100% efficiency, T_{H} in equation 20.4 would have to be raised to infinity or T_{L} be lowered to absolute zero. Neither option is possible. Thus, the efficiency of a Carnot engine is always less than 100%.

Note that the total work done by the system during the Carnot cycle in Derivation 20.1 is $W = W_{12} + W_{34}$, and the two contributions to the total work due to the two isothermal processes are $W_{12} = Q_{\mathrm{H}}$ and $W_{34} = -Q_{\mathrm{L}}$. Therefore, as a direct consequence of the First Law of Thermodynamics, the total mechanical work from a Carnot cycle can also be written as

$$W = Q_{\mathrm{H}} - Q_{\mathrm{L}}. \tag{20.5}$$

Since the efficiency is defined in general as $\epsilon = W/Q_{\mathrm{H}}$ (equation 20.1), the efficiency of a Carnot engine can thus also be expressed as

$$\epsilon = \frac{Q_{\mathrm{H}} - Q_{\mathrm{L}}}{Q_{\mathrm{H}}}. \tag{20.6}$$

In this formulation, the efficiency of a Carnot engine is determined by the heat taken from the warmer reservoir minus the heat given back to the cooler reservoir. For this expression for the efficiency of a Carnot engine to yield an efficiency of 100%, the heat returned to the cooler reservoir would have to be zero. Conversely, if the efficiency of the Carnot engine is less than 100%, the engine cannot convert all the heat it takes in from the warmer reservoir to useful work.

French physicist Nicolas Leonard Sadi Carnot (1796–1832), who developed the Carnot cycle in the 19th century, proved the following statement, known as **Carnot's Theorem:**

No heat engine operating between two thermal reservoirs can be more efficient than a Carnot engine operating between the two thermal reservoirs.

Concept Check 20.1

What is the maximum (Carnot) coefficient of performance of a refrigerator in a room with a temperature of 22.0 °C? The temperature inside the refrigerator is kept at 2.0 °C.

a) 0.10

b) 0.44

c) 3.0

d) 5.8

e) 13.8

We won't present the proof of Carnot's Theorem. However, we'll note the idea behind the proof after discussing the Second Law of Thermodynamics in Section 20.5

We can imagine running a Carnot engine in reverse, creating a "Carnot refrigerator." The maximum coefficient of performance for such a refrigerator operating between two thermal reservoirs is

$$K_{\text{max}} = \frac{T_{\text{L}}}{T_{\text{H}} - T_{\text{L}}}. \qquad \textbf{(20.7)}$$

Similarly, the maximum coefficient of performance for a heat pump operating between two thermal reservoirs is given by

$$K_{\text{heat pump max}} = \frac{T_{\text{H}}}{T_{\text{H}} - T_{\text{L}}}. \qquad \textbf{(20.8)}$$

Concept Check 20.2

What is the maximum (Carnot) coefficient of performance of a heat pump being used to warm a house to an interior temperature of 22.0 °C? The temperature outside the house is 2.0 °C.

a) 0.15

b) 1.1

c) 3.5

d) 6.5

e) 14.8

Note that the Carnot cycle constitutes the ideal thermodynamic process, which is the absolute upper limit on what is theoretically attainable. Real-world complications lower the efficiency drastically, as we'll see in Section 20.4. The typical coefficient of performance for a real refrigerator or heat pump is around 3.

EXAMPLE 20.3 Work Done by a Carnot Engine

A Carnot engine takes 3000 J of heat from a thermal reservoir with a temperature $T_{\mathrm{H}} = 500\ \mathrm{K}$ and discards heat to a thermal reservoir with a temperature $T_{\mathrm{L}} = 325\ \mathrm{K}$.

PROBLEM

How much work does the Carnot engine do in this process?

SOLUTION

We start with the definition of the efficiency, ϵ, of a heat engine (equation 20.1):

$$\epsilon = \frac{W}{Q_{\mathrm{H}}},$$

where W is the work that the engine does and Q_{H} is the heat taken from the warmer thermal reservoir. We can then use equation 20.4 for the efficiency of a Carnot engine:

$$\epsilon = 1 - \frac{T_{\mathrm{L}}}{T_{\mathrm{H}}}.$$

Combining these two expressions for the efficiency gives us

$$\frac{W}{Q_{\mathrm{H}}} = 1 - \frac{T_{\mathrm{L}}}{T_{\mathrm{H}}}.$$

Now we can express the work done by the Carnot engine:

$$W = Q_{\mathrm{H}}\left(1 - \frac{T_{\mathrm{L}}}{T_{\mathrm{H}}}\right).$$

Putting in the numerical values gives the amount of work done by the Carnot engine:

$$W = (3000\ \text{J})\left(1 - \frac{325\,\text{K}}{500\,\text{K}}\right) = 1050\,\text{J}.$$

Self-Test Opportunity 20.1

What is the efficiency of the Carnot engine in Example 20.3?

EXAMPLE 20.4 Maximum Efficiency of an Electric Power Plant

Sixty-three percent of the world's electricity is generated by burning fossil fuels to produce steam, which in turn drives alternators that produce electricity. Power plants can produce steam with a temperature as high as 600. °C by pressurizing the steam. The resulting waste heat must be exhausted into the environment, which is at a temperature of 20.0 °C.

PROBLEM

What is the maximum efficiency of such a power plant?

SOLUTION

The maximum efficiency of such a power plant is the efficiency of a Carnot heat engine (equation 20.4) operating between 20.0 °C and 600. °C:

$$\epsilon = 1 - \frac{T_{\mathrm{L}}}{T_{\mathrm{H}}} = 1 - \frac{293\ \mathrm{K}}{873\ \mathrm{K}} = 66.4\%.$$

Real power plants achieve a lower efficiency of around 40%. However, many well-designed plants do not simply exhaust the waste heat into the environment. Instead, they employ *cogeneration* or *combined heat and power* (CHP). The heat that normally would be lost is used to heat nearby buildings or houses. This heat can even be used to operate air conditioners that cool nearby structures, a process called *trigeneration*. By employing CHP, modern power plants can make use of up to 90% of the energy used to generate electricity. For example, the power plant at Michigan State University (Figure 20.7) burns natural gas to generate electricity for the campus. The waste

heat is used to heat campus buildings in the winter and air-condition them in the summer.

FIGURE 20.7 The natural gas–fired electric power plant at Michigan State University provides all the electricity used on the campus as well as heating campus buildings in the winter and air-conditioning them in the summer.

W. Bauer and G. D. Westfall

SOLVED PROBLEM 20.1 Cost to Operate an Electric Power Plant

An electric power plant operates steam turbines at a temperature of $557\ ^\circ\text{C}$ and uses cooling towers to keep the cooler thermal reservoir at a temperature of $38.3\ ^\circ\text{C}$. The operating cost of the plant for 1 yr is \$52.0 million. The plant managers propose using the water from a nearby lake to lower the temperature of the cooler reservoir to $8.90\ ^\circ\text{C}$. Assume that the plant operates at maximum possible efficiency.

PROBLEM

How much will the operating cost of the plant be reduced in 1 yr as a result of the change in reservoir temperature? Assume that the plant generates the same amount of electricity.

SOLUTION

THINK

We can calculate the efficiency of the power plant assuming that it operates at the theoretical Carnot efficiency, which depends only on the temperatures of the warmer thermal reservoir and the cooler thermal reservoir. We can calculate the amount of thermal energy put into the warmer reservoir and assume that the cost of operating the plant is proportional to that thermal energy. This thermal energy might come from the burning of fuel (coal, oil, or gas) or perhaps from a nuclear reactor. Lowering the temperature of the cooler reservoir will increase the efficiency of the power plant, and thus lower the required amount of thermal energy and the associated cost. The cost savings are then the operating cost of the original plant minus the operating cost of the improved plant.

SKETCH

Figure 20.8 is a sketch relating the thermodynamic quantities involved in the operation of an electric power plant. The temperature of the warmer reservoir is T_H, the thermal energy

supplied to the original power plant is Q_{H1}, the thermal energy supplied to the improved power plant is Q_{H2}, the useful work done by the power plant is *W,* the original temperature of the cooler reservoir is T_{L1}, and the temperature of the improved cooler reservoir is T_{L2}.

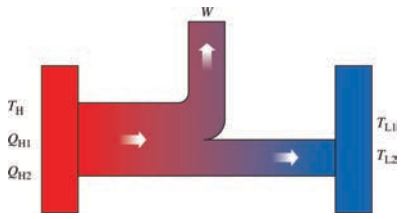

FIGURE 20.8 The thermodynamic quantities related to the operation of an electric power plant.

RESEARCH

The maximum efficiency of the power plant when operating with the cooling towers is given by the theoretical Carnot efficiency:

$$\epsilon_1 = \frac{T_H - T_{L1}}{T_H}. \qquad \text{(i)}$$

The efficiency of the power plant under this condition can also be expressed as

$$\epsilon_1 = \frac{W}{Q_{H1}}, \qquad \text{(ii)}$$

where Q_{H1} is the thermal energy supplied when the cooling towers are used. We can write similar expressions for the efficiency of the power plant when the lake is used to lower the temperature of the cooler reservoir:

$$\epsilon_2 = \frac{T_{\mathrm{H}} - T_{\mathrm{L2}}}{T_{\mathrm{H}}} \qquad \text{(iii)}$$

and

$$\epsilon_2 = \frac{W}{Q_{\mathrm{H2}}}. \qquad \text{(iv)}$$

The cost to operate the power plant is proportional to the thermal energy supplied to the warmer reservoir. We can thus equate the ratio of the original cost, c_1, to the lowered cost, c_2, with the ratio of the thermal energy originally required, Q_{H1}, to the thermal energy subsequently required, Q_{H2}:

$$\frac{c_1}{c_2} = \frac{Q_{\mathrm{H1}}}{Q_{\mathrm{H}_2}}.$$

SIMPLIFY

We can express the new cost as

$$c_2 = c_1 \frac{Q_{\mathrm{H2}}}{Q_{\mathrm{H1}}}.$$

We can get an expression for the thermal energy originally required using equations (i) and (ii):

$$Q_{\mathrm{H1}} = \frac{W}{\epsilon_1} = \frac{W}{\left(\frac{T_{\mathrm{H}} - T_{\mathrm{L1}}}{T_{\mathrm{H}}}\right)} = \frac{T_{\mathrm{H}} W}{T_{\mathrm{H}} - T_{\mathrm{L1}}}.$$

We can get a similar expression for the thermal energy required after the improvement using equations (iii) and (iv):

$$Q_{\mathrm{H2}} = \frac{W}{\epsilon_2} = \frac{W}{\left(\dfrac{T_{\mathrm{H}} - T_{\mathrm{L2}}}{T_{\mathrm{H}}}\right)} = \frac{T_{\mathrm{H}} W}{T_{\mathrm{H}} - T_{\mathrm{L2}}}.$$

We can now express the new cost as

$$c_2 = c_1 \frac{Q_{\mathrm{H2}}}{Q_{\mathrm{H1}}} = c_1 \frac{\left(\dfrac{T_{\mathrm{H}} W}{T_{\mathrm{H}} - T_{\mathrm{L2}}}\right)}{\left(\dfrac{T_{\mathrm{H}} W}{T_{\mathrm{H}} - T_{\mathrm{L1}}}\right)} = c_1 \frac{T_{\mathrm{H}} - T_{\mathrm{L1}}}{T_{\mathrm{H}} - T_{\mathrm{L2}}}.$$

Note that the work W done by the power plant cancels out because the plant generates the same amount of electricity in both cases. The cost savings are then

$$c_1 - c_2 = c_1 - c_1 \frac{T_{\mathrm{H}} - T_{\mathrm{L1}}}{T_{\mathrm{H}} - T_{\mathrm{L2}}} = c_1 \left(1 - \frac{T_{\mathrm{H}} - T_{\mathrm{L1}}}{T_{\mathrm{H}} - T_{\mathrm{L2}}}\right) = c_1 \frac{}{}$$

CALCULATE

Putting in the numerical values, we get

$$c_1 - c_2 = c_1 \frac{T_{\mathrm{L1}} - T_{\mathrm{L2}}}{T_{\mathrm{H}} - T_{\mathrm{L2}}} = (\$52.0\ \text{million}) \frac{311.45\ \mathrm{K} - 282}{830.15\ \mathrm{K} - 282}$$

ROUND

We report our result to three significant figures:

$$\text{Cost savings} = \$2.79\ \text{million}.$$

DOUBLE-CHECK

To double-check our result, we calculate the efficiency of the power plant using cooling towers:

$$\epsilon_1 = \frac{T_\text{H} - T_\text{L1}}{T_\text{H}} = \frac{830.15\,\text{K} - 311.45\,\text{K}}{830.15\,\text{K}} = 62.5\,\%.$$

The efficiency of the power plant using the lake to lower the temperature of the cooler reservoir is

$$\epsilon_2 = \frac{T_\text{H} - T_\text{L2}}{T_\text{H}} = \frac{830.15\,\text{K} - 282.05\,\text{K}}{830.15\,\text{K}} = 66.0\,\%.$$

These efficiencies seem reasonable. To check further, we verify that the ratio of the two efficiencies is equal to the inverse of the ratio of the two costs, because a higher efficiency means a lower cost. The ratio of the two efficiencies is

$$\frac{\epsilon_1}{\epsilon_2} = \frac{62.5\,\%}{66.0\,\%} = 0.947.$$

Page 634

The inverse ratio of the two costs is

$$\frac{c_2}{c_1} = \frac{\$52\text{ million} - \$2.79\text{ million}}{\$52\text{ million}} = 0.946.$$

These ratios agree to within rounding error. Thus, our result seems reasonable.

20.4 Real Engines and Efficiency

A real heat engine based on the Carnot cycle is not practical. However, many practical heat engines that are in everyday use are designed to operate via cyclical thermodynamic processes. For an example of the operation of a real-world engine, let's examine the Otto cycle. Again, we assume an ideal gas as the working medium.

Otto Cycle

The **Otto cycle** is used in the modern internal combustion engines inside automobiles. This cycle consists of two adiabatic processes and two constant-volume processes (Figure 20.9) and is the default configuration for a four-cycle internal combustion engine. The piston-cylinder arrangement of a typical internal combustion engine is shown in Figure 20.10.

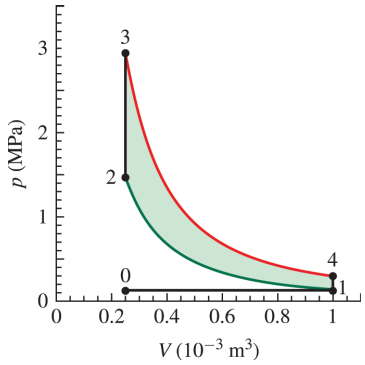

FIGURE 20.9 The Otto cycle, consisting of two adiabatic processes and two constant-volume processes.

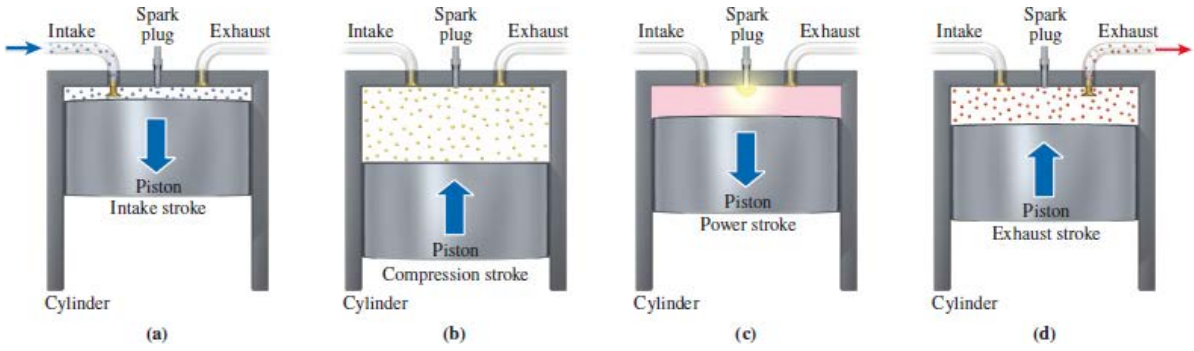

FIGURE 20.10 The four strokes of an internal combustion engine: (a) The intake stroke, during which the fuel-air mixture is drawn into the cylinder. (b) The compression stroke, in which the fuel-air mixture is compressed. (c) The power stroke, where the fuel-air mixture is ignited by the spark plug, releasing heat. (d) The exhaust stroke, during which the burned gases are pushed out of the cylinder.

The thermal energy is provided by the ignition of a fuel-air mixture. The cycle starts with the piston at the top of the cylinder and proceeds through the following steps:

- *Intake stroke.* The piston moves down with the intake valve open, drawing in the fuel-air mixture (point 0 to point 1 in Figure 20.9 and Figure 20.10a), and the intake valve closes.
- *Compression stroke.* The piston moves upward, compressing the fuel-air mixture adiabatically (point 1 to point 2 in Figure 20.9 and Figure 20.10b).
- The spark plug ignites the fuel-air mixture, increasing the pressure at constant volume (point 2 to point 3 in Figure 20.9).
- *Power stroke.* Hot gases push the piston down adiabatically (point 3 to point 4 in Figure 20.9 and Figure 20.10c).
- When the piston is all the way down (point 4 in Figure 20.9), the exhaust valve opens. This reduces the pressure at constant volume, provides the heat rejection, and moves the system back to point 1.
- *Exhaust stroke.* The piston moves up, forcing out the burned gases (point 1 to point 0 in Figure 20.9 and Figure 20.10d), and the exhaust valve closes.

The ratio of the expanded volume, V_1, to the compressed volume, V_2, is called the *compression ratio:*

$$r = \frac{V_1}{V_2}. \tag{20.9}$$

The efficiency, ϵ, of the Otto cycle can be expressed as a function of the compression ratio only:

$$\epsilon = 1 - r^{1-\gamma}. \qquad \textbf{(20.10)}$$

(In contrast, for the Carnot cycle, equation 20.4 showed that the efficiency depends only on the ratio of two temperatures.)

DERIVATION 20.2 Efficiency of the Otto Cycle

The Otto cycle begins at point 0 in Figure 20.9. The process from point 0 to point 1 simply draws the fuel-air mixture into the cylinder and plays no further role in the efficiency considerations. Neither does the inverse process from point 1 to point 0, the exhaust stroke, which removes the combustion products from the cylinder.

The process from point 1 to point 2 is adiabatic. The thermal energy transferred is zero, and the work done by the system (see Chapter 19) is given by

$$W_{12} = \frac{nR}{1-\gamma}(T_2 - T_1).$$

For the constant-volume process from point 2 to point 3, the work done by the system is zero, $W_{23} = 0$, and the thermal energy transferred to the system (see Chapter 18) is given by

$$Q_{23} = nC_V(T_3 - T_2).$$

The process from point 3 to point 4 is again adiabatic, and the thermal energy transferred is zero. The work done by the system is

$$W_{34} = \frac{nR}{1-\gamma}(T_4 - T_3).$$

The process from point 4 to point 1 takes place at constant volume, so the work done by the system is zero, $W_{41} = 0$, and the heat expelled from the system is

$$Q_{41} = nC_V(T_4 - T_1).$$

The total work done by the system is then simply the sum of the four contributions from the entire cycle (remember that $W_{23} = W_{41} = 0$)

$$W = W_{12} + W_{34} = \frac{nR}{1-\gamma}(T_2 - T_1) + \frac{nR}{1-\gamma}(T_4 - T_3) =$$

The factor $R/(1-\gamma)$ can be expressed in terms of the specific heat capacity, C_V;

$$\frac{R}{1-\gamma} = \frac{C_p - C_V}{1 - \frac{C_p}{C_V}} = -C_V.$$

The efficiency of the Otto cycle is then (net work done divided by the heat gained by the system per cycle)

$$\epsilon = \frac{W}{Q_{23}} = \frac{-nC_V(T_2 - T_1 + T_4 - T_3)}{nC_V(T_3 - T_2)} = 1 - \frac{(T_4 -}{(T_3 -}$$

We can use the fact that the process from point 1 to point 2 and the process from point 3 to point 4 are adiabatic to write (see Section 19.5)

$$T_1 V_1^{\gamma-1} = T_2 V_2^{\gamma-1} \Rightarrow T_2 = \left(\frac{V_1}{V_2}\right)^{\gamma-1} T_1 \qquad \text{(ii)}$$

and

$$T_3 V_2^{\gamma-1} = T_4 V_1^{\gamma-1} \Rightarrow T_3 = \left(\frac{V_1}{V_2}\right)^{\gamma-1} T_4, \qquad \text{(iii)}$$

where V_1 is the volume at points 1 and 4 and V_2 is the volume at points 2 and 3. Substituting the expressions for T_2 and T_3 from equations (ii) and (iii) into equation (i) for the efficiency, we obtain equation 20.10:

$$\epsilon = 1 - \frac{(T_4 - T_1)}{\left(\frac{V_1}{V_2}\right)^{\gamma-1} T_4 - \left(\frac{V_1}{V_2}\right)^{\gamma-1} T_1} = 1 - \left(\frac{V_1}{V_2}\right)^{1-\gamma} =$$

As a numerical example, the compression ratio of the Otto cycle shown in Figure 20.9 is 4, and so, the efficiency of that Otto cycle is $\epsilon = 1 - 4^{1-7/5} = 1 - 4^{-0.4} = 0.426$. Thus, the theoretical efficiency of an engine operating on the Otto cycle with a compression ratio of 4 is 42.6%. Note, however, that this is the theoretical upper limit for the efficiency at this compression ratio. In principle, an internal combustion engine can be made more efficient by increasing the compression ratio, but practical factors prevent that approach. For example, if the compression ratio is too high, the fuel-air mixture will detonate before the compression is complete. Very high compression ratios put high stresses on the components of the engine. The actual compression ratios of gasoline-powered internal combustion engines range from 8 to 12.

Self-Test Opportunity 20.2

How much would the theoretical efficiency of an internal combustion engine increase if the compression ratio were raised from 4 to 15?

Concept Check 20.3

Which of the four temperatures in the Otto cycle is the highest?

a) T_1

b) T_2

c) T_3

d) T_4

e) All four are identical.

Real Otto Engines

The actual efficiency of an internal combustion engine is about 20%. Why is this so much lower than the theoretical upper limit? There are many reasons. First, the “adiabatic” parts of the cycle do not really proceed without heat exchange between the gas in the piston and the engine block. This is obvious; we all know from experience that engines heat up while running, and this temperature rise is a direct consequence of heat leaking from the gas undergoing compression and ignition. Second, the gasoline-air mixture is not quite an ideal gas and thus has energy losses due to internal excitation. Third, during the ignition and heat rejection processes, the volume does not stay exactly constant, because both processes take some time, and the piston keeps moving continuously during that time. Fourth, during the intake and exhaust strokes, the pressure in the chamber is not exactly atmospheric pressure because of gas dynamics considerations. All of these effects, together with small friction losses, combine to reduce engine efficiency. All major car companies, as well as car racing crews, government and university labs, and even a few hobbyists, are continuously seeking ways to increase engine efficiency, because a higher efficiency means higher power output and/or better gas mileage. Since the oil crisis of the mid-1970s, the engine efficiency of U.S. automobiles has steadily increased (see Section 5.7), but even better miles-per-gallon performance is necessary for the United States to reduce its greenhouse gas emissions and its dependence on foreign oil.

SOLVED PROBLEM 20.2 Efficiency of an Automobile Engine

A car with a gasoline-powered internal combustion engine travels with a speed of 26.8 m/s (60.0 mph) on a level road and uses gas at a rate of 6.92 L/100 km (34.0 mpg). The energy content of gasoline is 34.8 MJ/L.

PROBLEM

If the engine has an efficiency of 20.0%, how much power is delivered to keep the car moving at a constant speed?

SOLUTION

THINK

We can calculate how much energy is being supplied to the engine by calculating the amount of fuel used and multiplying by the energy content of that fuel. The efficiency is the useful work divided by the energy being supplied; so, once we determine the energy supplied, we can find the useful work from the given efficiency of the engine. By dividing the work and the energy by an arbitrary time interval, we can determine the average power delivered.

SKETCH

Figure 20.11 shows a gasoline-powered automobile engine operating as a heat engine.

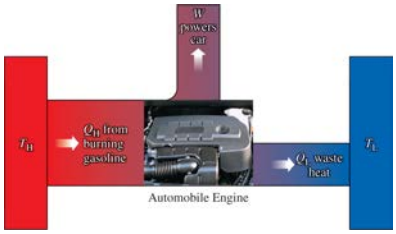

FIGURE 20.11 A gasoline-powered automobile engine operating as a heat engine to power a car traveling at constant speed *v* on a horizontal surface.

W. Bauer and G. D. Westfall

RESEARCH

The car is traveling at speed v. The rate, χ, at which the car burns gasoline, can be expressed in terms of the volume of gasoline burned per unit distance. We can calculate the volume of gasoline burned per unit time, V_t, by multiplying the speed of the car by the rate, χ, at which the car burns gasoline:

$$V_t = \chi v. \qquad \text{(i)}$$

The energy per unit time supplied to the engine by consuming fuel is the power, P, given by the volume of gasoline used per unit time multiplied by the energy content of gasoline, E_g:

$$P = V_t E_g. \qquad \text{(ii)}$$

The efficiency of the engine, ϵ, is given by equation 20.1:

$$\epsilon = \frac{W}{Q_{\mathrm{H}}},$$

where W is the useful work and Q_{H} is the thermal energy supplied to the engine. If we divide both W and Q_{H} by a time interval, t, we get

$$\epsilon = \frac{W/t}{Q_{\mathrm{H}}/t} = \frac{P_{\text{delivered}}}{P}, \qquad \text{(iii)}$$

where $P_{\text{delivered}}$ is the power delivered by the engine of the car.

SIMPLIFY

We can combine equations (i) through (iii) to obtain

$$P_{\text{delivered}} = \epsilon P = \epsilon V_{\mathrm{t}} E_{\mathrm{g}} = \epsilon \chi v E_{\mathrm{g}}.$$

CALCULATE

The power delivered is

$$P_{\text{delivered}} = \epsilon \chi v E_{\mathrm{g}} = (0.200)\left(\frac{6.92\ \mathrm{L}}{100 \cdot 10^3\ \mathrm{m}}\right)(26.8\ \mathrm{m/s})(3$$

ROUND

We report our result to three significant figures:

$$P_{\text{delivered}} = 12.900\ \mathrm{W} = 12.9\ \mathrm{kW} = 17.3\ \mathrm{hp}.$$

DOUBLE-CHECK

To double-check our result, we calculate the power required to keep the car moving at 60.0 mph against air resistance. The power required, P_{air}, is equal to the product of the force of air resistance, F_{drag}, and the speed of the car:

$$P_{\text{air}} = F_{\text{drag}} v. \qquad \text{(iv)}$$

The drag force created by air resistance is given by

$$F_{\text{drag}} = K v^2. \qquad \text{(v)}$$

The constant K has been found empirically to be

$$K = \tfrac{1}{2} c_{\text{d}} A \rho, \qquad \text{(vi)}$$

where c_{d} is the drag coefficient of the car, A is its front cross-sectional area, and ρ is the density of air. Combining equations (iv) through (vi) gives

$$P_{\text{air}} = F_{\text{drag}} v = \left(K v^2\right) v = \tfrac{1}{2} c_{\text{d}} A \rho v^3.$$

Using $c_{\text{d}} = 0.33$, $A = 2.2\ \text{m}^2$, and $\rho = 1.29\ \text{kg/m}^3$, we obtain

$$P_{\text{air}} = \frac{1}{2}(0.33)\left(2.2\ \text{m}^2\right)\left(1.29\ \text{kg/m}^3\right)(26.8\ \text{m/s})^3 = 9014$$

This result for the power required to overcome air resistance ($P_{\text{air}} = 9.0\,\text{kW} = 12\,\text{hp}$) is about 70% of the calculated value for the power delivered ($P_{\text{delivered}} = 12.9\,\text{kW} = 17.3\,\text{hp}$). The remaining power is used to overcome other kinds of friction, such as rolling friction. Thus, our answer seems reasonable.

Diesel Cycle

Diesel engines and gasoline engines have somewhat different designs. Diesel engines do not compress a fuel-air mixture, but rather air only (path from point 1 to point 2 in Figure 20.12, green curve). The fuel is introduced (between point 2 and point 3) only after the air has been compressed. The thermal energy from the compression ignites the mixture (thus, no spark plug is required). This combustion process pushes the piston out at constant pressure. After combustion, the combustion products push the piston out farther in the same adiabatic manner as in the Otto cycle (path from point 3 to point 4, red curve). The process of heat rejection to the environment at constant volume (between points 4 and 1 in the diagram) also proceeds in the same way as in the Otto cycle, as do the intake stroke (path from 0 to 1) and exhaust stroke (path from 1 to 0). Diesel engines have a higher compression ratio and thus a higher efficiency than gasoline-powered four-stroke engines, although they have a slightly different thermodynamic cycle.

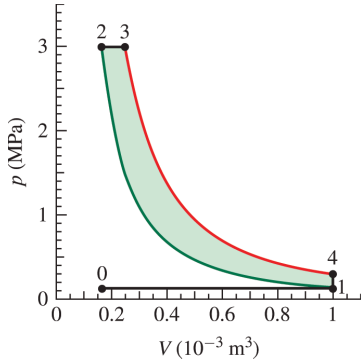

FIGURE 20.12 A *pV*-diagram for the Diesel cycle.

The efficiency of an ideal diesel engine is given by

$$\epsilon = 1 - r^{1-\gamma}\frac{\alpha^{\gamma} - 1}{\gamma(\alpha - 1)}, \qquad \textbf{(20.11)}$$

where the compression ratio is again $r = V_1/V_2$ (just as for the Otto cycle), γ is again the ratio of the specific heats at constant pressure and constant volume, $\gamma = C_p/C_V$ (introduced in Chapter 19), and $\alpha = V_3/V_2$ is called the *cut-off ratio,* the ratio between the final and initial volumes of the combustion phase. The derivation of this formula proceeds similarly to Derivations 20.1 and 20.2 for the Carnot and Otto cycles but is omitted here.

Concept Check 20.4

In which part of the Diesel cycle in Figure 20.12 is heat added?

a) on the path from point 0 to point 1

b) on the path from point 1 to point 2

c) on the path from point 2 to point 3

d) on the path from point 3 to point 4

e) on the path from point 4 to point 1

Hybrid Cars

Hybrid cars combine a gasoline engine and an electric motor to achieve higher efficiency than a gasoline engine alone can achieve. The improvement in efficiency results from using a smaller gasoline engine than would normally be necessary and an electric motor, run off a battery charged by the gasoline engine, to supplement the gasoline engine when higher power is required. For example, the Ford Escape Hybrid (Figure 20.13) has a 114-kW (153-hp) gasoline engine coupled with a 70-kW (94-hp) electric motor, and the Ford Escape has a 128-kW (171-hp) gasoline engine. In addition, the gasoline engine used in the Ford Escape Hybrid, as well as in the hybrid vehicles from Toyota and Honda, applies a thermodynamic cycle different from the Otto cycle. This *Atkinson cycle* includes variable valve timing to increase the expansion phase of the process, allowing more useful work to be extracted

from the energy consumed by the engine. An Atkinson-cycle engine produces less power per displacement than a comparable Otto-cycle engine but has higher efficiency.

FIGURE 20.13 The gasoline engine and electric motor of a hybrid car.

Koichi Kamoshida/Stringer/Getty Images

Concept Check 20.5

During which part(s) of the Diesel cycle in Figure 20.12 is mechanical work done by the engine?

a) on the path from point 0 to point 1 and on the path from point 1 to point 0

b) on the path from point 1 to point 2

c) on the path from point 2 to point 3 and on the path from point 3 to point 4

d) on the path from point 4 to point 1

In stop-and-go driving, hybrid cars have the advantage of using regenerative braking rather than normal brakes. Conventional brakes use friction to stop the car, which converts the kinetic energy of the car into wasted energy in the form of thermal energy (and wear on the brake pads). Regenerative brakes couple the wheels to an electric generator (which can be the electric motor

driving the car), which converts the kinetic energy of the car into electrical energy. This energy is stored in the battery of the hybrid car to be used later. In addition, the gasoline engine of a hybrid car can be shut off when the car is stopped, so the car uses no energy while waiting at a stoplight.

Page 639

In highway driving, hybrid cars take advantage of the fact that the gasoline engine can be run at a constant speed, corresponding to its most efficient operating speed, rather than having to run at a speed dictated by the speed of the car. Operation of the gasoline engine at a constant speed while the speed of the car changes is accomplished by a continuously variable transmission. The transmission couples both the gasoline engine and the electric motor to the drive wheels of the car, allowing the gasoline engine to run at its most efficient speed while taking power from the electric motor as needed.

Efficiency and the Energy Crisis

The efficiencies of engines and refrigerators are not just theoretical constructs but have very important economic consequences, which are extremely relevant to solving the energy crisis. The efficiencies and performance coefficients calculated in this chapter with the aid of thermodynamic principles are theoretical upper limits. Real-world complications always reduce the actual efficiencies of engines and performance coefficients of refrigerators. But engineering research can overcome these real-world complications and provide better performance of real devices, approaching the ideal limits.

One impressive example of performance improvement has occurred with refrigerators sold in the United States, according to data compiled by Steve Chu (see Figure 20.14). Between 1975 and 2003, the average size of a refrigerator in U.S. kitchens increased by about 20%, but through a combination of tougher energy standards and research and development on refrigerator design and technology, the average power consumption fell by two thirds, a total of 1200 kWh/yr, from 1800 kWh/yr in 1975 to 600 kWh/yr in 2003.

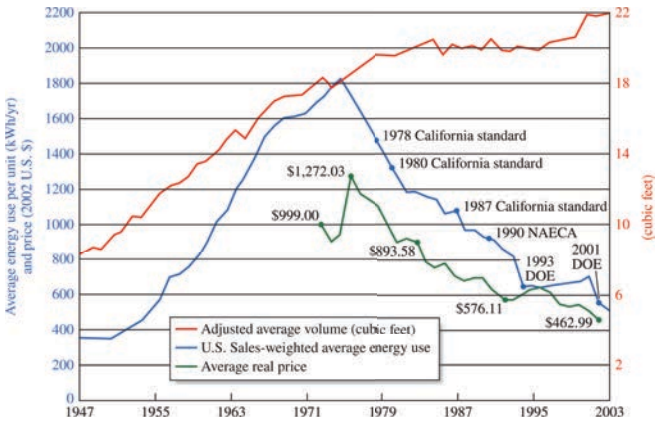

FIGURE 20.14 Average U.S. refrigerator volume (red line), price (green line), and energy use (blue line) from 1947 to 2003.

Since about 150 million new refrigerators and freezers are purchased each year in the United States, and each one saves approximately 1200 kWh/yr, a total energy savings of 180 billion

kWh $\left(6.5 \cdot 10^7 \text{ J} = 0.65 \text{ EJ}\right)$ is realized each year. In 2009, this savings was approximately twice as much as the combined energy produced through the use of wind power (30 billion kWh/yr), solar energy (2 billion kWh/yr), geothermal (14 billion kWh/yr), and biomass (54 billion kWh/yr).

Page 640

Energy consumption is directly proportional to energy cost, so the average U.S. household saves a total of almost $200 each year in electricity costs from using more efficient refrigerators relative to the 1975 standard. In addition, even though refrigerators have gotten much better, their price has fallen by more than half, also indicated in Figure 20.14. So a more energy-efficient refrigerator is not more expensive. And it keeps our food and favorite beverages just as cold as the 1975 model used to!

SOLVED PROBLEM 20.3 Freezing Water in a Refrigerator

Suppose we have 250 g of water at 0.00 °C. We want to freeze this water by putting it in a refrigerator operating in a room with a temperature of 22.0 °C. The temperature inside the refrigerator is maintained at −5.00 °C.

PROBLEM

What is the minimum amount of electrical energy that must be supplied to the refrigerator to freeze the water?

SOLUTION

THINK

The amount of heat that must be removed depends on the latent heat of fusion and the given mass of water. The most efficient refrigerator possible is a Carnot refrigerator, so we will use the theoretical maximum coefficient of performance of such a refrigerator. Knowing the amount of heat to be removed from the low-temperature reservoir and the coefficient of performance, we can calculate the minimum energy that must be supplied.

SKETCH

A heat flow diagram for the refrigerator is shown in Figure 20.15.

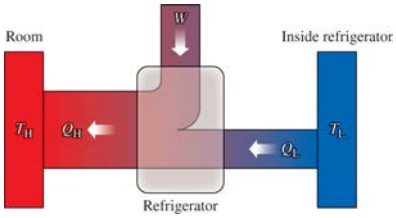

FIGURE 20.15 A heat flow diagram for a refrigerator that takes heat from its interior and exhausts it into the room using a source of electrical power.

RESEARCH

The most efficient refrigerator possible is a Carnot refrigerator. The maximum coefficient of performance of a Carnot refrigerator is given by equations 20.2 and 20.7:

$$K_{\max} = \frac{Q_{\mathrm{L}}}{W} = \frac{T_{\mathrm{L}}}{T_{\mathrm{H}} - T_{\mathrm{L}}}, \qquad \text{(i)}$$

where Q_{L} is the heat removed from inside the refrigerator, W is the work (in terms of electrical energy) that must be supplied, T_{L} is the temperature inside the refrigerator, and T_{H} is the temperature of the room. The amount of heat that must be removed to freeze a mass m of water is given by (see Chapter 18)

$$Q_{\mathrm{L}} = mL_{\mathrm{fusion}}, \qquad \text{(ii)}$$

where $L_{\mathrm{fusion}} = 334\ \mathrm{kJ/kg}$ is the latent heat of fusion of water (which can be found in Table 18.2).

SIMPLIFY

We can solve equation (i) for the energy that must be supplied to the refrigerator:

$$W = Q_{\mathrm{L}} \frac{T_{\mathrm{H}} - T_{\mathrm{L}}}{T_{\mathrm{L}}}.$$

Substituting the expression for the heat removed from equation (ii), we get

$$W = (mL_{\mathrm{fusion}}) \frac{T_{\mathrm{H}} - T_{\mathrm{L}}}{T_{\mathrm{L}}}.$$

CALCULATE

Putting in the numerical values gives

$$W = \frac{mL_{\mathrm{fusion}}}{K} = (0.250\,\mathrm{kg})(334\,\mathrm{kJ/kg}) \frac{295.15\,\mathrm{K} - 268.}{268.15\,\mathrm{K}}$$

ROUND

We report our result to three significant figures:

$$W = 8.41\,\mathrm{kJ}.$$

DOUBLE-CHECK

To double-check our result, let's calculate the heat removed from the water:

$$Q_{\mathrm{L}} = mL_{\mathrm{fusion}} = (0.250\,\mathrm{kg})(334\,\mathrm{kJ/kg}) = 83.5\,\mathrm{kJ}.$$

Using our result for the energy required to freeze the water, we can calculate the coefficient of performance of the refrigerator:

$$K = \frac{Q_{\mathrm{L}}}{W} = \frac{83.5\,\mathrm{kJ}}{8.41\,\mathrm{kJ}} = 9.93.$$

We can compare this result to the maximum coefficient of performance of a Carnot refrigerator:

$$K_{\mathrm{max}} = \frac{T_{\mathrm{L}}}{T_{\mathrm{H}} - T_{\mathrm{L}}} = \frac{268.15\,\mathrm{K}}{295.15\,\mathrm{K} - 268.15\,\mathrm{K}} = 9.93.$$

Thus, our result seems reasonable.

We can see from this result that a very sizable amount of work has to be input to freeze a relatively small quantity of water, even in the idealized case of a Carnot refrigerator. The work calculated here represents a lower boundary for the work that needs to be done by our real refrigerators to make ice cubes. Thus, it very important to pay attention to the efficiency of real refrigerators.

20.5 The Second Law of Thermodynamics

We saw in Section 20.1 that the First Law of Thermodynamics is satisfied whether a glass of cold water warms on standing at room temperature or becomes colder. However, the Second Law of Thermodynamics is a general principle that puts constraints on the amount and direction of thermal energy transfer between systems and on the possible efficiencies of heat engines. This principle goes beyond the energy conservation of the First Law of Thermodynamics.

Chapter 18 discussed Joule's famous experiment that demonstrated that mechanical work could be converted completely into heat, as illustrated in Figure 20.16. In contrast, experiments show that it is impossible to build a heat engine that completely converts heat into work. This concept is illustrated in Figure 20.17.

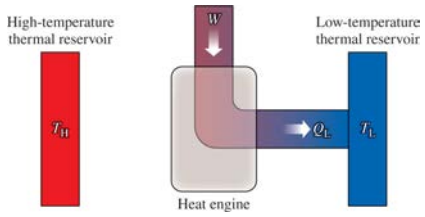

FIGURE 20.16 A heat flow diagram showing a system that converts work completely to heat.

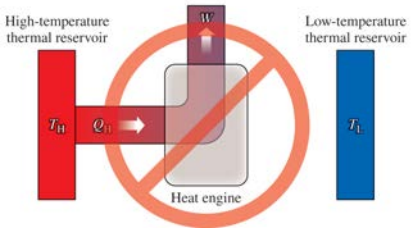

FIGURE 20.17 A heat flow diagram illustrating the impossible process of completely converting heat into useful work without rejecting heat into a low-temperature thermal reservoir.

In other words, it is not possible to construct a 100% efficient heat engine. This fact forms the basis of the **Second Law of Thermodynamics:**

> It is impossible for a system to undergo a process in which it absorbs heat from a thermal reservoir at a given temperature and converts that heat completely to mechanical work without rejecting heat to a thermal reservoir at a lower temperature.

This formulation is often called the *Kelvin-Planck statement of the Second Law of Thermodynamics*. As an example, consider a book sliding on a table. The book slides to a stop, and the mechanical energy of motion is turned into thermal energy. This thermal energy takes the form of random motion of the molecules of the book, the air, and the table. It is impossible to convert this random motion back into organized motion of the book. It is, however, possible to convert *some* of the random motion related to thermal energy back into mechanical energy. Heat engines do that kind of conversion.

If the Second Law were not true, various impossible scenarios could occur. For example, an electric power plant could operate by taking heat from the surrounding air, and an ocean liner could power itself by taking heat from the seawater. These scenarios do

not violate the First Law of Thermodynamics because energy is conserved. The fact that they cannot occur shows that the Second Law contains additional information about how nature works, beyond the principle of conservation of energy. The Second Law limits the ways in which energy can be used.

Another way to state the Second Law of Thermodynamics relates to refrigerators. We know that heat flows spontaneously from a warmer thermal reservoir to a cooler thermal reservoir. Heat never *spontaneously* flows from a cooler thermal reservoir to a warmer thermal reservoir. A refrigerator is a heat engine that moves heat from a cooler thermal reservoir to a warmer thermal reservoir; however, energy has to be supplied to the refrigerator for this transfer to take place, as shown in Figure 20.5b. The fact that it is impossible for a refrigerator to transfer thermal energy from a cooler reservoir to a warmer reservoir without using work is illustrated in Figure 20.18. This fact is the basis of another form of the Second Law of Thermodynamics:

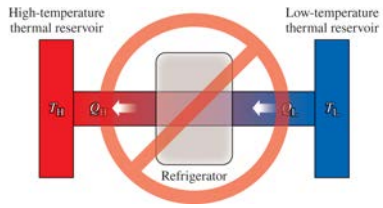

FIGURE 20.18 A heat flow diagram demonstrating the impossible process of moving heat from a low-temperature thermal reservoir to a high-temperature thermal reservoir without using any work.

It is impossible for any process to transfer thermal energy from a cooler thermal reservoir to a warmer thermal reservoir without any work having been done to accomplish the transfer.

This equivalent formulation is often called the *Clausius statement of the Second Law of Thermodynamics*.

DERIVATION 20.3 Carnot's Theorem

The following explains how to prove Carnot's Theorem, stated in Section 20.3. Suppose there are two thermal reservoirs, a heat engine working between these two reservoirs, and a Carnot engine operating in reverse as a refrigerator between the reservoirs, as shown in Figure 20.19.

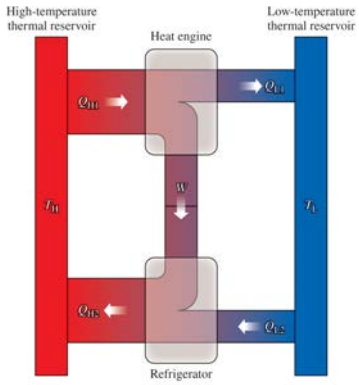

FIGURE 20.19 A heat engine between two thermal reservoirs produces work. A Carnot engine operating in reverse as a refrigerator between two thermal reservoirs is being driven by the work produced by the heat engine.

Let's assume that the Carnot refrigerator operates with the theoretical efficiency given by

$$\epsilon_2 = \frac{W}{Q_{\mathrm{H2}}}, \qquad \text{(i)}$$

where W is the work required to put heat Q_{H2} into the high-temperature reservoir. We also assume that this required work is provided by a heat engine operating between the same two reservoirs. The efficiency of the heat engine can be expressed as

$$\epsilon_1 = \frac{W}{Q_{\mathrm{H1}}}, \qquad \text{(ii)}$$

where Q_{H1} is the heat removed from the high-temperature reservoir by the heat engine. Since equations (i) and (ii) both contain the same work, *W,* we can solve each of them for the work and then set the expressions equal to each other:

$$\epsilon_1 Q_{\mathrm{H1}} = \epsilon_2 Q_{\mathrm{H2}}.$$

Thus, the ratio of the two efficiencies is

$$\frac{\epsilon_1}{\epsilon_2} = \frac{Q_{\mathrm{H2}}}{Q_{\mathrm{H1}}}.$$

If the efficiency of the heat engine is equal to the efficiency of the Carnot refrigerator $(\epsilon_1 = \epsilon_2)$, then we have $Q_{\mathrm{H1}} = Q_{\mathrm{H2}}$, which means that the heat removed from the high-temperature reservoir is equal to the heat added to the high-temperature reservoir. If the efficiency of the heat engine is higher than the efficiency of the Carnot refrigerator $(\epsilon_1 > \epsilon_2)$, then we have $Q_{\mathrm{H2}} > Q_{\mathrm{H1}}$, which means that more heat is gained than lost by the high-temperature reservoir. Applying the First Law of Thermodynamics to the overall system tells us that the heat engine working together with the Carnot refrigerator is then able to transfer thermal energy from the low-temperature reservoir to the high-temperature reservoir without any work being supplied. These two devices acting together would then violate the Clausius statement of the Second Law of

Thermodynamics. Thus, no heat engine can be more efficient than a Carnot engine.

The conversion of mechanical work to thermal energy (such as by friction) and the flow of heat from a warm thermal reservoir to a cool one are irreversible processes. The Second Law of Thermodynamics says that these processes can only be partially reversed, thereby acknowledging their inherent one-way quality.

20.6 Entropy

The Second Law of Thermodynamics as stated in Section 20.5 is somewhat different from other laws presented in previous chapters, such as Newton's laws, because it is phrased in terms of impossibilities. However, the Second Law can be stated in a more direct manner using the concept of **entropy.**

Throughout the last three chapters, we have discussed the notion of thermal equilibrium. If two objects at different temperatures are brought into thermal contact, both of their temperatures will asymptotically approach a common equilibrium temperature. What drives this system to thermal equilibrium is entropy, and the state of thermal equilibrium is the state of maximum entropy.

The direction of thermal energy transfer is not determined by energy conservation but by the change in entropy of a system. The change in entropy of a system, ΔS, during a process that takes the system from an initial state to a final state is defined as

$$\Delta S = \int_{\text{i}}^{\text{f}} \frac{dQ}{T}, \qquad \textbf{(20.12)}$$

where Q is the heat and T is the temperature in kelvins. The SI units for the change in entropy are joules per kelvin (J/K). It must be noted that equation 20.12 applies only to reversible processes; that is, the integration can only be carried out over a path representing a reversible process.

Note that entropy is defined in terms of its change from an initial to a final configuration. Entropy change is the physically meaningful quantity, not the absolute value of the entropy at any point. Another physical quantity for which only the change is important is the potential energy. The absolute value of the potential energy is always defined only relative to some arbitrary

additive constant, but the change in potential energy between initial and final states is a precisely measurable physical quantity that gives rise to force(s). In a manner similar to the way connections between forces and potential energy changes were established in Chapter 6, this section shows how to calculate entropy changes for given temperature changes and amounts of heat and work in different systems. At thermal equilibrium, the entropy has an extremum (a maximum). At mechanically stable equilibrium, the net force is zero, and therefore the potential energy has an extremum (a minimum, in this case).

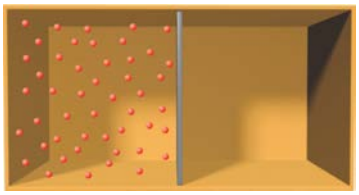
In an irreversible process in an isolated system, the entropy, *S,* of the system never decreases; it always increases or stays constant. In an isolated system, energy is always conserved, but entropy is not conserved. Thus, the change in entropy defines a direction for time; that is, time moves forward if the entropy of an isolated system is increasing.

The definition of entropy given by equation 20.12 rests on the macroscopic properties of a system, such as heat and temperature. Another definition of entropy, based on statistical descriptions of how the atoms and molecules of a system are arranged, is presented in the next section.

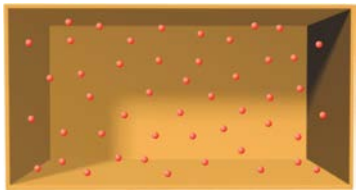
Since the integral in equation 20.12 can only be evaluated for a reversible process, how can we calculate the change in entropy for an irreversible process? The answer lies in the fact that entropy is a thermodynamic state variable, just like temperature, pressure, and volume. This means that we can calculate the entropy difference between a known initial state and a known final state even for an irreversible process if there is a reversible process (for which the integral in equation 20.12 can be evaluated!) that takes the system from the same initial to the same final state. Perhaps this is the subtlest point about thermodynamics conveyed in this entire chapter.

In order to illustrate this general method of computing the change in entropy for an irreversible process, let’s return to a situation described in Chapter 18, the free expansion of a gas.

Figure 20.20a shows a gas confined to the left half of a box. In Figure 20.20b, the barrier between the two halves has been removed, and the gas has expanded to fill the entire volume of the box. Clearly, once the gas has expanded to fill the entire volume of the box, the system will never spontaneously return to the state where all the gas molecules are located in the left half of the box. The state variables of the system before the barrier is removed are the initial temperature, T_i, the initial volume, V_i, and the initial entropy, S_i. After the barrier has been removed and the gas is again in equilibrium, the state of the system can be described in terms of the final temperature, T_f, the final volume, V_f, and the final entropy, S_f.



(a)



(b)

FIGURE 20.20 (a) A gas confined to half the volume of a box. (b) The barrier separating the two halves is removed, and the gas expands to fill the entire volume.

We cannot calculate the change in entropy of this system using equation 20.12 because the gas is not in equilibrium during the expansion phase. However, the change in the properties of the

system depends only on the initial and final states, not on how the system got from one to the other. Therefore, we can choose a process that the system could have undergone for which we can evaluate the integral in equation 20.12.

In the free expansion of an ideal gas, the temperature remains constant; thus, it seems reasonable to use the isothermal expansion of an ideal gas. We can then evaluate the integral in equation 20.12 to calculate the change in entropy of the system undergoing an isothermal process:

$$\Delta S = \int_{\mathrm{i}}^{\mathrm{f}} \frac{dQ}{T} = \frac{1}{T} \int_{\mathrm{i}}^{\mathrm{f}} dQ = \frac{Q}{T}. \qquad \textbf{(20.13)}$$

(We can move the factor $1/T$ outside the integral, because we are dealing with an isothermal process, for which the temperature is constant by definition.) As we saw in Chapter 19, the work done by an ideal gas in expanding from V_{i} to V_{f} at a constant temperature T is given by

$$W = nRT \ln\left(\frac{V_{\mathrm{f}}}{V_{\mathrm{i}}}\right).$$

For an isothermal process, the internal energy of the gas does not change; so $\Delta E_{\mathrm{int}} = 0$. Thus, as shown in Chapter 18, we can use the First Law of Thermodynamics to write

$$\Delta E_{\mathrm{int}} = W - Q = 0.$$

Consequently, for the isothermal process, the heat added to the system is

$$Q = W = nRT \ln\left(\frac{V_{\mathrm{f}}}{V_{\mathrm{i}}}\right).$$

The resulting entropy change for the isothermal process is then

$$\Delta S = \frac{Q}{T} = \frac{nRT \ln\left(\frac{V_\mathrm{f}}{V_\mathrm{i}}\right)}{T} = nR \ln\left(\frac{V_\mathrm{f}}{V_\mathrm{i}}\right). \quad \textbf{(20.14)}$$

The entropy change for the irreversible free expansion of a gas must be equal to the entropy change for the isothermal process because both processes have the same initial and final states and thus must have the same change in entropy.

For the irreversible free expansion of a gas, $V_\mathrm{f} > V_\mathrm{i}$, and so ln $(V_\mathrm{f}/V_\mathrm{i}) > 0$. Thus, $\Delta S > 0$ because n and R are positive numbers. In fact, the change in entropy of any irreversible process is always positive.

Therefore, the Second Law of Thermodynamics can be stated in a third way.

The entropy of an isolated system can never decrease.

EXAMPLE 20.5 Entropy Change for the Freezing of Water

Suppose we have 1.50 kg of water at a temperature of 0 °C. We put the water in a freezer, and enough heat is removed from the water to freeze it completely to ice at a temperature of 0 °C.

PROBLEM

How much does the entropy of the water-ice system change during the freezing process?

SOLUTION

The melting of ice is an isothermal process, so we can use equation 20.13 for the change in entropy:

$$\Delta S = \frac{Q}{T},$$

where Q is the heat that must be removed to change the water to ice at $T = 273.15$ K, the freezing point of water. The heat that must be removed to freeze the water is determined by the latent heat of fusion of water (ice), defined in Chapter 18. The heat that must be removed is

$$Q = mL_{\text{fusion}} = (1.50 \text{ kg})(334 \text{ kJ/kg}) = 501 \text{ kJ}.$$

Thus, the change in entropy of the water-ice system is

$$\Delta S = \frac{-501 \text{ kJ}}{273.15 \text{ K}} = -1830 \text{ J/K}.$$

Note that the entropy of the water-ice system of Example 20.5 decreased. How can the entropy of this system decrease? The Second Law of Thermodynamics states that the entropy of an isolated system can never decrease. However, the water-ice system is not an isolated system. The freezer used energy to remove heat

from the water to freeze it and exhausted the heat into the local environment. Thus, the entropy of that environment increased more than the entropy of the water-ice system decreased. This is a very important distinction.

A similar analysis can be applied to the origins of complex life forms, which have much lower entropy than their surroundings. The development of life forms with low entropy is accompanied by an increase in the overall entropy of the Earth. In order for a living subsystem of Earth to reduce its own entropy at the expense of its environment, it needs a source of energy. This source of energy can be chemical bonds or other types of potential energy, which in the end arises from the energy provided to Earth by solar radiation.

Evolution toward more and more complex life forms is not in contradiction with the Second Law of Thermodynamics, because the evolving life forms do not form an isolated system. A contradiction between biological evolution and the Second Law of Thermodynamics is sometimes falsely claimed by opponents of evolution in the evolution/creationism debate. From a thermodynamics standpoint, this argument has to be rejected unequivocally.

EXAMPLE 20.6 Entropy Change for the Warming of Water

Suppose we start with 2.00 kg of water at a temperature of 20.0 °C and warm the water until it reaches a temperature of 80.0 °C.

PROBLEM

What is the change in entropy of the water?

SOLUTION

We start with equation 20.12, relating the change in entropy to the integration of the differential flow of heat, dQ, with respect to temperature:

$$\Delta S = \int_{\text{i}}^{\text{f}} \frac{dQ}{T}. \qquad \text{(i)}$$

The heat, Q, required to raise the temperature of a mass, m, of water is given by

$$Q = cm\Delta T, \qquad \text{(ii)}$$

where $c = 4.19\ \text{kJ}/(\text{kg K})$ is the specific heat of water. We can rewrite equation (ii) in terms of the differential change in heat, dQ, and the differential change in temperature, dT:

$$dQ = cm\ dT.$$

Then we can rewrite equation (i) as

$$\Delta S = \int_{\mathrm{i}}^{\mathrm{f}} \frac{dQ}{T} = \int_{T_\mathrm{i}}^{T_\mathrm{f}} \frac{cm\,dT}{T} = cm \int_{T_1}^{T_\mathrm{f}} \frac{dT}{T} = cm \ln \frac{T_\mathrm{f}}{T_\mathrm{i}}.$$

With $T_\mathrm{i} = 293.15\ \mathrm{K}$ and $T_\mathrm{f} = 353.15\ \mathrm{K}$, the change in entropy is

$$\Delta S = [4.19\ \mathrm{kJ/(kg\ K)}](2.00\ \mathrm{kg}) \ln \frac{353.15\ \mathrm{K}}{293.15\ \mathrm{K}} = 1.56 \cdot 10$$

There is another important point regarding the macroscopic definition of entropy and the calculation of entropy with the aid of equation 20.12: The Second Law of Thermodynamics also implies that for all cyclical processes (such as the Carnot, Otto, and Diesel cycles)—that is, all processes for which the initial state is the same as the final state—the total entropy change over the entire cycle has to be greater than or equal to zero: $\Delta S \geq 0$. The entropy change is equal to zero for reversible processes, and greater than zero for irreversible ones. Note that the cyclic processes we have discussed here are all idealized reversible ones, but real processes are never quite completely reversible.

20.7 Microscopic Interpretation of Entropy

In Chapter 19, we saw that the internal energy of an ideal gas could be calculated by summing up the energies of the constituent particles of the gas. We can also determine the entropy of an ideal gas by studying the constituent particles. It turns out that this microscopic definition of entropy agrees with the macroscopic definition.

The ideas of order and disorder are intuitive. For example, a coffee cup is an ordered system. Smashing the cup by dropping it on the floor creates a system that is less ordered, or more disordered, than the original system. The disorder of a system can be described quantitatively using the concept of **microscopic states.** Another term for a microscopic state is a *degree of freedom*.

Suppose we toss n coins in the air, and half of them land heads up and half of them land tails up. The statement "half the coins are heads and half the coins are tails" is a description of the *macroscopic* state of the system of n coins. Each coin can have one of two *microscopic* states: heads or tails. Stating that half the coins are heads and half the coins are tails does not specify anything about the microscopic state of each coin, because there are many different possible ways to arrange the microscopic states of the coins without changing the macroscopic state. However, if all the coins are heads or all the coins are tails, the microscopic state of each coin is known. The macroscopic state consisting of half heads and half tails is a *disordered* system because very little is known about the microscopic state of each coin. The macroscopic state with all heads or the macroscopic state with all tails is an *ordered* system because the microscopic state of each coin is known.

To quantify this concept, imagine tossing four coins in the air. There is only one way to get four heads with such a toss, four ways to get three heads and one tail, six ways to get two heads and two tails, four ways to get one head and three tails, and only one way to get four tails. Thus, there are five possible macroscopic states and sixteen possible microscopic states (see Figure 20.21, where heads are represented as red circles, and tails as blue circles).

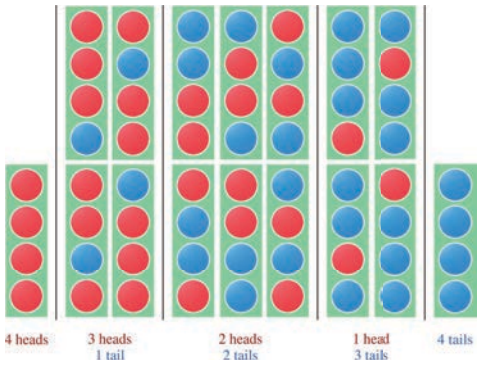


FIGURE 20.21 The sixteen possible microscopic states for four tossed coins, leading to five possible macroscopic states.

Now suppose we toss fifty coins in the air instead of four coins. There are $2^{50} = 1.13 \cdot 10^{15}$ possible microstates of this system of fifty tossed coins. The most probable macroscopic state consists of half heads and half tails. There are $1.26 \cdot 10^{14}$ possible microstates with half heads and half tails. The probability that half the coins will be heads and half will be tails is 11.2%, while the probability of having all fifty coins land heads up is 1 in $1.13 \cdot 10^{15}$.

Let's apply these concepts to a real system of gas molecules: a mole of gas, or Avogadro's number of molecules, at pressure p, volume V, and temperature T. These three quantities describe the macroscopic state of the gas. The microscopic description of the system needs to specify the momentum and position of each molecule of the gas. Each molecule has three components of its momentum and three components of its position. Thus, at any given time, the gas can be in an extremely large number of microscopic states, depending on the positions and velocities of each of its $6.02 \cdot 10^{23}$ molecules. If the gas undergoes free

expansion, the number of possible microscopic states increases and the system becomes more disordered. Because the entropy of a gas undergoing free expansion increases, the increase in disorder is related to the increase of entropy. This idea can be generalized as follows:

> The most probable macroscopic state of a system is the state with the largest number of microscopic states, which is also the macroscopic state with the greatest disorder.

Let w be the number of possible microscopic states for a given macroscopic state. It can be shown that the entropy of the macroscopic state is given by

$$S = k_{\mathrm{B}} \ln w, \qquad \textbf{(20.15)}$$

where k_{B} is the Boltzmann constant. This equation was first written down by the Austrian physicist Ludwig Boltzmann and is his most significant accomplishment (it is chiseled into his tombstone). You can see from equation 20.15 that increasing the number of possible microscopic states increases the entropy.

The important aspect of a thermodynamic process is not the absolute entropy, but the change in entropy between an initial state and a final state. Taking equation 20.15 as the definition of entropy, the smallest number of microstates is one and the smallest entropy that can exist is then zero. According to this definition, entropy can never be negative. In practice, determining the number of possible microscopic states is difficult except for special systems. However, the change in the number of possible microscopic states can often be determined, thus allowing the change in entropy of the system to be found.

Consider a system that initially has w_{i} microstates and then undergoes a thermodynamic process to a macroscopic state with w_{f} microstates. The change in entropy is

$$\Delta S = S_{\mathrm{f}} - S_{\mathrm{i}} = k_{\mathrm{B}} \ln w_{\mathrm{f}} - k_{\mathrm{B}} \ln w_{\mathrm{i}} = k_{\mathrm{B}} \ln \frac{w_{\mathrm{f}}}{w_{\mathrm{i}}} \cdot \textbf{(20.16)}$$

Thus, the change in entropy between two macroscopic states depends on the ratio of the number of possible microstates.

The definition of the entropy of a system in terms of the number of possible microstates leads to further insight into the Second Law of Thermodynamics, which states that the entropy of an isolated system can never decrease. This statement of the Second Law, combined with equation 20.15, means that *an isolated system can never undergo a thermodynamic process that lowers the number of possible microstates.* For example, if the process depicted in Figure 20.20 were to occur in reverse—that is, the gas underwent free contraction into a volume half its original size—the number of possible microstates for each molecule would decrease by a factor of 2. The probability of finding one gas molecule in half of the original volume then is $\frac{1}{2}$, and the probability of finding all the gas molecules in half of the original volume is $\left(\frac{1}{2}\right)^N$, where N is the number of molecules. If there are 100 gas molecules in the system, then the probability that all 100 molecules end up in half the original volume is $7.9 \cdot 10^{-31}$. We would have to check the system approximately $1/\left(7.9 \cdot 10^{-31}\right) \approx 10^{30}$ times to find the molecules in half the volume just once. Checking once per second, this would take about 10^{13} billion years, whereas the age of the universe is only 13.7 billion years. If the system contains Avogadro's number of gas molecules, then the probability that the molecules will all be in half of the volume is even smaller. Thus, although the probability that this process will happen is not zero, it is so small that we can treat it as zero. We can thus conclude that the Second Law of Thermodynamics, even if expressed in terms of probabilities, is never violated in any practical situation.

EXAMPLE 20.7 Entropy Increase during Free Expansion of a Gas

Let's consider the free expansion of a gas like that shown in Figure 20.20. Initially 0.500 mole of nitrogen gas is confined to a volume of $0.500\ \mathrm{m}^3$. When the barrier is removed, the gas expands to fill the new volume of $1.00\ \mathrm{m}^3$.

PROBLEM

What is the change in entropy of the gas?

SOLUTION

We can use equation 20.14 to calculate the change in entropy of the system, assuming we can treat the system as an isothermal expansion of an ideal gas:

$$\begin{aligned}\Delta S &= nR \ln\left(\frac{V_\mathrm{f}}{V_\mathrm{i}}\right) = nR \ln\left(\frac{1.00\ \mathrm{m}^3}{0.500\ \mathrm{m}^3}\right) = nR \ln 2 \\ &= (0.500\ \mathrm{mole})\,[8.31\mathrm{J}/(\mathrm{mol\ K})](\ln 2) \\ &= 2.88\ \mathrm{J/K}.\end{aligned}$$

Another approach is to examine the number of microstates of the system before and after the expansion to calculate the change in entropy. In this system, the number of gas molecules is

$$N = nN_\mathrm{A},$$

where N_A is Avogadro's number. Before the expansion, there were w_i microstates for the gas molecules in the left half of the container. After the expansion, any of the molecules could be in the left half or the right half of the container. Therefore, the number of microstates after the expansion is

$$w_f = 2^N w_i.$$

Using equation 20.16 and remembering that $nR = Nk_B$, we can express the change in entropy of the system as

$$\Delta S = k_B \ln \frac{w_f}{w_i} = k_B \ln \frac{2^N w_i}{w_i} = Nk_B \ln 2 = nR \ln 2.$$

Thus, we get the same result for the change in entropy of a freely expanding gas by looking at the microscopic properties of the system as by using the macroscopic properties of the system in equation (i).

Concept Check 20.6

All reversible thermodynamic processes *always* proceed at

a) constant pressure.

b) constant temperature.

c) constant entropy.

d) constant volume.

e) none of the above.

Entropy Death

The universe is the ultimate isolated system. The vast majority of thermodynamic processes in the universe are irreversible, and thus the entropy of the universe as a whole is continuously increasing and asymptotically approaching its maximum. Thus, if the universe exists long enough, all energy will be evenly distributed throughout its volume. In addition, if the universe keeps expanding forever, then gravity—the only long-range force of importance—will not be able to pull objects together any more. This latter condition is the main difference from the early universe in the first moments after the Big Bang, when matter and energy were also distributed very evenly, as revealed by the analysis of the cosmic microwave background radiation (touched on in Chapter 17 and to be discussed in more depth in Chapter 39). But in the early universe, gravity was very strong, as a result of the concentration of matter in a very small space, and was able to develop minute fluctuations and contract matter into stars and galaxies. Thus, even though matter and energy were evenly distributed in the very early universe, the entropy was not near its maximum, and the entire universe was very far from thermal equilibrium.

In the long-term future of the universe, all stars, which currently represent sources of energy for other objects such as our planet, will eventually be extinct. Then, life will become impossible, because life needs an energy source to be able to lower entropy locally. As the universe asymptotically approaches its state of maximum entropy, every subsystem of the universe will reach thermodynamic equilibrium.

Sometimes this long-term fate of the universe is referred to as *heat death*. However, the temperature of the universe at that time will not be high, as this name may suggest, but very close to absolute zero and very nearly the same everywhere.

This is not something we have to worry about soon, because some estimates place the entropy death of the universe at about 10^{100} years into the future (with an uncertainty of many orders of magnitude). Obviously, the long-term future of the universe is very interesting and is currently an area of intense research. New discoveries about dark matter and dark energy may change our

picture of the long-term future of the universe. But as it stands now, the universe will not go out with a bang, but with a whimper.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- In a *reversible* process, a system is always close to being in thermodynamic equilibrium. Making a small change in the state of the system can reverse any change in the thermodynamic variables of the system.
- An *irreversible* process involves heat flow with a finite temperature difference, free expansion of a gas, or conversion of mechanical work to thermal energy.
- A heat engine is a device that turns thermal energy into useful work.
- The efficiency, ϵ, of a heat engine is defined as $\epsilon = W/Q_{\mathrm{H}}$, where W is the useful work extracted from the engine and Q_{H} is the energy provided to the engine in the form of heat.
- A refrigerator is a heat engine operating in reverse.
- The coefficient of performance, K, of a refrigerator is defined as $K = Q_{\mathrm{L}}/W$, where Q_{L} is the heat extracted from the cooler thermal reservoir and W is the work required to extract that heat.
- An ideal heat engine is one in which all the processes involved are reversible.
- A Carnot engine uses the Carnot cycle, an ideal thermodynamic process consisting of two isothermal processes and two adiabatic processes. The Carnot engine is the most efficient engine that can operate between two thermal reservoirs.
- The efficiency of a Carnot engine is given by $\epsilon = (T_{\mathrm{H}} - T_{\mathrm{L}})/T_{\mathrm{H}}$, where T_{H} is the temperature of the warmer thermal reservoir and T_{L} is the temperature of the cooler thermal reservoir.
- The coefficient of performance of a Carnot refrigerator is $K_{\max} = T_{\mathrm{L}}/(T_{\mathrm{H}} - T_{\mathrm{L}})$, where T_{H} is the temperature of

the warmer thermal reservoir and T_{L} is the temperature of the cooler thermal reservoir.

- The Otto cycle describes the operation of internal combustion engines. It consists of two adiabatic processes and two constant-volume processes. The efficiency of an engine using the Otto cycle is given by $\epsilon = 1 - r^{1-\gamma}$, where $r = V_1/V_2$ is the compression ratio and $\gamma = C_p/C_V$.

- The Second Law of Thermodynamics can be stated as follows: It is impossible for a system to undergo a process in which it absorbs heat from a thermal reservoir at a given temperature and converts that heat completely to mechanical work without rejecting heat to a thermal reservoir at a lower temperature.
- The Second Law of Thermodynamics can also be stated as follows: It is impossible for any process to transfer thermal energy from a cooler thermal reservoir to a warmer thermal reservoir without any work having been done to accomplish the transfer.
- For reversible processes, the change in entropy of a system is defined as $\Delta S = \int_{\mathrm{i}}^{\mathrm{f}} \frac{dQ}{T}$, where dQ is the differential heat added to the system, T is the temperature, and the integration is carried out from an initial thermodynamic state to a final thermodynamic state.
- A third way to state the Second Law of Thermodynamics is as follows: The entropy of an isolated system can never decrease.
- The entropy of a macroscopic system can be defined in terms of the number of possible microscopic states, w, of the system: $S = k_{\mathrm{B}} \ln w$, where k_{B} is the Boltzmann constant.

ANSWERS TO SELF-TEST OPPORTUNITIES

20.1 The efficiency is given by

$$\epsilon = 1 - \frac{T_{\mathrm{L}}}{T_{\mathrm{H}}} = 1 - \frac{325\ \mathrm{K}}{500\ \mathrm{K}} = 0.35\ (\text{or } 35\%).$$

20.2 The ratio of the two efficiencies is

$$\frac{\epsilon_{15}}{\epsilon_{10}} = \frac{1 - 15^{-0.4}}{1 - 4^{-0.4}} = \frac{66.1\%}{42.6\%} = 1.55, \text{which is a } 55\% \text{ improv}$$

PROBLEM-SOLVING GUIDELINES

1. With problems in thermodynamics, you need to pay close attention to the signs of work (W) and heat (Q). Work done by a system is positive, and work done on a system is negative; heat that is transferred to a system is positive, and heat that is emitted by a system is negative.

2. Some problems involving heat engines deal with power and rate of thermal energy transfer. Power is work per unit time ($P = W/t$) and rate of thermal energy transfer is heat per unit time (Q/t). You can treat these quantities much like work and heat, but remember that they include a time dimension.

3. Entropy may seem a bit like energy, but these are very different concepts. The First Law of Thermodynamics is a conservation law—energy is conserved. The Second Law of Thermodynamics is not a conservation law—entropy is not conserved; it always either stays the same or increases and never decreases in an isolated system. You may need to identify initial and final states to calculate an entropy change, but remember that entropy can change.

4. Remember that the entropy of an isolated system always stays the same or increases (never decreases), but be sure a problem situation is really about an isolated system. Entropy of a system that is not isolated can decrease if offset by a larger entropy increase of the surroundings; don't assume that all entropy changes must be positive.

5. Do not apply the formula $\Delta S = \int_{\text{i}}^{\text{f}} \frac{dQ}{T}$ for entropy change without being sure you are dealing with a reversible process. If you need to calculate entropy change for an irreversible process, you first need to find an equivalent reversible process that connects the same initial and final states.

6. For problems involving heat engines, it is almost always useful to sketch a flow diagram showing the heat and the work, like the sketches in all the solved problems in this chapter.

MULTIPLE-CHOICE QUESTIONS

20.1 Which of the following processes always results in an increase in the energy of a system?

a) The system loses heat and does work on the surroundings.

b) The system gains heat and does work on the surroundings.

c) The system loses heat and has work done on it by the surroundings.

d) The system gains heat and has work done on it by the surroundings.

e) None of the above will increase the system's energy.

20.2 What is the magnitude of the change in entropy when 6.00 g of steam at 100 ˚C is condensed to water at 100 ˚C?

a) 46.6 J/K

b) 52.4 J/K

c) 36.3 J/K

d) 34.2 J/K

20.3 The change in entropy of a system can be calculated because

a) it depends only on the initial and final states.

b) any process is reversible.

c) entropy always increases.

d) None of the above applies.

20.4 An ideal gas undergoes an isothermal expansion. What will happen to its entropy?

a) It will increase.

b) It will decrease.

c) It's impossible to determine.

d) It will remain unchanged.

20.5 Which of the following processes (all constant-temperature expansions) produces the most work?

a) An ideal gas consisting of 1 mole of argon at 20 °C expands from 1 L to 2 L.

b) An ideal gas consisting of 1 mole of argon at 20 °C expands from 2 L to 4 L.

c) An ideal gas consisting of 2 moles of argon at 10 °C expands from 2 L to 4 L.

d) An ideal gas consisting of 1 mole of argon at 40 °C expands from 1 L to 2 L.

e) An ideal gas consisting of 1 mole of argon at 40 °C expands from 2 L to 4 L.

20.6 A heat engine operates with an efficiency of 0.5. What can the temperatures of the high-temperature and low-temperature reservoirs be?

a) $T_{\mathrm{H}} = 600\ \mathrm{K}$ and $T_{\mathrm{L}} = 100\ \mathrm{K}$

b) $T_{\mathrm{H}} = 600\ \mathrm{K}$ and $T_{\mathrm{L}} = 200\ \mathrm{K}$

c) $T_{\mathrm{H}} = 500\ \mathrm{K}$ and $T_{\mathrm{L}} = 200\ \mathrm{K}$

d) $T_{\mathrm{H}} = 500\ \mathrm{K}$ and $T_{\mathrm{L}} = 300\ \mathrm{K}$

e) $T_{\mathrm{H}} = 600\ \mathrm{K}$ and $T_{\mathrm{L}} = 300\ \mathrm{K}$

20.7 The number of macrostates that can result from rolling a set of N six-sided dice is the number of different totals that can be obtained by adding the pips on the N faces that end up on top. The number of macrostates is

a) 6^N.

b) $6N$.

c) $6N - 1$.

d) $5N + 1$.

20.8 What capacity must a heat pump with a coefficient of performance of 3 have to heat a home that loses thermal energy at

a rate of 12 kW on the coldest day of the year?

a) 3 kW

b) 4 kW

c) 10 kW

d) 30 kW

e) 40 kW

20.9 Which of the following statements about the Carnot cycle is (are) incorrect?

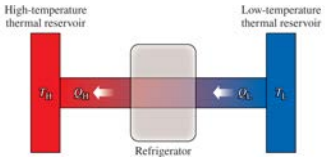
a) The maximum efficiency of a Carnot engine is 100% since the Carnot cycle is an ideal process.

b) The Carnot cycle consists of two isothermal processes and two adiabatic processes.

c) The Carnot cycle consists of two isothermal processes and two isentropic processes (constant entropy).

d) The efficiency of the Carnot cycle depends solely on the temperatures of the two thermal reservoirs.

20.10 Can a heat engine like the one shown in the figure operate?



a) yes

b) no

c) need to know the specific cycle used by the engine to answer

d) yes, but only with a monatomic gas

e) yes, but only with a diatomic gas

20.11 An ideal heat engine is one that

a) uses only reversible processes.

b) uses only irreversible processes.

c) has an efficiency of 100%.

d) has an efficiency of 50%.

e) does no work.

20.12 When a coin is tossed, it can land heads up or tails up. You toss a coin 10 times, and it comes up heads every time. What is the probability that the coin will come up heads on the 11th toss?

a) 10%

b) 20%

c) 50%

d) 90%

e) 100%

20.13 In your rectangular living room, two robot vacuum cleaners move around randomly, cleaning the floor. What is the probability that both robot vacuum cleaners are in one half of the room at the same time?

a) 10%

b) 25%

c) 50%

d) 75%

e) 90%

20.14 A refrigerator operates by

a) doing work to move heat from a low-temperature thermal reservoir to a high-temperature thermal reservoir.

b) doing work to move heat from a high-temperature thermal reservoir to a low-temperature thermal reservoir.

c) using thermal energy to produce useful work.

d) moving heat from a low-temperature thermal reservoir to a high-temperature thermal reservoir without doing work.

e) moving heat from a high-temperature thermal reservoir to a low-temperature thermal reservoir without doing work.

CONCEPTUAL QUESTIONS

20.15 One of your friends begins to talk about how unfortunate the Second Law of Thermodynamics is, how sad it is that entropy must always increase, leading to the irreversible degradation of useful energy into heat and the decay of all things. Is there any counterargument you could give that would suggest that the Second Law is in fact a blessing?

20.16 While looking at a very small system, a scientist observes that the entropy of the system spontaneously decreases. If true, is this a Nobel-winning discovery or is it not that significant?

20.17 Why might a heat pump have an advantage over a space heater that converts electrical energy directly into thermal energy?

20.18 Imagine dividing a box into two equal parts, part A on the left and part B on the right. Four identical gas atoms, numbered 1 through 4, are placed in the box. What are most probable and second most probable distributions (for example, 3 atoms in A, 1 atom in B) of gas atoms in the box? Calculate the entropy, S, for these two distributions. Note that the configuration with 3 atoms in A and 1 atom in B and that with 1 atom in A and three atoms in B count as different configurations.

20.19 A key feature of thermodynamics is the fact that the internal energy, E_{int}, of a system and its entropy, S, are *state variables;* that is, they depend only on the thermodynamic state of the system and not on the processes by which it reached that state (unlike, for example, the heat content, Q). This means that the differentials $dE_{\text{int}} = Tds - pdV$ and $dS = T^{-1}dE_{\text{int}} + pT^{-1}dV$, where T is temperature (in kelvins), p is pressure, and V is volume, are exact differentials as defined in calculus. What relationships follow from this fact?

20.20 Other state variables useful for characterizing different classes of processes can be defined from E_{int}, S, p, and V. These

include the enthalpy, $H \equiv E_{\text{int}} + pV$, the Helmholtz free energy, $A \equiv E_{\text{int}} - TS$, and the Gibbs free energy, $G \equiv E_{\text{int}} + pV - TS$.

a) Write the differential equations for *dH, dA,* and *dG*. Use the First Law to simplify.

b) All of these are also exact differentials. What relationships follow from this fact?

20.21 Prove that Boltzmann's microscopic definition of entropy, $S = k_{\text{B}} \ln w$, implies that entropy is an *additive* variable: Given two systems, A and B, in specified thermodynamic states, with entropies S_{A} and S_{B}, respectively, show that the corresponding entropy of the combined system is $S_{\text{A}} + S_{\text{B}}$.

20.22 Explain how it is possible for a heat pump like that in Example 20.2 to operate with a power of only 6.28 kW and heat a house that is losing thermal energy at a rate of 21.98 kW.

20.23 The temperature at the cloud tops of Saturn is approximately 150. K. The atmosphere of Saturn produces tremendous winds; wind speeds of 600. km/h have been inferred from spacecraft measurements. Can the wind chill factor on Saturn produce a temperature at (or below) absolute zero? How, or why not?

20.24 Is it a violation of the Second Law of Thermodynamics to capture all the exhaust heat from a steam engine and funnel it back into the system to do work? Why or why not?

20.25 You are given a beaker of water. What can you do to increase its entropy? What can you do to decrease its entropy?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 20.2

20.26 With each cycle, a 2500.-W engine extracts 2100. J from a thermal reservoir at 90.0 $^\circ$C and expels 1500. J into a thermal reservoir at 20.0 $^\circ$C. What is the work done for each cycle? What is the engine's efficiency? How much time does each cycle take?

•**20.27** A refrigerator with a coefficient of performance of 3.80 is used to cool 2.00 L of mineral water from room temperature (25.0 $^\circ$C) to 4.00 $^\circ$C. If the refrigerator uses 480. W, how long will it take the water to reach 4.00 $^\circ$C? Recall that the heat capacity of water is 4.19 kJ/(kg K) and the density of water is 1.00 g/cm^3. Assume that all other contents of the refrigerator are already at 4.00 $^\circ$C.

•**20.28** The burning of fuel transfers $4.00 \cdot 10^5$ W of power into the engine of a 2000.-kg vehicle. If the engine's efficiency is 25.0%, determine the maximum speed the vehicle can achieve 5.00 s after starting from rest.

•**20.29** A heat engine consists of a heat source that causes a monatomic gas to expand, pushing against a piston, thereby doing work. The gas begins at a pressure of 300. kPa, a volume of 150. cm^3, and room temperature, 20.0 $^\circ$C. On reaching a volume of 450. cm^3, the piston is locked in place, and the heat source is removed. At this point, the gas cools back to room temperature. Finally, the piston is unlocked and used to isothermally compress the gas back to its initial state.

a) Sketch the cycle on a *pV*-diagram.

b) Determine the work done on the gas and the heat flow out of the gas in each part of the cycle.

c) Using the results of part (b), determine the efficiency of the engine.

•**20.30** A heat engine cycle often used in refrigeration, is the *Brayton cycle,* which involves an adiabatic compression, followed by an isobaric expansion, an adiabatic expansion, and finally an isobaric compression. The system begins at temperature T_1 and transitions to temperatures T_2, T_3, and T_4 after respective parts of the cycle.

a) Sketch this cycle on a pV-diagram.

b) Show that the efficiency of the overall cycle is given by $\epsilon = 1 - (T_4 - T_1)/(T_3 - T_2)$.

•20.31 Suppose a Brayton engine (see Problem 20.30) is run as a refrigerator. In this case, the cycle begins at temperature T_1, and the gas is isobarically expanded until it reaches temperature T_4. Then the gas is adiabatically compressed, until its temperature is T_3. It is then isobarically compressed, and the temperature changes to T_2. Finally, it is adiabatically expanded until it returns to temperature T_1.

a) Sketch this cycle on a pV-diagram.

b) Show that the coefficient of performance of the engine is given by $K = (T_4 - T_1)/(T_3 - T_2 - T_4 + T_1)$.

Section 20.3

20.32 It is desired to build a heat pump that has an output temperature of 23.0 °C. Calculate the maximum coefficient of performance for the pump when the input source is (a) outdoor air on a cold winter day at −10.0 °C and (b) groundwater at 9.00 °C.

20.33 Consider a Carnot engine that works between thermal reservoirs with temperatures of 1000.0 K and 300.0 K. The average power of the engine is 1.00 kJ per cycle.

a) What is the efficiency of this engine?

b) How much energy is extracted from the warmer reservoir per cycle?

c) How much energy is delivered to the cooler reservoir?

20.34 A Carnot refrigerator is operating between thermal reservoirs with temperatures of 27.0 °C and 0.00 °C.

a) How much work will need to be input to extract 10.0 J of heat from the colder reservoir?

b) How much work will be needed if the colder reservoir is at –20.0 °C?

20.35 It has been suggested that the vast amount of thermal energy in the oceans could be put to use. The process would rely on the temperature difference between the top layer of the ocean and the bottom; the temperature of the water at the bottom is fairly constant, but the water temperature at the surface changes depending on the time of day, the season, and the weather. Suppose the temperature of the water at the top is 10.0 °C and the temperature of the water at the bottom is 4.00 °C. What is the maximum efficiency with which thermal energy could be extracted from the ocean under these conditions?

•**20.36** A Carnot engine takes an amount of heat $Q_{\mathrm{H}} = 100.$ J from a high-temperature reservoir at temperature $T_{\mathrm{H}} = 1000.\,^{\circ}\mathrm{C}$, and exhausts the remaining heat into a low-temperature reservoir at $T_{\mathrm{L}} = 10.0\ ^{\circ}\mathrm{C}$. Find the amount of work that is obtained from this process.

•**20.37** A Carnot engine operates between a warmer reservoir at a temperature T_1 and a cooler reservoir at a temperature T_2. It is found that increasing the temperature of the warmer reservoir by a factor of 2 while keeping the same temperature for the cooler reservoir increases the efficiency of the Carnot engine by a factor of 2 as well. Find the efficiency of the engine and the ratio of the temperatures of the two reservoirs in their original form.

•**20.38** A certain refrigerator is rated as being 32.0% as efficient as a Carnot refrigerator. To remove 100. J of heat from the interior at 0.00 $^\circ$C and eject it to the outside at 22.0 $^\circ$C, how much work must the refrigerator motor do?

Section 20.4

20.39 A refrigerator has a coefficient of performance of 5.00. If the refrigerator absorbs 40.0 cal of heat from the low-temperature reservoir in each cycle, what is the amount of heat expelled into the high-temperature reservoir?

20.40 A heat pump has a coefficient of performance of 5.00. If the heat pump absorbs 40.0 cal of heat from the cold outdoors in each cycle, what is the amount of heat expelled to the warm indoors?

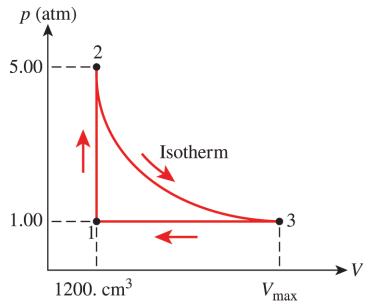
20.41 An Otto engine has a maximum efficiency of 20.0%; find the compression ratio. Assume that the gas is diatomic.

•**20.42** An outboard motor for a boat is cooled by lake water at 15.0 °C and has a compression ratio of 10.0. Assume that the air is a diatomic gas.

a) Calculate the efficiency of the engine's Otto cycle.

b) Using your answer to part (a) and the fact that the efficiency of the Carnot cycle is greater than that of the Otto cycle, estimate the maximum temperature of the engine.

•**20.43** A heat engine uses 100. mg of helium gas and follows the cycle shown in the figure.



a) Determine the pressure, volume, and temperature of the gas at points 1, 2, and 3.

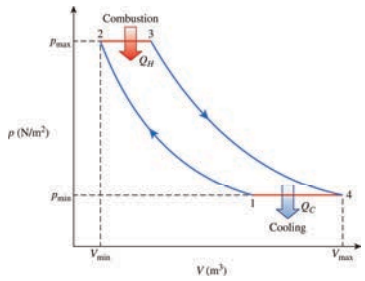
b) Determine the engine's efficiency.

c) What would be the maximum efficiency of the engine for it to be able to operate between the maximum and minimum temperatures?

•• **20.44** Gas turbine engines like those of jet aircraft operate on a thermodynamic cycle known as the *Brayton cycle*. The basic Brayton cycle, as shown in the figure, consists of two adiabatic processes—the compression and the expansion of gas through the turbine—and two isobaric processes. Heat is transferred to the gas during combustion in a constant-pressure process (path from point 2 to point 3) and removed from the gas in a heat exchanger during a constant-pressure process (path from point 4 to point 1). The key parameter for this cycle is the pressure ratio, defined as $r_p = p_{\max}/p_{\min} \equiv p_2/p_1$, and this is the only parameter needed to calculate the efficiency of a Brayton engine.

a) Determine an expression for the efficiency.

b) Calculate the efficiency of a Brayton engine that uses a diatomic gas and has a pressure ratio of 10.0.



Sections 20.6 and 20.7

20.45 One end of a metal rod is in contact with a thermal reservoir at 700. K, and the other end is in contact with a thermal reservoir at 100. K. The rod and reservoirs make up an isolated system. If 8500. J are conducted from one end of the rod to the other uniformly (no change in temperature along the rod) what is the change in entropy of (a) each reservoir, (b) the rod, and (c) the system?

20.46 The entropy of a macroscopic state is given by $S = k_{\mathrm{B}} \ln w$, where k_{B} is the Boltzmann constant and w is the number of possible microscopic states. Calculate the change in entropy when n moles of an ideal gas undergo free expansion to fill the entire volume of a box after a barrier between the two halves of the box is removed.

20.47 A proposal is submitted for a novel engine that will operate between 400. K and 300. K.

a) What is the theoretical maximum efficiency of the engine?

b) What is the total entropy change per cycle if the engine operates at maximum efficiency?

20.48 A 10.0-kg block initially slides at 10.0 m/s on a flat rough surface and eventually stops. If the block cools to the ambient temperature, which is 27.0 °C, what is the entropy change of the system?

20.49 Suppose an atom of volume V_{A} is inside a container of volume V. The atom can occupy any position within this volume. For this simple model, the number of states available to the atom is given by V/V_{A}. Now suppose the same atom is inside a container of volume $2V$. What will be the change in entropy?

•**20.50** An ideal gas is enclosed in a cylinder with a movable piston at the top. The walls of the cylinder are insulated, so no heat can enter or exit. The gas initially occupies volume V_1 and has pressure p_1 and temperature T_1. The piston is then moved very rapidly to a volume of $V_2 = 3V_1$. The process happens so rapidly that the enclosed gas does not do any work. Find p_2, T_2, and the change in entropy of the gas.

•20.51 Electrons have a property called *spin* that can be either up or down, analogous to the way a coin can be heads or tails. Consider five electrons. Calculate the entropy, $S_{5\text{up}}$, for the state where the spins of all five electrons are up. Calculate the entropy, $S_{3\text{up}}$, for the state where three spins are up and two are down.

•20.52 A 0.545-kg iron bar is taken from a forge at 1000.0 $^\circ$C and dropped into 10.00 kg of water at 22.0 $^\circ$C. Assuming that no energy is lost as heat to the surroundings as the water and bar reach their final temperature, determine the total entropy change of the water-bar system.

••20.53 If the Earth is treated as a spherical blackbody of radius 6371 km, absorbing heat from the Sun at a rate given by the solar constant $\left(1370.\ \text{W/m}^2\right)$ and immersed in space that has the approximate temperature $T_{\text{sp}} = 50.0$ K, it radiates heat back into space at an equilibrium temperature of 278.9 K. (This is a refinement of the model in used in Example 18.8.) Estimate the rate at which the Earth gains entropy in this model.

•• 20.54 Suppose a person metabolizes 2000. kcal/day.

a) With a core body temperature of 37.0 $^\circ$C and an ambient temperature of 20.0 $^\circ$C, what is the maximum (Carnot) efficiency with which the person can perform work?

b) If the person could work with that efficiency, at what rate, in watts, would he or she have to shed waste heat to the surroundings?

c) With a skin area of 1.50 m^2, a skin temperature of 27.0 $^\circ$C, and an effective emissivity of $e = 0.600$, at what *net* rate does this person radiate heat to the 20.0 $^\circ$C surroundings?

d) The rest of the waste heat must be removed by evaporating water, either as perspiration or from the lungs. At body temperature, the latent heat of vaporization of water is 575 cal/g. At what rate, in grams per hour, does this person lose water?

e) Estimate the rate at which the person gains entropy. Assume that all the required evaporation of water takes place in the lungs, at the core body temperature of 37.0 $^\circ$C.

Additional Exercises

20.55 A nonpolluting source of energy is geothermal energy, from the heat inside the Earth. Estimate the maximum efficiency for a heat engine operating between the center of the Earth and the surface of the Earth (use Table 17.1).

20.56 In some of the thermodynamic cycles discussed in this chapter, one isotherm intersects one adiabatic curve. For an ideal gas, by what factor is the adiabatic curve steeper than the isotherm?

20.57 The internal combustion engines in today's cars operate on the Otto cycle. The efficiency of this cycle, $\epsilon_{\text{Otto}} = 1 - r^{1-\gamma}$, as derived in this chapter, depends on the compression ratio, $r = V_{\text{max}}/V_{\text{min}}$. Increasing the efficiency of an Otto engine can be done by increasing the compression ratio. This, in turn, requires fuel with a higher octane rating, to avoid self-ignition of the fuel-air mixture. The following table for a particular engine shows some octane ratings and the maximum compression ratio the engine must have before self-ignition (knocking) sets in.

Octane Rating of Fuel	Maximum Compression Ratio without Knocking
91	8.5
93	9.0
95	9.8
97	10.5

Calculate the maximum theoretical efficiency of an internal combustion engine running on each of these four types of gasoline and the percentage increase in efficiency between using fuel with an octane rating of 91 and using fuel with an octane rating of 97.

20.58 Consider a room air conditioner using a Carnot cycle at maximum theoretical efficiency and operating between the temperatures of 18.0 °C (indoors) and 35.0 °C (outdoors). For each 1.00 J of heat flowing out of the room into the air conditioner:

a) How much heat flows out of the air conditioner to the outdoors?

b) By approximately how much does the entropy of the room decrease?

c) By approximately how much does the entropy of the outdoor air increase?

20.59 Assume that it takes 0.0700 J of energy to heat a 1.00-g sample of mercury from 10.000 °C to 10.500 °C and that the heat capacity of mercury is constant, with a negligible change in volume as a function of temperature. Find the change in entropy if this sample is heated from 10.0 °C to 100. °C.

20.60 An inventor claims that he has created a water-driven engine with an efficiency of 0.200 that operates between thermal reservoirs at 4.0 °C and 20.0 °C. Is this claim valid?

20.61 Consider a system consisting of rolling a six-sided die. What happens to the entropy of the system if an additional die is added? Does it double? What happens to the entropy if the number of dice is three?

20.62 A 1200-kg car traveling at 30.0 m/s crashes into a wall on a hot day (27 °C). What is the total change in entropy?

20.63 If liquid nitrogen is boiled slowly—that is, reversibly—to transform it into nitrogen gas at a pressure $P = 100.0$ kPa, its entropy increases by $\Delta S = 72.1$ J/(mol K). The latent heat of vaporization of nitrogen at its boiling temperature at this pressure is $L_{\text{vap}} = 5.568$ kJ/mol. Using these data, calculate the boiling temperature of nitrogen at this pressure.

•**20.64** Find the net change in entropy when 100. g of water at 0 °C is added to 100. g of water at 100. °C.

•**20.65** A coal-burning power plant produces 3000. MW of thermal energy, which is used to boil water and produce

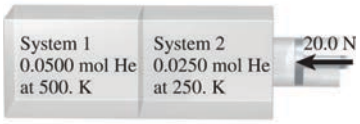
supersaturated steam at 300. °C. This high-pressure steam turns a turbine producing 1000. MW of electrical power. At the end of the process, the steam is cooled to 30.0 °C and recycled.

a) What is the maximum possible efficiency of the plant?

b) What is the actual efficiency of the plant?

c) To cool the steam, river water runs through a condenser at a rate of $4.00 \cdot 10^7$ gal/h. If the water enters the condenser at 20.0 °C, what is its exit temperature?

•**20.66** Two equal-volume compartments of a box are joined by a thin wall as shown in the figure. The left compartment is filled with 0.0500 mole of helium gas at 500. K, and the right compartment contains 0.0250 mole of helium gas at 250. K. The right compartment also has a piston to which a force of 20.0 N is applied.



a) If the wall between the compartments is removed, what will the final temperature of the system be?

b) How much heat will be transferred from the left compartment to the right compartment?

c) What will be the displacement of the piston due to this transfer of heat?

d) What fraction of the heat will be converted into work?

•**20.67** A volume of 6.00 L of a monatomic ideal gas, originally at 400. K and a pressure of 3.00 atm (called state 1), undergoes the following processes, all done reversibly:

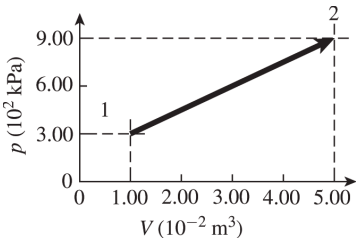
$1 \rightarrow 2$ isothermal expansion to $V_2 = 4V_1$

$2 \rightarrow 3$ isobaric compression

$3 \rightarrow 1$ adiabatic compression to its original state

Find the entropy change for each process.

•**20.68** The process shown in the pV-diagram is performed on 3.00 moles of a monatomic gas. Determine the amount of heat input for this process.



•**20.69** Suppose 1.00 mole of a monatomic ideal gas at a pressure of 4.00 atm and a volume of 30.0 L is isothermically expanded to a pressure of 1.00 atm and a volume of 120.0 L. Next, it is compressed at a constant pressure until its volume is 30.0 L, and then its pressure is increased at the constant volume of 30.0 L. What is the efficiency of this heat engine cycle?

•• **20.70** Two cylinders, A and B, have equal inside diameters and pistons of negligible mass connected by a rigid rod. The pistons can move freely. The rod is a short tube with a valve. The valve is initially closed (see the figure).

Cylinder A and its piston are thermally insulated, and cylinder B is in thermal contact with a thermostat, which has temperature $T = 27.0\ ^\circ\text{C}$. Initially, the piston of cylinder A is fixed, and inside the cylinder is a mass, $m = 0.320$ kg, of argon at a pressure higher than atmospheric pressure. Inside cylinder B, there is a mass of oxygen at normal atmospheric pressure. When the piston of cylinder A is freed, it moves very slowly, and at equilibrium, the volume of the argon in cylinder A is eight times higher, and the density of the oxygen has increased by a factor of 2. The thermostat receives heat $Q = 7.479 \cdot 10^4$ J.

a) Based on the kinetic theory of an ideal gas, show that the thermodynamic process taking place in the cylinder A satisfies $T\,V^{\,2/3} = \text{constant}$.

b) Calculate *p, V,* and *T* for the argon in the initial and final states. The molar mass of argon is $\mu = 39.95\ \mathrm{g/mol}$.

c) Calculate the final pressure of the mixture of the gases if the valve in the rod is opened.

MULTI-VERSION EXERCISES

20.71 A house's air conditioner has an energy efficiency rating of 10.47. The house absorbs thermal energy at a rate of 5.375 kJ/s. How much does it cost, in dollars, to run the air conditioner for a day if electricity costs 12.85 ¢/kWh?

20.72 A house's air conditioner has an energy efficiency rating of 10.71. The house absorbs thermal energy at a rate of 5.437 kJ/s. It costs $5.605 to run the air conditioner for a day. What is the electric company charging for electricity, in cents per kilowatt-hour?

20.73 An air conditioner is used to cool a house in the summer. The house absorbs thermal energy at a rate of 5.499 kJ/s. It costs $5.818 to run the air conditioner for a day when electricity costs 14.13 ¢/kWh. What is the energy efficiency rating of the air conditioner?

20.74 What is the minimum amount of work that must be done to extract 288.1 J of heat from a massive object at a temperature of 24.93 °C while releasing heat to a high-temperature reservoir at 195.3 °C?

20.75 The minimum amount of work that must be done to extract 425.5 J of heat from a massive object at a temperature of 25.05 °C while releasing heat to a high-temperature reservoir is 118.5 J. What is the temperature of the high-temperature reservoir?

20.76 The minimum amount of work that must be done to extract 562.9 J of heat from a massive object at a low temperature while releasing heat to a high-temperature reservoir at 120.9 °C is 180.7 J. What is the temperature of the massive object?

20.77 A water-cooled engine produces 1833 W of power. Water enters the engine block at 11.25 ˚C and exits at 26.69 ˚C. The rate of water flow is 132.3 L/h. What is the engine's efficiency?

20.78 A water-cooled engine produces 1061 W of power and has an efficiency of 0.3591. Water enters the engine block at 11.35 ˚C and exits at 27.33 ˚C. What is the water flow rate, in liters per hour?

20.79 A water-cooled engine has an efficiency of 0.2815. Water enters the engine block at 11.45 ˚C and exits at 27.97 ˚C. The rate of water flow is 171.5 L/h. How much power does the engine produce?

Many people think of static electricity as the annoying spark that occurs when they reach for a metal object like a doorknob on a dry day, after they have been walking on a carpet (Figure 21.1). In fact, many electronics manufacturers place small metal plates on equipment so that users can discharge any spark on the plate and not damage the more sensitive parts of the equipment. However, static electricity is more than just an occasional annoyance; it is the starting point for any study of electricity and magnetism, forces that have changed human society as radically as anything since the discovery of fire or the wheel.

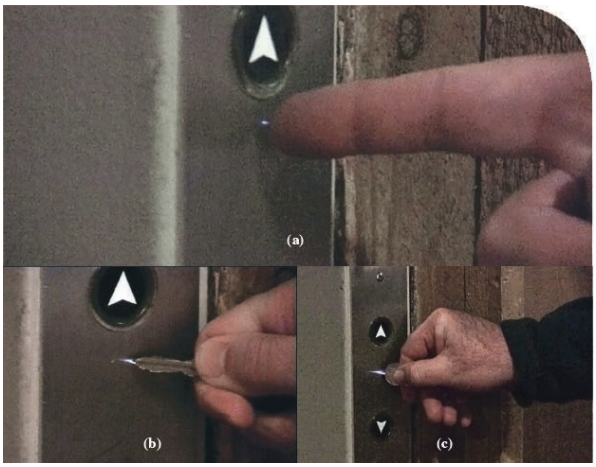

FIGURE 21.1 (a) A spark due to static electricity occurs between a person's finger and a metal surface near an elevator button. (b) and (c) Similar sparks are generated when the person holds a metal object like a car key or a coin, but are painless because the spark forms between the metal surface and the metal object.

W. Bauer and G. D. Westfall

In this chapter, we examine the properties of electric charge. A moving electric charge gives rise to a separate phenomenon, called *magnetism,* which is covered in later chapters. Here we look at charged objects that are not moving—hence the term *electrostatics*. All objects have charge, since charged particles make up atoms and molecules. We often don't notice the effects of electrical charge because most objects are electrically neutral. The forces that hold atoms together and that keep objects separate even when they're in contact, are all electric in nature.

WHAT WE WILL LEARN

- Electric charge gives rise to a force between charged particles or objects.
- Electricity and magnetism together make up the electromagnetic force, one of the four fundamental forces of nature.
- There are two kinds of electric charge, positive and negative. Like charges repel, and unlike charges attract.
- Electric charge is quantized, meaning that it occurs only in integral multiples of a smallest elementary quantity. Electric charge is also conserved.
- Most materials around us are electrically neutral.
- The electron is an elementary particle, and its charge is the smallest observable quantity of electric charge.
- Insulators conduct electricity poorly or not at all. Conductors conduct electricity well but not perfectly—some energy losses occur.
- Semiconductors can be made to change between a conducting state and a nonconducting state.
- Superconductors conduct electricity perfectly.
- Objects can be charged directly by contact or indirectly by induction.
- The force that two stationary electric charges exert on each other is proportional to the product of the charges and varies as the inverse square of the distance between the two charges.
- Electrostatic forces between particles can be added as vectors by the process of superposition.

21.1 Electromagnetism

Perhaps no mystery puzzled ancient civilizations more than electricity, which they observed primarily in the form of lightning strikes (Figure 21.2). The destructive force inherent in lightning, which could set objects on fire and kill people and animals, seemed godlike. The ancient Greeks, for example, believed Zeus, father of the gods, had the ability to throw lightning bolts. The Germanic tribes ascribed this power to the god Thor and the Romans to the god Jupiter. Characteristically, the ability to cause lightning belonged to the god at the top (or near the top) of the hierarchy.

FIGURE 21.2
Lightning strikes over Chongqing, China.

View Stock/age fotostock

The ancient Greeks knew that if you rubbed a piece of amber with a piece of cloth, you could attract small, light objects with the amber. We now know that rubbing amber with a cloth transfers negatively charged particles called *electrons* from the cloth to the amber. (The words *electron* and *electricity* derive from the Greek word for amber.) Lightning also consists of a flow of electrons. The early Greeks and others also knew about naturally occurring magnetic objects called *lodestones,* which were found in deposits of magnetite, a mineral consisting of iron oxide. These objects were used to construct compasses as early as 300 BC.

The relationship between electricity and magnetism was not understood until the middle of the 19th century. The following

chapters will reveal how electricity and magnetism can be unified into a common framework called *electromagnetism*. However, unification of forces does not stop there. During the early part of the 20th century, two more fundamental forces were discovered: the weak force, which operates in beta decay (in which an electron and a neutrino are spontaneously emitted from certain types of nuclei), and the strong force, which acts inside the atomic nucleus. We'll study these forces in more detail in Chapter 39 on particle physics. Currently, the electromagnetic and weak forces are viewed as two aspects of the electroweak force (Figure 21.3). For the phenomena discussed in this and the following chapters, this electroweak unification has no influence; it becomes important in the highest-energy particle collisions. Because the energy scale for the electroweak unification is so high, most textbooks continue to speak of four fundamental forces: gravitational, electromagnetic, weak, and strong.

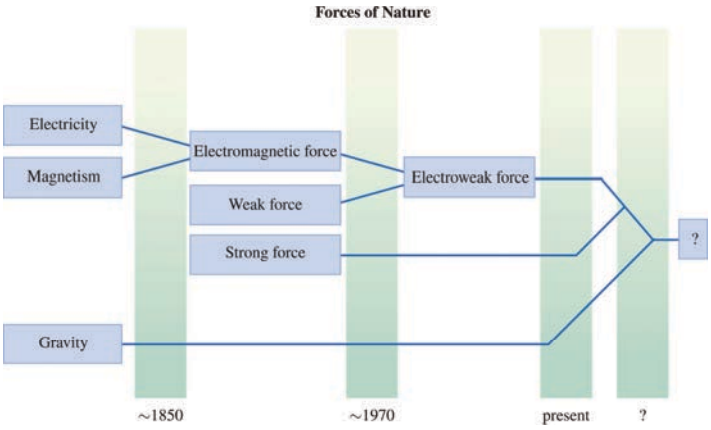

FIGURE 21.3 The history of the unification of fundamental forces.

Today, a large number of physicists believe that the electroweak force and the strong force can also be unified, that is, described in a common framework. Several theories propose ways to accomplish this, but so far experimental evidence is missing. Interestingly, the force that has been known longer than any of the other fundamental forces, gravity, seems to be hardest to shoehorn into a unified framework with the other fundamental forces. Quantum gravity, supersymmetry, and string theory are current foci of cutting-edge physics research in which theorists are attempting to construct this grand unification and discover the (hubristically

named) Theory of Everything. They are mainly guided by symmetry principles and the conviction that nature must be elegant and simple.

Page 659

We'll return to these considerations in Chapters 39 and 40. In this chapter, we consider electric charge, how materials react to electric charge, static electricity, and the forces resulting from electric charges. **Electrostatics** covers situations where charges stay in place and do not move.

21.2 Electric Charge

Let's look a little deeper into the cause of the electric sparks that you occasionally receive on a dry winter day if you walk across a carpet and then touch a metal doorknob. (Electrostatic sparks have even ignited gas fumes while someone is filling the tank at a gas station. This is not an urban legend; a few of these cases have been caught on gas station surveillance cameras.) The process that causes this sparking is called **charging.** Charging consists of the transfer of negatively charged particles, called **electrons,** from the atoms and molecules of the material of the carpet to the soles of your shoes. This charge can move relatively easily through your body, including your hands. The built-up electric charge discharges through the metal of the doorknob, creating a spark.

The two types of electric charge found in nature are **positive charge** and **negative charge.** Normally, objects around us do not seem to be charged; instead, they are electrically neutral. Neutral objects contain roughly equal numbers of positive and negative charges that largely cancel each other. Only when positive and negative charges are not balanced do we observe the effects of electric charge.

If you rub a glass rod with a cloth, the glass rod becomes charged and the cloth acquires a charge of the opposite sign. If you rub a plastic rod with fur, the rod and fur also become oppositely charged. If you bring two charged glass rods together, they repel each other. Similarly, if you bring two charged plastic rods together, they also repel each other. However, a charged glass rod and a charged plastic rod will attract each other. This difference arises because the glass rod and the plastic rod have opposite charge. These observations led to the following law:

Law of Electric Charges

Like charges repel and opposite charges attract.

The unit of electric charge is the **coulomb (C)**, named after the French physicist Charles-Augustine de Coulomb $(1736 - 1806)$. The coulomb is defined in terms of the SI unit for current, the ampere (A), named after another French physicist, André-Marie Ampère $(1775 - 1836)$. Neither the ampere nor the coulomb can be derived in terms of the other SI units: meter, kilogram, and second. Instead, the ampere is another fundamental SI unit. For this reason, the SI system of units is sometimes called *MKSA (meter-kilogram-second-ampere) system*. The charge unit is defined as

$$1\,\mathrm{C} = 1\,\mathrm{A\,s}. \tag{21.1}$$

The definition of the ampere must wait until we discuss current in later chapters. However, we can define the magnitude of the coulomb by simply specifying the charge of a single electron:

$$q_\mathrm{e} = -e, \tag{21.2}$$

where q_e is the charge and e has the (currently best accepted and experimentally measured) value

$$e = 1.602176565(35) \cdot 10^{-19}\mathrm{C}. \tag{21.3}$$

(Usually it is enough to carry only the first two to four significant digits of this mantissa. We will use a value of 1.602 in this chapter, but you should keep in mind that equation 21.3 gives the full accuracy to which this charge has been measured.)

The charge of the electron is an intrinsic property of the electron, just like its mass. The charge of the **proton,** another

basic particle of atoms, is exactly the same magnitude as that of the electron, only the proton's charge is positive:

$$q_{\mathrm{p}} = +e. \tag{21.4}$$

The choice of which charge is positive and which charge is negative is arbitrary. The conventional choice of $q_{\mathrm{e}} < 0$ and $q_{\mathrm{p}} > 0$ is due to the American statesman, scientist, and inventor Benjamin Franklin $(1706 - 1790)$, who pioneered studies of electricity.

Concept Check 21.1

How many electrons does it take to make 1.00 C of charge?

a) $1.60 \cdot 10^{19}$

b) $6.60 \cdot 10^{19}$

c) $3.20 \cdot 10^{16}$

d) $6.24 \cdot 10^{18}$

e) $6.66 \cdot 10^{17}$

One coulomb is an extremely large unit of charge. We'll see later in this chapter just how big it is when we investigate the magnitude of the forces of charges on each other. Units of μC (microcoulombs, 10^{-6} C), nC (nanocoulombs, 10^{-9} C), and pC (picocoulombs, 10^{-12} C) are commonly used.

Benjamin Franklin also proposed that charge is conserved. Charge is not created or destroyed, simply moved from one object to another.

Law of Charge Conservation

The total electric charge of an isolated system is conserved.

This law is the fourth conservation law we have encountered so far, the first three being the conservation laws for total energy, momentum, and angular momentum. Conservation laws are a common thread that runs throughout all of physics and thus throughout this book as well.

It is important to note that there is a conservation law for charge, but *not* for mass. We'll see later in this book that mass and energy are not independent of each other. What is sometimes described in introductory chemistry as conservation of mass is not an exact conservation law, but only an approximation used to keep track of the number of atoms in chemical reactions. (It is a good approximation to a large number of significant figures but not an exact law, like charge conservation.) Conservation of charge applies to all systems, from the macroscopic system of plastic rod and fur down to systems of subatomic particles.

Elementary Charge

Electric charge occurs only in integral multiples of a minimum size. This is expressed by saying that charge is **quantized.** The smallest observable unit of electric charge is the charge of the electron, which is $-1.602 \cdot 10^{-19}$ C (as defined in equation 21.3).

The fact that electric charge is quantized was verified in an ingenious experiment carried out in 1910 by American physicist Robert A. Millikan $(1868 - 1953)$ and known as the *Millikan oil drop experiment* (Figure 21.4). In this experiment, oil drops were sprayed into a chamber where electrons were knocked out of the drops by some form of radiation, usually X-rays. The resulting positively charged drops were allowed to fall between two electrically charged plates. Adjusting the charge of the plates caused the drops to stop falling and allowed their charge to be measured. What Millikan observed was that charge was quantized rather than continuous. (A quantitative analysis of this experiment will be presented in Chapter 23 on electric potential.) That is, this experiment and its subsequent refinements established that charge comes only in integer multiples of the charge of an electron. In everyday experiences with electricity, we do not notice that charge is quantized because most electrical phenomena involve huge numbers of electrons.

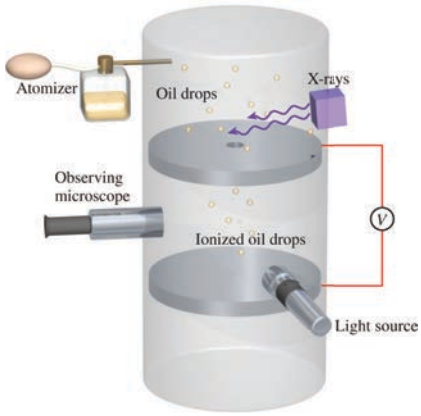

FIGURE 21.4
Schematic drawing of the Millikan oil drop experiment.

In Chapter 13, we discussed the facts that matter is composed of atoms and that an atom consists of a nucleus containing charged protons and neutral neutrons. A schematic drawing of a carbon atom is shown in Figure 21.5. A carbon atom has six protons and (usually) six neutrons in its nucleus. This nucleus is surrounded by six electrons. Note that this drawing is not to scale. In the actual atom, the distance of the electrons from the nucleus is much larger (by a factor on the order of 10,000) than the size of the nucleus. In addition, the electrons are shown in circular orbits, which is also not quite correct. In Chapter 38, we'll see that the locations of electrons in the atom can be characterized only by probability distributions.

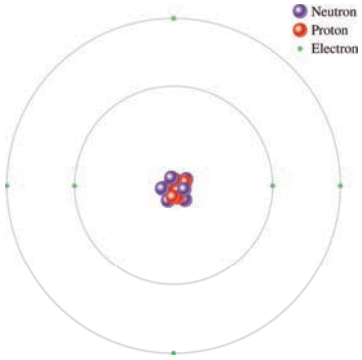

FIGURE 21.5 In a carbon atom, the nucleus contains six neutrons and six protons. The nucleus is surrounded by six electrons. Note that this drawing is schematic and not to scale.

As mentioned earlier, a proton has a positive charge with a magnitude that is *exactly* equal to the magnitude of the negative charge of an electron. In a neutral atom, the number of negatively charged electrons is equal to the number of positively charged protons. The mass of the electron is much smaller than the mass of the proton or the neutron. Therefore, most of the mass of an atom resides in the nucleus. Electrons can be removed from atoms relatively easily. For this reason, electrons are typically the carriers of electricity, rather than protons or atomic nuclei.

The electron is a fundamental particle and has no substructure: It is a point particle with zero radius (at least, according to current understanding). However, high-energy probes have been used to look inside the proton. A proton is composed of charged particles called *quarks,* held together by uncharged particles called *gluons.* Quarks have a charge of $\pm\frac{1}{3}$ or $\pm\frac{2}{3}$ times the charge of the electron. These fractionally charged particles cannot exist independently and have never been observed directly, despite numerous extensive searches. Just like the charge of an electron,

the charges of quarks are intrinsic properties of these elementary particles.

A proton is composed of two *up quarks* (each with charge $+\frac{2}{3}e$) and one *down quark* (with charge $-\frac{1}{3}e$), giving the proton a charge of $q_{\text{p}} = (2)\left(+\frac{2}{3}e\right) + (1)\left(-\frac{1}{3}e\right) = +e$, as illustrated in Figure 21.6a. The electrically neutral neutron (hence the name!) is composed of an up quark and two down quarks, as shown in Figure 21.6b, so its charge is $q_{\text{n}} = (1)\left(+\frac{2}{3}e\right) + (2)\left(-\frac{1}{3}e\right) = 0$. In Chapter 39, we'll see that there are other, much more massive, quarks named *strange, charm, bottom,* and *top,* which have the same charges as the up and down quarks. There are also much more massive electron-like particles named *muon* and *tau*. But the basic fact remains that all of the matter in everyday experience is made up of electrons (with electrical charge $-e$), up and down quarks (with electrical charges $+\frac{2}{3}e$ and $-\frac{1}{3}e$, respectively), and gluons (zero charge).

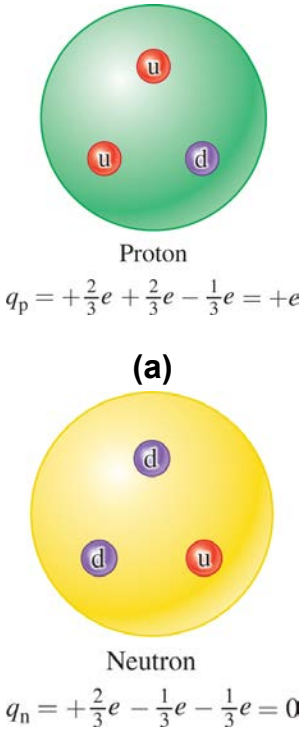

FIGURE 21.6 (a) A proton contains two up quarks (u) and one down quark (d). (b) A neutron contains one up quark (u) and two down quarks (d).

It is remarkable that the charges of the quarks inside a proton add up to *exactly* the same magnitude as the charge of the electron. This fact is still a puzzle, pointing to some deep symmetry in nature that is not yet understood.

Because all macroscopic objects are made of atoms, which in turn are made of electrons and atomic nuclei consisting of protons and neutrons, the charge, q, of any object can be expressed in

terms of the sum of the number of protons, N_{p}, minus the sum of the number of electrons, N_{e}, that make up the object:

$$q = e(N_{\mathrm{p}} - N_{\mathrm{e}}). \tag{21.5}$$

EXAMPLE 21.1 Net Charge

PROBLEM

If we wanted a block of iron of mass 3.25 kg to acquire a positive charge of 0.100 C, what fraction of the electrons would we have to remove?

SOLUTION

Iron has mass number 56. Therefore, the number of iron atoms in the 3.25-kg block is

$$N_{\text{atom}} = \frac{(3.25\ \text{kg})\left(6.022 \cdot 10^{23}\ \text{atoms/ mole}\right)}{0.0560\ \text{kg/ mole}} = 3.495 \cdot$$

Note that we have used Avogadro's number, $6.022 \cdot 10^{23}$, and the definition of the mole, which specifies that the mass of 1 mole of a substance in grams is just the mass number of the substance—in this case, 56.

Because the atomic number of iron is 26, which equals the number of protons or electrons in an iron atom, the total number of electrons in the 3.25-kg block is

$$N_{\text{e}} = 26 N_{\text{atom}} = (26)\left(3.495 \cdot 10^{25}\right) = 9.09 \cdot 10^{26}\text{electron}$$

We use equation 21.5 to find the number of electrons, $N_{\Delta\text{e}}$, that we would have to remove. Because the number of electrons equals the number of protons in the original uncharged object, the difference in the number of protons and electrons is the number of removed electrons, $N_{\Delta\text{e}}$:

$$q = e \cdot N_{\Delta\text{e}} \Rightarrow N_{\Delta\text{e}} = \frac{q}{e} = \frac{0.100\ \text{C}}{1.602 \cdot 10^{-19}\ \text{C}} = 6.24 \cdot 10^{17}$$

Finally, we obtain the fraction of electrons we would have to remove:

$$\frac{N_{\Delta e}}{N_e} = \frac{6.24 \cdot 10^{17}}{9.09 \cdot 10^{26}} = 6.87 \cdot 10^{-10}.$$

We would have to remove fewer than one in a billion electrons from the iron block in order to put the sizable positive charge of 0.100 C on it.

Self-Test Opportunity 21.1

Give the charge of the following elementary particles or atoms in terms of the elementary charge $e = 1.602 \cdot 10^{-19}$C.

a) proton

b) neutron

c) helium atom (two protons, two neutron, and two electrons)

d) hydrogen atom (one proton and one electron)

e) up quark

f) down quark

g) electron

h) alpha particle (two protons and two neutrons)

21.3 Insulators, Conductors, Semiconductors, and Superconductors

Materials that conduct electricity well are called **conductors.** Materials that do not conduct electricity are called **insulators.** (Of course, there are good and poor conductors and good and poor insulators, depending on the properties of the specific materials.)

The electronic structure of a material refers to the way in which electrons are bound to nuclei, as we'll discuss in later chapters. For now, we are interested in the relative propensity of the atoms of a material to either give up or acquire electrons. For insulators, no free movement of electrons occurs because the material has no loosely bound electrons that can escape from its atoms and thereby move freely throughout the material. Even when external charge is placed on an insulator, this external charge cannot move appreciably. Typical insulators are glass, plastic, and cloth.

On the other hand, materials that are conductors have an electronic structure that allows the free movement of some electrons. The positive charges of the atoms of a conducting material do not move, since they reside in the heavy nuclei. Typical solid conductors are metals. Copper, for example, is a very good conductor and is therefore used in electrical wiring.

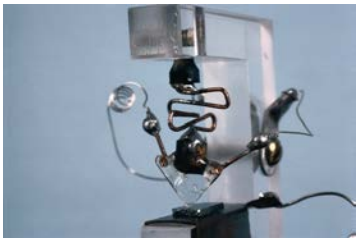
Page 663

Fluids and organic tissue can also serve as conductors. Pure distilled water is not a very good conductor. However, dissolving common table salt (NaCl), for example, in water improves its conductivity tremendously, because the positively charged sodium ions $\left(Na^{+}\right)$ and negatively charged chlorine ions $\left(Cl^{-}\right)$ can move

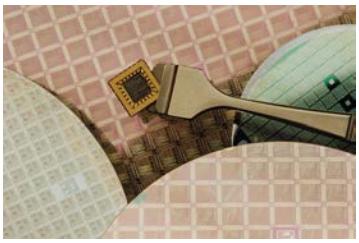
within the water to conduct electricity. In liquids, unlike solids, positive as well as negative charge carriers are mobile. Organic tissue is not a very good conductor, but it conducts electricity well enough to make large currents dangerous to us. (We'll learn more about electric current in Chapters 25 and 26, where these terms, which are in everyday use, will be defined precisely.)

Semiconductors

A class of materials called **semiconductors** can change from being an insulator to being a conductor and back to an insulator again. Semiconductors were discovered only a little more than 50 years ago but are the backbone of the entire computer and consumer electronics industries. The first widespread use of semiconductors was in transistors (Figure 21.7a); modern computer chips (Figure 21.7b) perform the functions of millions of transistors. Computers and basically all modern consumer electronics products and devices (televisions, cameras, video game players, cell phones, etc.) would be impossible without semiconductors. Gordon Moore, cofounder of Intel, famously stated that due to advancing technology, the power of the average computer's CPU (central processing unit) doubles every 18 months, which is an empirical average over the last 5 decades. This doubling phenomenon is known as *Moore's Law*. Physicists have been and will undoubtedly continue to be the driving force behind this process of scientific discovery, invention, and improvement.



(a)



(b)

FIGURE 21.7 (a) Replica of the first transistor, invented in 1947 by John Bardeen, Walter H. Brattain, and William B. Shockley. (b) Modern computer chips made from silicon wafers contain many tens of millions of transistors.

a: Kim Steele/Getty Images; **b:** Geostock/Getty Images

Semiconductors are of two kinds: intrinsic and extrinsic. Examples of *intrinsic semiconductors* are chemically pure crystals of gallium arsenide, germanium, or, especially, silicon. Engineers produce *extrinsic semiconductors* by *doping,* which is the addition of minute amounts (typically 1 part in 10^6) of other materials that

can act as electron donors or electron receptors. Semiconductors doped with electron donors are called *n-type* (*n* stands for "negative charge"). If the doping substance acts as an electron receptor, the hole left behind by an electron that attaches to a receptor can also travel through the semiconductor and acts as an effective positive charge carrier. These semiconductors are consequently called *p-type* (*p* stand for "positive charge"). Thus, unlike normal solid conductors in which only negative charges move, semiconductors have movement of negative or positive charges (which are really electron holes, that is, missing electrons).

Superconductors

Superconductors are materials that have zero resistance to the conduction of electricity, as opposed to normal conductors, which conduct electricity well but with some losses. Materials are superconducting only at very low temperatures. A typical superconductor is a niobium-titanium alloy that must be kept near the temperature of liquid helium (4.2 K) to retain its superconducting properties. During the last 20 years, new materials called *high-T_c superconductors* (T_c stands for "critical temperature," which is the maximum temperature that allows superconductivity) have been developed. These are superconducting at the temperature at which nitrogen can exist as a liquid (77.3 K). Materials that are superconductors at room temperature (300 K) have not yet been found, but they would be extremely useful. Research directed at developing such materials and theoretically explaining what physical phenomena cause high-T_c superconductivity is currently in progress.

The topics of conductivity, superconductivity, and semiconductors will be discussed in more quantitative detail in Chapters 25 and 28.

21.4 Electrostatic Charging

Giving a static charge to an object is a process known as **electrostatic charging.** Electrostatic charging can be understood through a series of simple experiments. A power supply serves as a ready source of positive and negative charge. The battery in your car is a similar power supply; it uses chemical reactions to create a separation between positive and negative charge. Several insulating paddles can be charged with positive or negative charge from the power supply. In addition, a conducting connection is made to the Earth. The Earth is a nearly infinite reservoir of charge, capable of effectively neutralizing electrically charged objects in contact with it. This taking away of charge is called **grounding,** and an electrical connection to the Earth is called a **ground.**

An **electroscope** is a device that gives an observable response when it is charged. You can build a relatively simple electroscope by using two strips of very thin metal foil that are attached at one end and are allowed to hang straight down adjacent to each other from an isolating frame. Kitchen aluminum foil is not suitable, because it is too thick, but hobby shops sell thinner metal foils. For the isolating frame, you can use a Styrofoam coffee cup turned sideways, for example.

The lecture-demonstration-quality electroscope shown in Figure 21.8 has two conductors that in their neutral position are touching and oriented in a vertical direction. One of the conductors is hinged at its midpoint so that it will move away from the fixed conductor if a charge appears on the electroscope. These two conductors are in contact with a conducting ball on top of the electroscope, which allows charge to be applied or removed easily.

FIGURE 21.8 A typical electroscope used in lecture demonstrations.

W. Bauer and G. D. Westfall

An uncharged electroscope is shown in Figure 21.9a. The power supply is used to give a negative charge to one of the insulating paddles. When the paddle is brought near the ball of the electroscope, as shown in Figure 21.9b, the electrons in the conducting ball of the electroscope are repelled, which produces a net negative charge on the conductors of the electroscope. This negative charge causes the movable conductor to rotate because the stationary conductor also has negative charge and repels it. Because the paddle did not touch the ball, the charge on the movable conductors is **induced.** If the charged paddle is then taken away, as illustrated in Figure 21.9c, the induced charge reduces to zero, and the movable conductor returns to its original position, because the total charge on the electroscope did not change in the process.

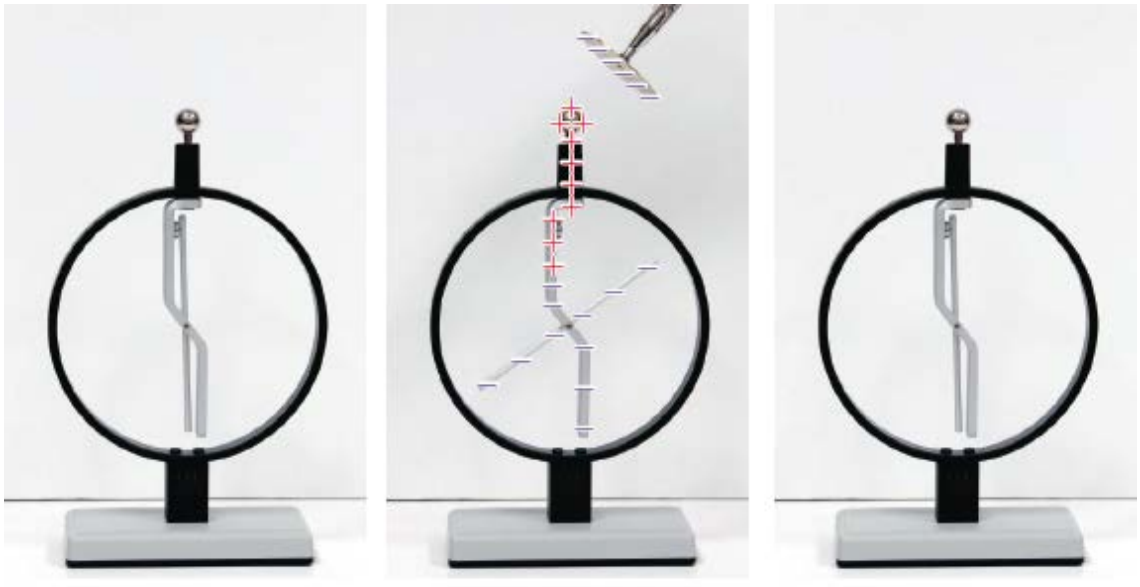


FIGURE 21.9 Inducing a charge: (a) An uncharged electroscope. (b) A negatively charged paddle is brought near the electroscope. (c) The negatively charged paddle is taken away.

W. Bauer and G. D. Westfall

Concept Check 21.2

The hinged conductor moves away from the fixed conductor if a charge is applied to the electroscope, because

a) like charges repel each other.

b) like charges attract each other.

c) unlike charges attract each other.

d) unlike charges repel each other.

If the same process is carried out with a positively charged paddle, the electrons in the conductors are attracted to the paddle and flow into the conducting ball. This leaves a net positive charge on the conductors, causing the movable conducting arm to rotate again. Note that the net charge of the electroscope is zero in both

cases and that the motion of the conductor indicates only that the paddle is charged. When the positively charged paddle is removed, the movable conductor again returns to its original position. It is important to note that we cannot determine the sign of this charge!

On the other hand, if a negatively charged insulating paddle *touches* the ball of the electroscope, as shown in Figure 21.10b, electrons will flow from the paddle to the conductor, producing a net negative charge. When the paddle is removed, the charge remains and the movable arm remains rotated, as shown in Figure 21.10c. Similarly, if a positively charged insulating paddle touches the ball of the uncharged electroscope, the electroscope transfers electrons to the positively charged paddle and becomes positively charged. Again, both a positively charged paddle and a negatively charged paddle have the same effect on the electroscope, and we have no way of determining whether the paddles are positively charged or negatively charged. This process is called **charging by contact.**

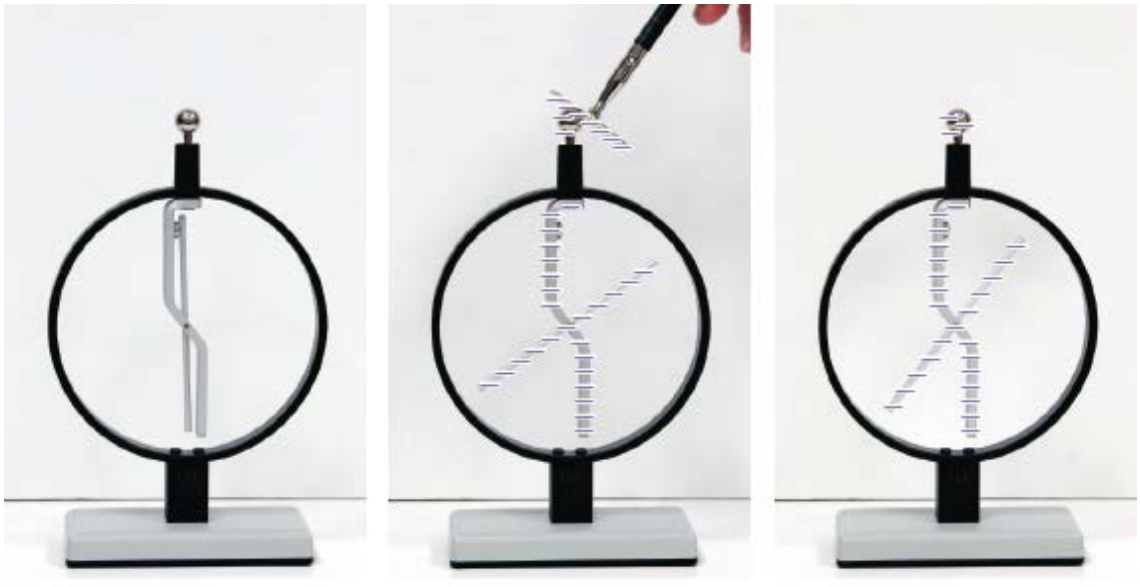

FIGURE 21.10 Charging by contact: (a) An uncharged electroscope. (b) A negatively charged paddle touches the electroscope. (c) The negatively charged paddle is removed.

W. Bauer and G. D. Westfall

The two different kinds of charge can be demonstrated by first touching a negatively charged paddle to the electroscope, producing a rotation of the movable arm, as shown in Figure 21.10. If a positively charged paddle is then brought into contact with the electroscope, the movable arm returns to the uncharged position. The charge is neutralized (assuming that both paddles originally had the same absolute value of charge). Thus, there are two kinds of charge. However, because charges are manifestations of mobile electrons, a negative charge is an excess of electrons and a positive charge is a deficit of electrons.

The electroscope can be given a charge without touching it with the charged paddle, as shown in Figure 21.11. The uncharged electroscope is shown in Figure 21.11a. A negatively charged paddle is brought close to the ball of the electroscope but not touching it, as shown in Figure 21.11b. In Figure 21.11c, the electroscope is connected to a ground. Then, while the charged paddle is still close to but not touching the ball of the electroscope, the ground connection is removed in Figure 21.11d. Next, when the paddle is moved away from the electroscope in Figure 21.11e, the

electroscope is still positively charged (but with a smaller deflection than in Figure 21.11b). The same process also works with a positively charged paddle. This process is called **charging by induction** and yields an electroscope charge that has the opposite sign from the charge on the paddle.

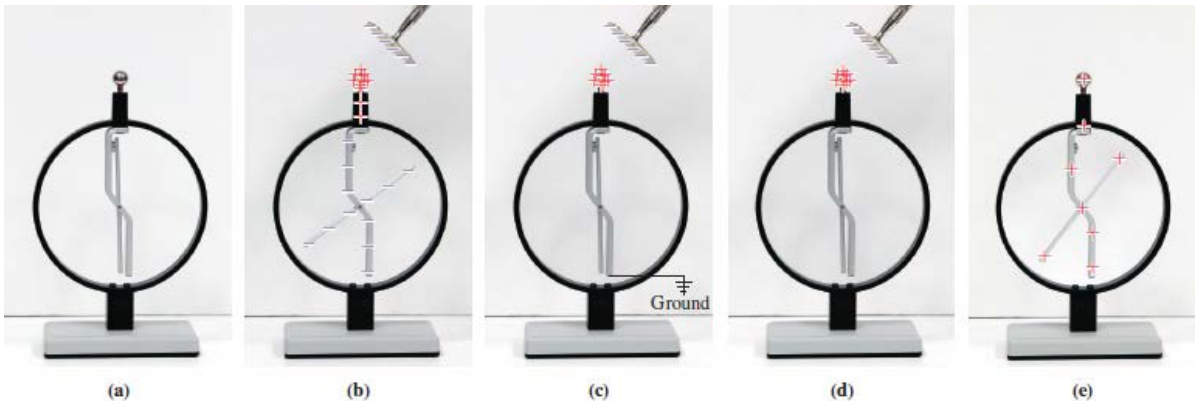

FIGURE 21.11 Charging by induction: (a) An uncharged electroscope. (b) A negatively charged paddle is brought close to the electroscope. (c) A ground is connected to the electroscope. (d) The connection to the ground is removed. (e) The negatively charged paddle is taken away, leaving the electroscope positively charged.

W. Bauer and G. D. Westfall

Triboelectric Charging

As mentioned earlier, rubbing two materials together will charge them. We have not addressed two basic questions about this effect: First, what really causes it? And second, which of two given materials gets charged positively and which negatively?

The effect is called *triboelectric charging*, which implies that friction (see the discussion of tribology in Chapter 4) plays a role. Amazingly, as with many aspects of friction, the microscopic causes of triboelectric charging are still not completely understood. The prevailing theory is that when the surfaces of the two materials involved in the charging process come into contact, adhesion takes place and chemical bonds are formed between atoms at the surfaces. As the surfaces separate, some of these newly formed bonds rupture and leave more of the electrons involved in the bonding on the material with the greater work function. We will discuss the work function in Chapter 36 when we consider the photoelectric effect, but for now we can view it as the electrostatic potential energy that binds electrons to atoms in a material.

Recent research results obtained by examining surfaces with atomic force microscopes suggest, however, that triboelectric charging can also occur when two pieces of the *same* material are rubbed against each other. In addition, it has been found that the charging process transfers not only electrons but sometimes also small specks (a few nanometers across) of material.

Which material gets charged positively and which negatively? This question has been answered by a long series of experiments whose results are summarized in Figure 21.12 in the form of a list of some common materials that may be rubbed together. If you rub two materials from this list against each other, the one nearer the top will receive a net positive charge and the other a net negative charge.

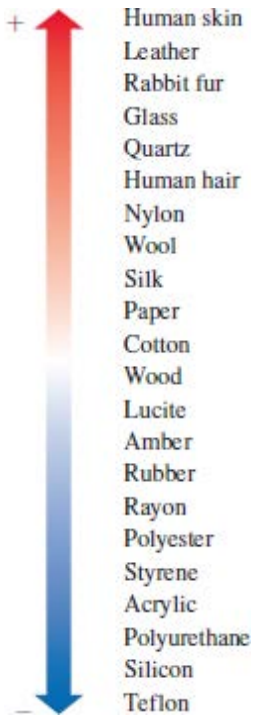

FIGURE 21.12
Triboelectric series for some common materials.

Finally, as a rule of thumb, more intense rubbing creates greater charge transfer. This occurs because more intense contact increases friction, which in turn creates more microscopic points of charge transfer on the surfaces of the materials.

21.5 Electrostatic Force—Coulomb's Law

The law of electric charges is evidence of a force between any two charges at rest. Experiments show that for the electrostatic force exerted by a charge q_2 on a charge q_1, $\vec{F}_{2\to1}$, the force on q_1 points toward q_2 if the charges have opposite signs and away from q_2 if the charges have like signs (Figure 21.13). This force on one charge due to another charge always acts along the line between the two charges. **Coulomb's Law** gives the magnitude of this force as

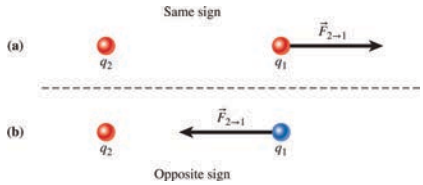

FIGURE 21.13 The force exerted by charge 2 on charge 1: (a) two charges with the same sign; (b) two charges with opposite signs.

$$F = k\frac{|q_1 q_2|}{r^2}, \tag{21.6}$$

where q_1 and q_2 are electric charges, $r = \vec{r}_1 - \vec{r}_2$ is the distance between them, and

$$k = 8.99 \cdot 10^9 \frac{\text{N m}^2}{\text{C}^2} \qquad \textbf{(21.7)}$$

is **Coulomb's constant.** You can see that 1 coulomb is a *very* large charge. If two charges of 1 C each were at a distance of 1 m apart, the magnitude of the force they would exert on each other would be 8.99 billion N. For comparison, this force equals the weight of 450 fully loaded space shuttles!

Concept Check 21.3

You place two charges a distance *r* apart. Then you double each charge and double the distance between the charges. How does the force between the two charges change?

a) The new force is twice as large.

b) The new force is half as large.

c) The new force is four times larger.

d) The new force is four times smaller.

e) The new force is the same.

The relationship between Coulomb's constant and another constant, ϵ_0, called the **electric permittivity of free space,** is

$$k = \frac{1}{4\pi\epsilon_0}. \qquad \textbf{(21.8)}$$

Consequently, the value of ϵ_0 is

$$\epsilon_0 = 8.85 \cdot 10^{-12} \frac{\mathrm{C}^2}{\mathrm{N\,m}^2}. \qquad \textbf{(21.9)}$$

An alternative way of writing equation 21.6 is then

$$F = \frac{1}{4\pi\epsilon_0} \frac{|q_1 q_2|}{r^2}. \qquad \textbf{(21.10)}$$

As you'll see in the next few chapters, some equations in electrostatics are more convenient to write with k, while others are more easily written in terms of $1/(4\pi\epsilon_0)$.

Concept Check 21.4

What do the forces acting on the charge q_3 in Figure 21.15 indicate about the signs of the three charges?

a) All three charges must be positive.

b) All three charges must be negative.

c) Charge q_3 must be zero.

d) Charges q_1 and q_2 must have opposite signs.

e) Charges q_1 and q_2 must have the same sign, and q_3 must have the opposite sign.

Note that the charges in equations 21.6 and 21.10 can be positive or negative, so the product of the charges can also be positive or negative. Since opposite charges attract and like charges repel, a negative value for the product $q_1 q_2$ signifies attraction and a positive value means repulsion.

Finally, Coulomb's Law for the force due to charge 2 on charge 1 can be written in vector form:

$$\overrightarrow{F}_{2\to 1} = -k\frac{q_1 q_2}{r^3}\left(\overrightarrow{r}_2 - \overrightarrow{r}_1\right) = -k\frac{q_1 q_2}{r^2}\hat{r}_{21}. \quad \textbf{(21.11)}$$

In this equation, $\hat{r}_{21}$ is a unit vector pointing from q_2 to q_1 (see Figure 21.14). The negative sign indicates that the force is repulsive if both charges are positive or both charges are negative. In that case, $\overrightarrow{F}_{2\to 1}$ points away from charge 2, as depicted in Figure 21.14a. On the other hand, if one of the charges is positive and the other negative, then $\overrightarrow{F}_{2\to 1}$ points toward charge 2, as shown in Figure 21.14b.

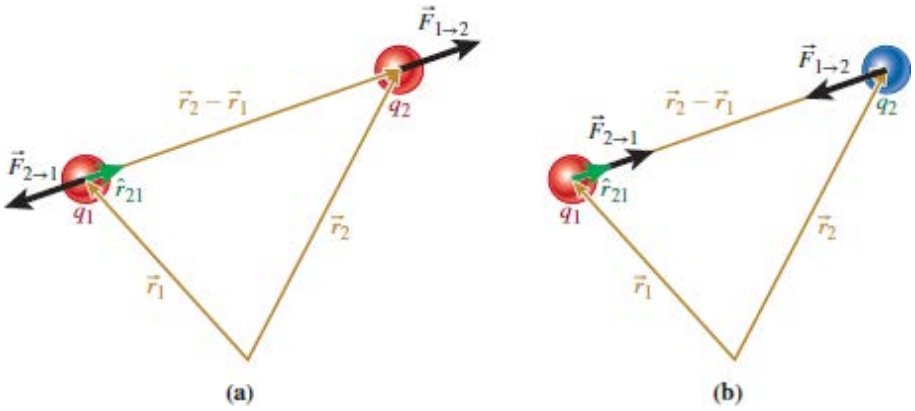

FIGURE 21.14 Vector representation of the electrostatic forces that two charges exert on each other: (a) two charges of like sign; (b) two charges of opposite sign.

If charge 2 exerts the force $\overrightarrow{F}_{2\to 1}$ on charge 1, then the force $\overrightarrow{F}_{1\to 2}$ that charge 1 exerts on charge 2 is simply obtained from Newton's Third Law (see Chapter 4): $\overrightarrow{F}_{1\to 2} = -\overrightarrow{F}_{2\to 1}$.

Superposition Principle

So far in this chapter, we have been dealing with two charges. Now let's consider three point charges, q_1, q_2, and q_3, at positions x_1, x_2, and x_3, respectively, as shown in Figure 21.15. The force exerted by charge 1 on charge 3, $\vec{F}_{1\to3}$, is given by

$$\vec{F}_{1\to3} = -\frac{kq_1q_3}{(x_3 - x_1)^2}\hat{x}.$$

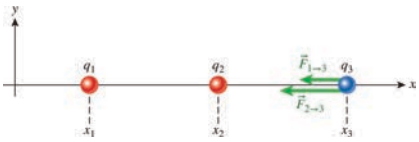

FIGURE 21.15 The forces exerted on charge 3 by charge 1 and charge 2.

Concept Check 21.5

Assuming that the lengths of the vectors in Figure 21.15 are proportional to the magnitudes of the forces they represent, what do they indicate about the magnitudes of the charges q_1 and q_2? (*Hint:* The distance between x_1 and x_2 is the same as the distance between x_2 and x_3.)

a) $|q_1| < |q_2|$

b) $|q_1| = |q_2|$

c) $|q_1| > |q_2|$

d) The answer cannot be determined from the information given in the figure.

The force exerted by charge 2 on charge 3 is

$$\vec{F}_{2\to 3} = \frac{kq_2q_3}{(x_3 - x_2)^2}\hat{x}.$$

The force that charge 1 exerts on charge 3 is not affected by the presence of charge 2. The force that charge 2 exerts on charge 3 is not affected by the presence of charge 1. In addition, the forces exerted by charge 1 and charge 2 on charge 3 add vectorially to produce a net force on charge 3:

$$\vec{F}_{\text{net}\to 3} = \vec{F}_{1\to 3} + \vec{F}_{2\to 3}.$$

This superposition of forces is completely analogous to that described in Chapter 4 for the forces of gravity and friction.

In general, we can express the electrostatic force, $\vec{F}\left(\vec{r}\right)$, acting on a charge q at position $\vec{r}$ due to a collection of charges, q_i, at positions $\vec{r}_i$ as

$$\vec{F}\left(\vec{r}\right) = kq\sum_{i=1}^{n} q_i \frac{\vec{r}_i - \vec{r}}{\left|\vec{r}_i - \vec{r}\right|^3}. \qquad \textbf{(21.12)}$$

We obtain this result using superposition of the forces and equation 21.11 for each pairwise interaction.

Concept Check 21.6

Three charges are arranged on a straight line as shown in the figure. What is the direction of the electrostatic force on the *middle* charge?

a) ➡

b) ⬅

c) ⬇

d) ⬆

e) There is no force on that charge.

Concept Check 21.7

Three charges are arranged on a straight line as shown in the figure. What is the direction of the electrostatic force on the *right* charge? (Note that the left charge is double what it was in Concept Check 21.6.)

a) ➡

b) ⬅

c) ⬇

d) ⬆

e) There is no force on that charge.

EXAMPLE 21.2 Electrostatic Force inside the Atom

PROBLEM 1

What is the magnitude of the electrostatic force that the two protons inside the nucleus of a helium atom exert on each other?

SOLUTION 1

The two protons and two neutrons in the nucleus of the helium atom are held together by the strong force; the electrostatic force is pushing the protons apart. The charge of each proton is $q_{\mathrm{p}} = +e$. A distance of approximately $r = 2 \cdot 10^{-15}\,\mathrm{m}$ separates the two protons. Using Coulomb's Law, we can find the force:

$$F = k\frac{|q_{\mathrm{p}}q_{\mathrm{p}}|}{r^2} = \left(8.99 \cdot 10^{9}\,\frac{\mathrm{N\,m^2}}{\mathrm{C^2}}\right)\frac{\left(+1.6 \cdot 10^{-19}\mathrm{C}\right)\left(+1.}{\left(2 \cdot 10^{-15}\mathrm{m}\right.}$$

Therefore, the two protons in the atomic nucleus of a helium atom are being pushed apart with a force of 58 N (approximately the weight of a small dog). Considering the size of the nucleus, this is an astonishingly large force. Why do atomic nuclei not simply explode? The answer is that an even stronger force, the aptly named strong force, keeps them together.

PROBLEM 2

What is the magnitude of the electrostatic force between a gold nucleus and an electron of the gold atom in an orbit with radius $4.88 \cdot 10^{-12}\mathrm{m}$?

SOLUTION 2

The negatively charged electron and the positively charged gold nucleus attract each other with a force whose magnitude is

$$F = k\frac{|q_{\mathrm{e}}q_{\mathrm{N}}|}{r^2},$$

where the charge of the electron is $q_{\mathrm{e}} = -e$ and the charge of the gold nucleus is $q_{\mathrm{N}} = +79e$. The force between the electron and the nucleus is then

$$F = k\frac{|q_{\mathrm{e}}q_{\mathrm{N}}|}{r^2} = \left(8.99 \cdot 10^{9}\,\frac{\mathrm{N\,m^2}}{\mathrm{C^2}}\right)\frac{\left(1.6 \cdot 10^{-19}\mathrm{C}\right)\left[(79)\right(}{\left(4.88 \cdot 10^{-}\right.}$$

Thus, the magnitude of the electrostatic force exerted on an electron in a gold atom by the nucleus is about 100,000 times less than that between protons inside a nucleus.

Page 669

Note: The gold nucleus has a mass that is approximately 400,000 times that of the electron. But the force the gold nucleus exerts on the electron has exactly the same magnitude as the force that the electron exerts on the gold nucleus. You may say that this is obvious from Newton's Third Law (see Chapter 4), which is true. But it is worth emphasizing that this basic law holds for electrostatic forces as well.

EXAMPLE 21.3 Equilibrium Position

PROBLEM

Two charged particles are placed as shown in Figure 21.16: $q_1 = 0.15\mu C$ is located at the origin, and $q_2 = 0.35\,\mu C$ is located on the positive x-axis at $x_2 = 0.40\,\text{m}$. Where should a third charged particle, q_3, be placed to be at an equilibrium point (such that the forces on it sum to zero)?

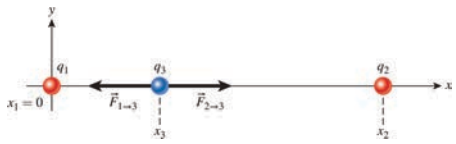

FIGURE 21.16
Placement of three charged particles. The third particle is shown as having a negative charge.

SOLUTION

Let's first determine where *not* to put the third charge. If the third charge is placed anywhere off the x-axis, there will always be a force component pointing toward or away from the x-axis. Thus, we can find an equilibrium point (a point where the forces sum to zero) only *on* the x-axis. The x-axis can be divided into three different segments: $x \leq x_1 = 0$, $x_1 < x < x_2$, and $x_2 \leq x$. For $x \leq x_1 = 0$, the force vectors from both q_1 and q_2 acting on q_3 will point in the positive direction if the charge is negative and in the negative direction if the charge is positive. Because we are looking for a location where the two forces cancel, the segment $x \leq x_1 = 0$ can be excluded. A similar argument excludes $x \geq x_2$.

In the remaining segment of the x-axis, $x_1 < x < x_2$, the forces from q_1 and q_2 on q_3 point in opposite directions. We look for the location, x_3, where the absolute magnitudes of both forces are equal and the forces thus sum to zero. We express the equality of the two forces as

$$\overrightarrow{F}_{1\to 3} \;=\; \overrightarrow{F}_{2\to 3}\ ,$$

which we can rewrite as

$$k\frac{|q_1 q_3|}{(x_3 - x_1)^2} = k\frac{|q_3 q_2|}{(x_2 - x_3)^2}.$$

We now see that the magnitude and sign of the third charge do not matter because that charge cancels out, as does the constant k, giving us

$$\frac{q_1}{(x_3 - x_1)^2} = \frac{q_2}{(x_2 - x_3)^2}$$

or

$$q_1(x_2 - x_3)^2 = q_2(x_3 - x_1)^2. \qquad \textbf{(i)}$$

Taking the square root of both sides and solving for x_3, we find

$$\sqrt{q_1}(x_2 - x_3) = \sqrt{q_2}(x_3 - x_1),$$

or

$$x_3 = \frac{\sqrt{q_1}x_2 + \sqrt{q_2}x_1}{\sqrt{q_1} + \sqrt{q_2}}.$$

We can take the square root of both sides of equation (i) because $x_1 < x_3 < x_2$, and so both of the roots, $x_2 - x_3$ and $x_3 - x_1$, are assured to be positive.

Inserting the numbers given in the problem statement, we obtain

$$x_3 = \frac{\sqrt{q_1}x_2 + \sqrt{q_2}x_1}{\sqrt{q_1} + \sqrt{q_2}} = \frac{\sqrt{0.15\,\mu\text{C}}(0.4\,\text{m})}{\sqrt{0.15\,\mu\text{C}} + \sqrt{0.35\,\mu\text{C}}} = 0.16$$

This result makes sense because we expect the equilibrium point to reside closer to the smaller charge.

SOLVED PROBLEM 21.1 Charged Balls

PROBLEM

Two identical charged balls hang from the ceiling by insulated ropes of equal length, $\ell = 1.50\,\text{m}$ (Figure 21.17). A charge $q = 25.0\,\mu\text{C}$ is applied to each ball. Then the two balls hang at rest, and each supporting rope has an angle of 25.0° with respect to the vertical (Figure 21.17a). What is the mass of each ball?

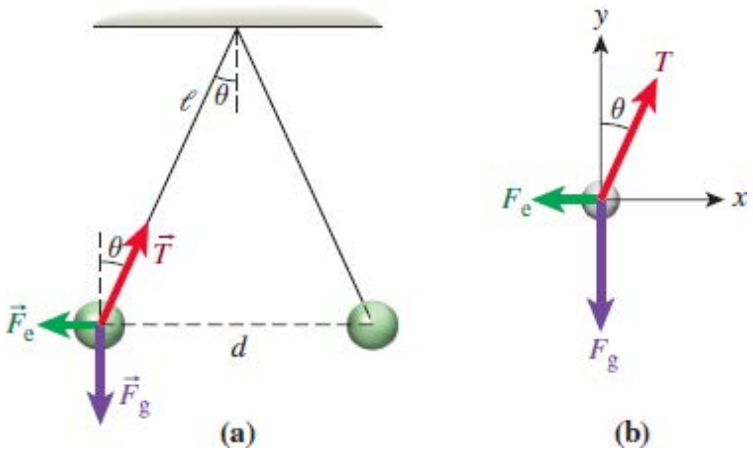

FIGURE 21.17 (a) Two charged balls hanging from the ceiling in their equilibrium position. (b) Free-body diagram for the left-hand charged ball.

SOLUTION

THINK

Each charged ball has three forces acting on it: the force of gravity, the repulsive electrostatic force, and the tension in the supporting rope. Using the first condition for static equilibrium from Chapter 11, we know that the sum of all the forces on each ball must be zero. We can resolve the components of the three forces and set them equal to zero, allowing us to solve for the mass of the charged balls.

SKETCH

A free-body diagram for the left-hand ball is shown in Figure 21.17b.

RESEARCH

The condition for static equilibrium says that the sum of the x-components of the three forces acting on the ball must equal zero and the sum of y-components of these forces must equal zero. The sum of the x-components of the forces is

$$T \sin\theta - F_{\mathrm{e}} = 0, \qquad \textbf{(i)}$$

where T is the magnitude of the string tension, θ is the angle of the string relative to the vertical, and F_{e} is the magnitude of the electrostatic force. The sum of the y-components of the forces is

$$T \cos\theta - F_{\mathrm{g}} = 0. \qquad \textbf{(ii)}$$

The force of gravity, F_{g}, is just the weight of the charged ball:

$$F_{\mathrm{g}} = mg, \qquad \textbf{(iii)}$$

where m is the mass of the charged ball. The electrostatic force the two balls exert on each other is given by

$$F_{\mathrm{e}} = k\frac{q^2}{d^2}, \qquad \textbf{(iv)}$$

where d is the distance between the two balls. We can express the distance between the two balls in terms of the length of the string, ℓ, by looking at Figure 21.17a. We see that

$$\sin\theta = \frac{d/2}{\ell}. \qquad \textbf{(v)}$$

We can then express the electrostatic force in terms of the angle with respect to the vertical, θ, and the length of the string, ℓ:

$$F_{\mathrm{e}} = k\frac{q^2}{(2\ell\sin)^2} = k\frac{q^2}{4\ell^2\sin^2\theta}.$$

SIMPLIFY

We divide equation (i) by equation (ii):

$$\frac{T\sin\theta}{T\cos\theta} = \frac{F_{\mathrm{e}}}{F_{\mathrm{g}}},$$

which, after the (unknown) string tension is canceled out, becomes

$$\tan\theta = \frac{F_{\mathrm{e}}}{F_{\mathrm{g}}}.$$

Substituting from equations (iii) and (v) for the force of gravity and the electrostatic force, we get

$$\tan\theta = \frac{k\dfrac{q^2}{4\ell^2\sin^2\theta}}{mg} = \frac{kq^2}{4mg\ell^2\sin^2\theta}.$$

Solving for the mass of the ball, we obtain

$$m = \frac{kq^2}{4g\ell^2 \sin^2\theta \, \tan\theta}.$$

CALCULATE

Putting in the numerical values gives

$$m = \frac{\left(8.99 \cdot 10^9 \text{ N m}^2/\text{C}^2\right)(25.0\,\mu\text{C})^2}{4(9.81 \text{ m/s}^2)(1.50 \text{ m})^2\left(\sin^2 25.0^\circ\right)(\tan 25.0^\circ)} = 0.$$

ROUND

We report our result to three significant figures:

$$m = 0.764 \text{ kg}.$$

DOUBLE-CHECK

To double-check, we make the small-angle approximations that sin $\sin\theta \approx \tan\theta \approx \theta$ and $\cos\theta \approx 1$. The tension in the string then approaches mg, and we can express the x-components of the forces as

$$T\sin\theta \approx mg\theta = F_\text{e} = k\frac{q^2}{d^2} \approx k\frac{q^2}{(2\ell\theta)^2}.$$

Solving for the mass of the charged ball, we get

$$m = \frac{kq^2}{4g\ell^2\theta^3} = \frac{\left(8.99 \cdot 10^9 \text{N m}^2/\text{C}^2\right)(25.0\,\mu\text{C})^2}{4(9.81\text{m/s}^2)(1.50 \text{ m})^2(0.436 \text{ rad})^3} = 0.$$

which is close to our answer.

Self-Test Opportunity 21.2

A positive point charge $+q$ is placed at point *P,* to the right of two charges q_1 and q_2, as shown in the figure. The net electrostatic force on the positive charge $+q$ is found to be zero. Identify each of the following statements as true or false.

a) Charge q_2 must have the opposite sign from q_1 and be smaller in magnitude.

b) The magnitude of charge q_1 must be smaller than the magnitude of charge q_2.

c) Charges q_1 and q_2 must have the same sign.

d) If q_1 is negative, then q_2 must be positive.

e) Either q_1 or q_2 must be positive.

Electrostatic Precipitator

An application of electrostatic charging and electrostatic forces is the cleaning of emissions from coal-fired power plants. A device called an **electrostatic precipitator (ESP)** is used to remove ash and other particulates produced when coal is burned to generate electricity. The operation of this device is illustrated in Figure 21.18.

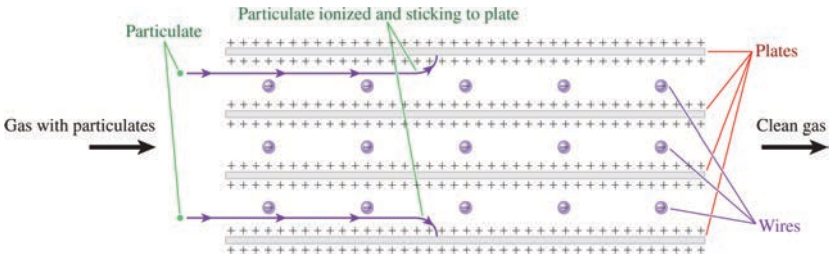

FIGURE 21.18 Operation of an electrostatic precipitator used to clean the exhaust gas of a coal-fired power plant. The view is from the top of the device.

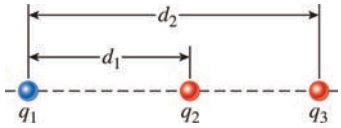
Concept Check 21.8

Consider three charges placed along the *x*-axis, as shown in the figure.



The values of the charges are $q_1 = -8.10\,\mu\text{C}$, $q_2 = 2.16\,\mu\text{C}$, and $q_3 = 2.16\,\text{pC}$. The distance between q_1 and q_2 is $d_1 = 1.71\,\text{m}$. The distance between q_1 and q_3 is $d_2 = 2.62\,\text{m}$. What is the magnitude of the total electrostatic force exerted on q_3 by q_1 and q_2?

a) $2.77 \cdot 10^{-8}\,\text{N}$

b) $7.92 \cdot 10^{-6}\,\text{N}$

c) $1.44 \cdot 10^{-5}\,\text{N}$

d) $2.22 \cdot 10^{-4}\,\text{N}$

e) $6.71 \cdot 10^{-2}\,\text{N}$

The ESP consists of wires and plates, with the wires held at a high negative voltage relative to the series of plates held at a positive voltage. (Here the term *voltage* is used colloquially; in Chapter 23, the concept will be defined in terms of electric potential difference.) In Figure 21.18, the exhaust gas from the coal-burning process enters the ESP from the left. Particulates passing near the wires pick up a negative charge. These particles are then attracted to one of the positive plates and stick there. The gas continues through the ESP, leaving the ash and other particulates behind. The accumulated material is then shaken off the plates to a hamper below. This waste can be used for many purposes, including construction materials and fertilizer.

Figure 21.19 shows an example of a coal-fired power plant that incorporates an ESP.

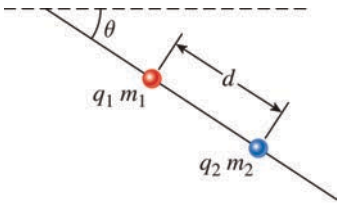
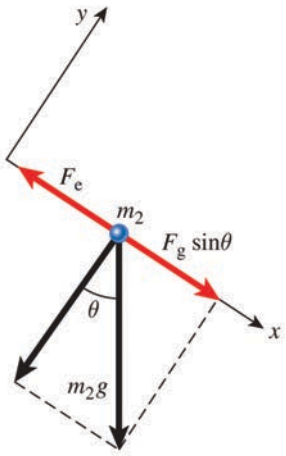
SOLVED PROBLEM 21.2 Bead on a Wire

PROBLEM

A bead with charge $q_1 = +1.28\,\mu\text{C}$ is fixed in place on an insulating wire that makes an angle of $\theta = 42.3^\circ$ with respect to the horizontal (Figure 21.20a). A second bead with charge $q_2 = -5.06\,\mu\text{C}$ slides without friction on the wire. At a distance $d = 0.380\,\text{m}$ between the beads, the net force on the second bead is zero. What is the mass, m_2, of the second bead?



(a)



(b)

FIGURE 21.20 (a) Two charged beads on a wire. (b) Free-body diagram of the forces acting on the second bead.

SOLUTION

THINK

The force of gravity pulling the bead of mass m_2 down the wire is offset by the attractive electrostatic force between the positive charge on the first bead and the negative charge on the second bead. The second bead can be thought of as sliding on an inclined plane.

SKETCH

Figure 21.20b shows a free-body diagram of the forces acting on the second bead. We have defined a coordinate system in which the positive x-direction is down the wire. The force exerted on m_2 by the wire can be omitted because this force has only a y-component, and we can solve the problem by analyzing just the x-components of the forces.

RESEARCH

The attractive electrostatic force between the two beads balances the component of the force of gravity that acts on the second bead down the wire. The electrostatic force acts in the negative x-direction and its magnitude is given by

$$F_{\mathrm{e}} = k\frac{|q_1 q_2|}{d^2}. \qquad \textbf{(i)}$$

The x-component of the force of gravity acting on the second bead corresponds to the component of the weight of the second bead that is parallel to the wire. Figure 21.20b indicates that the component of the weight of the second bead down the wire is given by

$$F_{\mathrm{g}} = m_2 g \sin\theta. \qquad \textbf{(ii)}$$

SIMPLIFY

For equilibrium, the electrostatic force and the gravitational force are equal: $F_{\mathrm{e}} = F_{\mathrm{g}}$. Substituting the expressions for these

forces from equations (i) and (ii) yields

$$k\frac{|q_1 q_2|}{d^2} = m_2 \sin\theta.$$

Solving this equation for the mass of the second bead gives us

$$m_2 = \frac{k\,|q_1 q_2|}{d^2 g \sin\theta}.$$

CALCULATE

We put in the numerical values and get

$$m_2 = \frac{kq_1 q_2}{d^2 g \sin\theta} = \frac{\left(8.99 \cdot 10^9\ \mathrm{N\,m^2/C^2}\right)(1.28\ \mu\mathrm{C})(5.06\ \mu$$
$$(0.380\ \mathrm{m})^2\left(9.81\ \mathrm{m/s^2}\right)(\sin 42.3^\circ)$$

ROUND

We report our result to three significant figures:

$$m_2 = 0.0611\ \mathrm{kg} = 61.1\ \mathrm{g}.$$

DOUBLE-CHECK

To double-check, let's calculate the mass of the second bead assuming that the wire is vertical, that is, $\theta = 90^\circ$. We can then set the weight of the second bead equal to the electrostatic force between the two beads:

$$k\frac{|q_1 q_2|}{d^2} = m_2 g.$$

Solving for the mass of the second bead, we obtain

$$m_2 = \frac{kq_1 q_2}{d^2 g} = \frac{\left(8.99 \cdot 10^9\ \mathrm{N\,m^2/C^2}\right)(1.28\ \mu\mathrm{C})(5.06\ \mu\mathrm{C})}{(0.380\ \mathrm{m})^2(9.81\ \mathrm{m/s^2})}$$

As the angle of the wire relative to the horizontal decreases, the calculated mass of the second bead will increase. Our result of 0.0611 kg is somewhat higher than the mass that can be supported with a vertical wire, so it seems reasonable.

Laser Printer

Another example of a device that applies electrostatic forces is the laser printer. The operation of such a printer is illustrated in Figure 21.21. The paper path follows the blue arrows. Paper is taken from the paper tray or fed manually through the alternate paper feed. The paper passes over a drum where the toner is placed on the surface of the paper and then passes through a fuser that melts the toner and permanently affixes it to the paper.

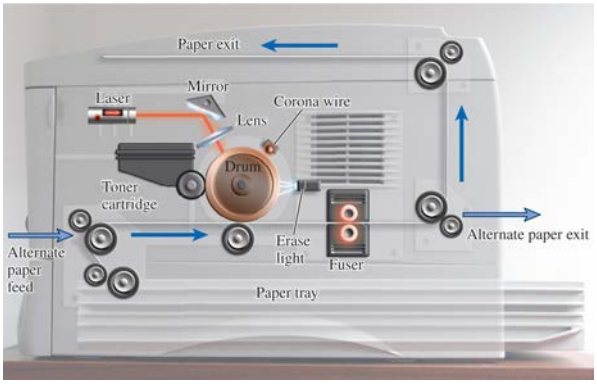


FIGURE 21.21 The operation of a typical laser printer.

W. Bauer and G. D. Westfall

The drum consists of a metal cylinder coated with a special photosensitive material. The photosensitive surface is an insulator that retains charge in the absence of light, but discharges quickly if light is incident on the surface. The drum rotates so that its surface speed is the same as the speed of the moving paper. The basic principle of the operation of the drum is illustrated in Figure 21.22.

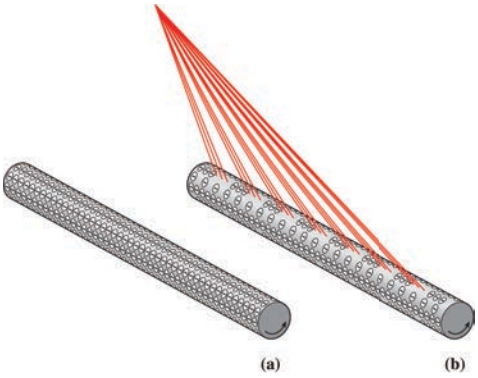

FIGURE 21.22 (a) The completely charged drum of a laser printer. This drum will produce a blank page. (b) A drum on which one line of information is being recorded by a laser. Wherever the laser strikes the charged drum, the negative charge is neutralized, and the discharged area will attract toner that will produce an image on the paper.

The drum is negatively charged with electrons using a wire held at high voltage. Then laser light is directed at the surface of the drum. Wherever the laser light strikes the surface of the drum, the surface at that point is discharged. A laser is used because its beam is narrow and remains focused. A line of the image being printed is written one pixel (picture element or dot) at a time using a laser beam directed by a moving mirror and a lens. A typical laser printer can write 600 – 1200 pixels per inch. The surface of the drum then passes by a roller that picks up toner from the toner cartridge. Toner consists of small, black, insulating particles composed of a plastic-like material. The toner roller is charged to the same negative voltage as the drum. Therefore, wherever the surface of the drum has been discharged, electrostatic forces deposit toner on the surface of the drum. Any portion of the drum

surface that has not been exposed to the laser will not pick up toner.

As the drum rotates, it next comes in contact with the paper. The toner is then transferred from the surface of the drum to the paper. As the drum rotates, any remaining toner is scraped off and the surface is neutralized with an erase light or a rotating erase drum in preparation for printing the next image. The paper then continues on to the fuser, which melts the toner, producing a permanent image on the paper.

SOLVED PROBLEM 21.3 Four Charged Objects

Consider four charges placed at the corners of a square with side length 1.25 m, as shown in Figure 21.23a.

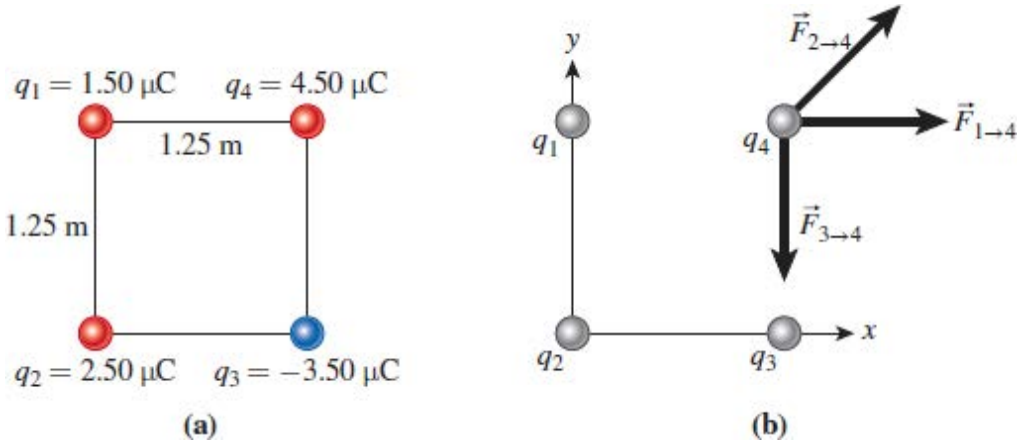

FIGURE 21.23 (a) Four charges placed at the corners of a square. (b) The forces exerted on q_4 by the other three charges.

PROBLEM

What are the magnitude and the direction of the electrostatic force on q_4 resulting from the other three charges?

SOLUTION

THINK

The electrostatic force on q_4 is the vector sum of the forces resulting from its interactions with the other three charges. Thus, it is important to avoid simply adding the individual force magnitudes algebraically. Instead we need to determine the individual force components in each spatial direction and

add those to find the components of the net force vector. Then we need to calculate the length of that net force vector.

SKETCH

Figure 21.23b shows the four charges in an xy-coordinate system with its origin at the location of q_2.

RESEARCH

The net force on q_4 is the vector sum of the forces $\vec{F}_{1\to4}$, $\vec{F}_{2\to4}$, and $\vec{F}_{3\to4}$. The x-component of the summed forces is

$$F_x = k\frac{|q_1 q_4|}{d^2} + k\frac{|q_2 q_4|}{\left(\sqrt{2}d\right)^2}\cos 45^\circ = \frac{kq_4}{d^2}\left(q_1 + \frac{q}{}\right.$$

where d is the length of a side of the square and, as Figure 21.23b indicates, the x-component of $\vec{F}_{3\to4}$ is zero. The y-component of the summed forces is

$$F_y = k\frac{|q_2 q_4|}{\left(\sqrt{2}d\right)^2}\sin 45^\circ - k\frac{|q_3 q_4|}{d^2} = \frac{kq_4}{d^2}\left(\frac{q_2}{2}\sin\right.$$

where, as Figure 21.23b indicates, the y-component of $\vec{F}_{1\to4}$ is zero.

The magnitude of the net force is given by

$$F = \sqrt{F_x^2 + F_y^2}, \qquad \textbf{(iii)}$$

and the angle of the net force is given by

$$\tan\theta = \frac{F_y}{F_x}.$$

SIMPLIFY

We substitute the expressions for F_x and F_y from equations (i) and (ii) into equation (iii):

$$F = \sqrt{\left[\frac{kq_4}{d^2}\left(q_1 + \frac{q_2}{2}\cos 45^\circ\right)\right]^2 + \left[\frac{kq_4}{d^2}\left(\frac{q_2}{2}\sin 45^\circ + q_3\right)\right]^2}$$

We can rewrite this as

$$F = \frac{kq_4}{d^2}\sqrt{\left(q_1 + \frac{q_2}{2}\cos 45^\circ\right)^2 + \left(\frac{q_2}{2}\sin 45^\circ + q_3\right)^2}.$$

For the angle of the force, we get

$$\theta = \tan^{-1}\left(\frac{F_y}{F_x}\right) = \tan^{-1}\frac{\frac{kq_4}{d^2}\left(\frac{q_2}{2}\sin 45^\circ + q_3\right)}{\frac{kq_4}{d^2}\left(q_1 + \frac{q_2}{2}\cos 45^\circ\right)} =$$

CALCULATE

Putting in the numerical values, we get

$$\frac{q_2}{2}\sin 45^\circ = \frac{q_2}{2}\cos 45^\circ = \frac{2.50\,\mu\text{C}}{2\sqrt{2}} = 0.883883\,\mu\text{C}.$$

The magnitude of the force is then

$$F = \frac{\left(8.99 \cdot 10^9\ \mathrm{N\,m^2/C^2}\right)(4.50\,\mu\mathrm{C})}{(1.25\ \mathrm{m})^2}\sqrt{(1.50\,\mu\mathrm{C}+0.883}$$
$$= 0.0916379\ \mathrm{N}.$$

For the direction of the force, we obtain

$$\theta = \tan^{-1}\frac{\left(\frac{q_2}{2}\sin 45^\circ + q_3\right)}{\left(q_1 + \frac{q_2}{2}\cos 45^\circ\right)} = \tan^{-1}\left(\frac{(0.883883\,\mu}{(1.50\,\mu\mathrm{C}+($$

ROUND

We report our results to three significant figures:

$$F = 0.0916\ \mathrm{N}$$

and

$$\theta = -47.7^\circ.$$

DOUBLE-CHECK

To double-check our result, we calculate the magnitude of the three forces acting on q_4. For $\overrightarrow{F}_{1\to 4}$, we get

$$F_{1\to 4} = k\frac{|q_1 q_4|}{r_{14}^2} = \frac{\left(8.99 \cdot 10^9\ \mathrm{N\,m^2/C^2}\right)(1.50\,\mu\mathrm{C})(4.50\,\mu}{(1.25\ \mathrm{m})^2}$$

For $\overrightarrow{F}_{2\to 4}$, we get

$$F_{2\to4} = k\frac{|q_2 q_4|}{r_{24}^2} = \frac{\left(8.99\cdot10^9\ \mathrm{N\,m^2/C^2}\right)(2.50\,\mu\mathrm{C})(4.50\,\mu}{\left[\sqrt{2}(1.25\ \mathrm{m})\right]^2}$$

For $F_{3\to4}$, we get

$$F_{3\to4} = k\frac{|q_3 q_4|}{r_{34}^2} = \frac{\left(8.99\cdot10^9\ \mathrm{N\,m^2/C^2}\right)(3.50\,\mu\mathrm{C})(4.50\,\mu}{(1.25\ \mathrm{m})^2}$$

All three of the magnitudes of the individual forces are of the same order as our result for the net force. This gives us confidence that our answer is not off by a large factor.

The direction we obtained also seems reasonable, because it orients the resulting force downward and to the right, as could be expected from looking at Figure 21.23b.

Concept Check 21.9

b) ↖

c) ↗

d) ↘

e) There is no force on that charge.

21.6 Coulomb's Law and Newton's Law of Gravitation

Coulomb's Law describing the electrostatic force between two electric charges, F_{e}, has a form similar to Newton's Law describing the gravitational force between two masses, F_{g}:

$$F_g = G\frac{m_1 m_2}{r^2} \text{ and } F_{\text{e}} = k\frac{|q_1 q_2|}{r^2},$$

where m_1 and m_2 are the two masses, q_1 and q_2 are the two electric charges, and r is the distance of separation. Both forces vary with the inverse square of the distance. The electrostatic force can be attractive or repulsive because charges can have positive or negative signs. (See Figure 21.14a and b.) The gravitational force is always attractive because there is only one kind of mass. (For the gravitational force, only the case depicted in Figure 21.14b is possible.) The relative strengths of the forces are given by the proportionality constants *k* and *G*.

EXAMPLE 21.4 Forces between Electrons

Let's evaluate the relative strengths of the two interactions by calculating the ratio of the electrostatic force and the gravitational force that two electrons exert on each other. This ratio is given by

$$\frac{F_e}{F_g} = \frac{kq_e^2}{Gm_{\mathrm{e}}^2}.$$

Because the dependence on distance is the same for both forces, there is no dependence on distance in the ratio of the two forces—it cancels out. The mass of an electron is $m_{\mathrm{e}} = 9.109 \cdot 10^{-31}\mathrm{kg}$, and its charge is $q_{\mathrm{e}} = -1.602 \cdot 10^{-19}\mathrm{C}$. Using the value of Coulomb's constant given in equation 21.7, $k = 8.99 \cdot 10^9\ \mathrm{N\,m^2/C^2}$, and the value of the universal gravitational constant, $G = 6.67 \cdot 10^{-11}\ \mathrm{N\,m^2/kg^2}$, we find numerically

$$\frac{F_{\mathrm{e}}}{F_{\mathrm{g}}} = \frac{\left(8.99 \cdot 10^9\ \mathrm{N\,m^2/C^2}\right)\left(1.602 \cdot 10^{-19}\ \mathrm{C}\right)^2}{\left(6.67 \cdot 10^{-11}\ \mathrm{N\,m^2/kg^2}\right)\left(9.109 \cdot 10^{-31}\ \mathrm{kg}\right)^2} = 4.1$$

Therefore, the electrostatic force between electrons is stronger than the gravitational force between them by more than 42 orders of magnitude.

Concept Check 21.11

The proton's mass is ~2000 times larger than the electron's mass. Therefore, the ratio F_e/F_g for two protons is _____ the value calculated in Example 21.4 for two electrons.

a) ~4 million times smaller than

b) ~2000 times smaller than

c) the same as

d) ~2000 times larger than

e) ~4 million times larger than

Despite the relative weakness of the gravitational force, it is the only force that matters on the astronomical scale. The reason for this dominance is that all stars, planets, and other objects of astronomical relevance carry no net charge. Therefore, there is no net electrostatic interaction between them, and gravity dominates.

Coulomb's Law of electrostatics applies to macroscopic systems down to the atom, though subtle effects in atomic and subatomic systems require use of a more sophisticated approach called *quantum electrodynamics*. Newton's law of gravitation fails in subatomic systems and also must be modified for some phenomena in astronomical systems, such as the precessional motion of Mercury around the Sun. These fine details of the gravitational interaction are governed by Einstein's theory of general relativity.

The similarities between the gravitational and electrostatic interactions will be covered further in the next two chapters, which address electric fields and electric potential.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- There are two kinds of electric charge, positive and negative. Like charges repel, and unlike charges attract.
- The quantum (elementary quantity) of electric charge is $e = 1.602 \cdot 10^{-19}\ \mathrm{C}$.
- The electron has charge $q_\mathrm{e} = -e$, and the proton has charge $q_\mathrm{p} = +e$. The neutron has zero charge.
- The net charge of an object is given by e times the number of protons, N_p, minus e times the number of electrons, N_e, that make up the object: $q = e.\,(N_\mathrm{p} - N_\mathrm{e})$.
- The total charge in an isolated system is always conserved.
- Objects can be charged directly by contact or indirectly by induction.
- Coulomb's Law describes the force that two stationary charges exert on each other:
  $$F = k\frac{|q_1 q_2|}{r^2} = \frac{1}{4\pi\epsilon_0}\frac{|q_1 q_2|}{r^2}.$$
- The constant in Coulomb's Law is
  $$k = \frac{1}{4\pi\epsilon_0} = 8.99 \cdot 10^9 \frac{\mathrm{N\,m^2}}{\mathrm{C^2}}.$$
- The electric permittivity of free space is
  $$\epsilon_0 = 8.85 \cdot 10^{-12} \frac{\mathrm{C^2}}{\mathrm{N\,m^2}}.$$

PROBLEM-SOLVING GUIDELINES

1. For problems involving Coulomb's Law, drawing a free-body diagram showing the electrostatic force vectors acting on a charged particle is often helpful. Pay careful attention to signs; a negative force between two particles indicates attraction, and a positive force indicates repulsion. Be sure that the directions of forces in the diagram match the signs of forces in the calculations.

2. Use symmetry to simplify your work. However, be careful to take account of charge magnitudes and signs as well as distances. Two charges at equal distances from a third charge do not exert equal forces on that charge if they have different magnitudes or signs.

3. Units in electrostatics often have prefixes indicating powers of 10: Distances may be given in cm or mm; charges may be given in μC, nC, or pC; masses may be given in kg or g. Other units are also common. The best way to proceed is to convert all quantities to basic SI units, to be compatible with the value of k or $1/4\pi\epsilon_0$.

MULTIPLE-CHOICE QUESTIONS

21.1 When a metal plate is given a positive charge, which of the following is taking place?

a) Protons (positive charges) are transferred to the plate from another object.

b) Electrons (negative charges) are transferred from the plate to another object.

c) Electrons (negative charges) are transferred from the plate to another object, and protons (positive charges) are also transferred to the plate from another object.

d) It depends on whether the object conveying the charge is a conductor or an insulator.

21.2 The force between a charge of 25 μC and a charge of -10 μC is 8.0 N. What is the separation between the two charges?

a) 0.28 m

b) 0.53 m

c) 0.45 m

d) 0.15 m

21.3 A charge Q_1 is positioned on the x-axis at $x = a$. Where should a charge $Q_2 = -4Q_1$ be placed to produce a net electrostatic force of zero on a third charge, $Q_3 = Q_1$, located at the origin?

a) at the origin

b) at $x = 2a$

c) at $x = -2a$

d) at $x = -a$

21.4 Which one of these systems has the most negative charge?

a) 2 electrons

b) 3 electrons and 1 proton

c) 5 electrons and 5 protons

d) N electrons and $N - 3$ protons

e) 1 electron

21.5 Two point charges are fixed on the x-axis: $q_1 = 6.0\,\mu\text{C}$ is located at the origin, O, with $x_1 = 0.0\,\text{cm}$, and $q_2 = -3.0\,\mu\text{C}$ is located at point A, with $x_2 = 8.0\,\text{cm}$. Where should a third charge, q_3, be placed on the x-axis so that the total electrostatic force acting on it is zero?

a) 19 cm

b) 27 cm

c) 0.0 cm

d) 8.0 cm

e) -19 cm

21.6 Which of the following situations produces the largest net force on the charge Q?

a) Charge $Q = 1\,\text{C}$ is 1 m from a charge of $-2\,\text{C}$.

b) Charge $Q = 1\,\text{C}$ is 0.5 m from a charge of $-1\,\text{C}$.

c) Charge $Q = 1\,\text{C}$ is halfway between a charge of $-1\,\text{C}$. and a charge of 1 C that are 2 m apart.

d) Charge $Q = 1\,\text{C}$ is halfway between two charges of $-2\,\text{C}$ that are 2 m apart.

e) Charge $Q = 1\,\text{C}$ is a distance of 2 m from a charge of $-4\,\text{C}$.

21.7 Two protons placed near one another with no other objects close by would

a) accelerate away from each other.

b) remain motionless.

c) accelerate toward each other.

d) be pulled together at constant speed.

e) move away from each other at constant speed.

21.8 Two lightweight metal spheres are suspended near each other from insulating threads. One sphere has a net charge; the other sphere has no net charge. The spheres will

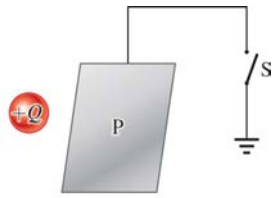
a) attract each other.

b) exert no net electrostatic force on each other.

c) repel each other.

d) do any of these things depending on the sign of the net charge on the one sphere.

21.9 A metal plate is connected by a conductor to a ground through a switch. The switch is initially closed. A charge $+Q$ is brought close to the plate without touching it, and then the switch is opened. After the switch is opened, the charge $+Q$ is removed. What is the charge on the plate then?



a) The plate is uncharged.

b) The plate is positively charged.

c) The plate is negatively charged.

d) The plate could be either positively or negatively charged, depending on the charge it had before $+Q$ was brought near.

21.10 You bring a negatively charged rubber rod close to a grounded conductor without touching it. Then you disconnect the ground. What is the sign of the charge on the conductor after you remove the charged rod?

a) negative

b) positive

c) no charge

d) cannot be determined from the information given

21.11 When a rubber rod is rubbed with rabbit fur, the rod becomes

a) negatively charged.

b) positively charged.

c) neutral.

d) either negatively charged or positively charged, depending on whether the fur is always moved in the same direction or is moved back and forth.

21.12 When a glass rod is rubbed with a polyester scarf, the rod becomes

a) negatively charged.

b) positively charged.

c) neutral.

d) either negatively charged or positively charged, depending on whether the scarf is always moved in the same direction or is moved back and forth.

21.13 Consider an electron with mass m and charge $-e$ moving in a circular orbit with radius r around a fixed proton with mass M and charge $+e$. The electron is held in orbit by the electrostatic force between itself and the proton. Which one of the following expressions for the speed of the electron is correct?

a) $v = \sqrt{\dfrac{ke^2}{mr}}$

b) $v = \sqrt{\dfrac{GM}{r}}$

c) $v = \sqrt{\dfrac{2ke^2}{mr^2}}$

d) $v = \sqrt{\dfrac{me^2}{kr}}$

e) $v = \sqrt{\dfrac{ke^2}{2Mr}}$

21.14 Consider an electron with mass m and charge $-e$ located a distance r from a fixed proton with mass M and charge $+e$. The electron is released from rest. Which one of the following expressions for the magnitude of the initial acceleration of the electron is correct?

a) $a = \dfrac{2ke^2}{mMr}$

b) $a = \sqrt{\dfrac{2e^2}{mkr}}$

c) $a = \dfrac{1}{2}me^2k^2$

d) $a = \dfrac{2ke^2}{mr}$

e) $a = \dfrac{ke^2}{mr^2}$

CONCEPTUAL QUESTIONS

21.15 If two charged particles (the charge on each is Q) are separated by a distance d, there is a force F between them. What is the force if the magnitude of each charge is doubled and the distance between them changes to $2d$?

21.16 Suppose the Sun and the Earth were each given an equal amount of charge of the same sign, just sufficient to cancel their gravitational attraction. How many times the charge on an electron would that charge be? Is this number a large fraction of the number of charges of either sign in the Earth?

21.17 It is apparent that the electrostatic force is *extremely* strong, compared to gravity. In fact, the electrostatic force is the basic force governing phenomena in daily life—the tension in a string, the normal forces between surfaces, friction, chemical reactions, and so forth—except weight. Why then did it take so long for scientists to understand this force? Newton came up with his gravitational law long before electricity was even crudely understood.

21.18 Occasionally, people who gain static charge by shuffling their feet on the carpet will have their hair stand on end. Why does this happen?

21.19 Two positive charges, each equal to Q, are placed a distance $2d$ apart. A third charge, $-0.2Q$, is placed exactly halfway between the two positive charges and is displaced a distance $x \ll d$ that is, x is much smaller than d) perpendicular to the line connecting the positive charges. What is the force on this charge? For $x \ll d$, how can you approximate the motion of the negative charge?

21.20 Why does a garment taken out of a clothes dryer sometimes cling to your body when you wear it?

21.21 Two charged spheres are initially a distance d apart. The magnitude of the force on each sphere is F. They are moved closer

to each other such that the magnitude of the force on each of them is 9*F*. By what factor has the distance between the two spheres changed?

21.22 How is it possible for one electrically neutral atom to exert an electrostatic force on another electrically neutral atom?

21.23 The scientists who first contributed to the understanding of the electrostatic force in the 18th century were well aware of Newton's law of gravitation. How could they deduce that the force they were studying was *not* a variant or some manifestation of the gravitational force?

21.24 Two charged particles move solely under the influence of the electrostatic forces between them. What shapes can their trajectories have?

21.25 Rubbing a balloon causes it to become negatively charged. The balloon then tends to cling to the wall of a room. For this to happen, must the wall be positively charged?

21.26 Two electric charges are placed on a line, as shown in the figure. Is it possible to place a charged particle (that is free to move) anywhere on the line between the two charges and have it not move?

21.27 Two electric charges are placed on a line as shown in the figure. Where on the line can a third charge be placed so that the force on that charge is zero? Does the sign or the magnitude of the third charge make any difference to the answer?

21.28 When a positively charged rod is brought close to a neutral conductor without touching it, will the rod experience an attractive force, a repulsive force, or no force at all? Explain.

21.29 When you exit a car and the humidity is low, you often experience a shock from static electricity created by sliding across the seat. How can you discharge yourself without experiencing a

painful shock? Why is it dangerous to get back into your car while fueling your car?

EXERCISES

Section 21.2

21.30 How many electrons are required to yield a total charge of 1.00 C?

21.31 The *faraday* is a unit of charge frequently encountered in electrochemical applications and named for the British physicist and chemist Michael Faraday. It consists of exactly 1 mole of elementary charges. Calculate the number of coulombs in 1.000 faraday.

21.32 Another unit of charge is the *electrostatic unit* (esu). It is defined as follows: Two point charges, each of 1 esu and separated by 1 cm, exert a force of exactly 1 dyne on each other: $1\text{ dyne} = 1\text{g cm/s}^2 = 1 \cdot 10^{-5}\text{ N}$.

a) Determine the relationship between the esu and the coulomb.

b) Determine the relationship between the esu and the elementary charge.

21.33 A current of 5.00 mA is enough to make your muscles twitch. Calculate how many electrons flow through your skin if you are exposed to such a current for 10.0 s.

•**21.34** How many electrons does 1.00 kg of water contain?

•**21.35** The Earth is constantly being bombarded by cosmic rays, which consist mostly of protons. These protons are incident on the Earth's atmosphere from all directions at a rate of 1245. protons per square meter per second. Assuming that the depth of Earth's atmosphere is 120.0 km, what is the total charge incident on the atmosphere in 5.000 min? Assume that the radius of the surface of the Earth is 6378. km.

•**21.36** Performing an experiment similar to Millikan's oil drop experiment, a student measures these charge magnitudes:

$3.26 \cdot 10^{-19}\text{ C}$

$6.39 \cdot 10^{-19}\text{ C}$

$5.09 \cdot 10^{-19}$ C

$4.66 \cdot 10^{-19}$ C

$1.53 \cdot 10^{-19}$ C

Find the charge on the electron using these measurements.

Section 21.3

•**21.37** A silicon sample is doped with phosphorus at 1 part per $1.00 \cdot 10^6$. Phosphorus acts as an electron donor, providing one free electron per atom. The density of silicon is $2.33\ \mathrm{g/cm^3}$, and its atomic mass is $28.09\ \mathrm{g/mol}$.

a) Calculate the number of free (conduction) electrons per unit volume of the doped silicon.

b) Compare the result from part (a) with the number of conduction electrons per unit volume of copper wire, assuming that each copper atom produces one free (conduction) electron. The density of copper is $8.96\ \mathrm{g/cm^3}$, and its atomic mass is $63.54\ \mathrm{g/mol}$.

Section 21.5

21.38 Two charged spheres are 8.00 cm apart. They are moved closer to each other by enough that the force on each of them increases four times. How far apart are they now?

21.39 Two identically charged particles separated by a distance of 1.00 m repel each other with a force of 1.00 N. What is the magnitude of the charges?

21.40 How far apart must two electrons be placed on the Earth's surface for there to be an electrostatic force between them equal to the weight of one of the electrons?

21.41 In solid sodium chloride (table salt), chloride ions have one more electron than they have protons, and sodium ions have one more proton than they have electrons. These ions are separated by about 0.28 nm. Calculate the electrostatic force between a sodium ion and a chloride ion.

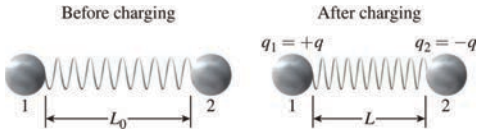
21.42 In gaseous sodium chloride, chloride ions have one more electron than they have protons, and sodium ions have one more proton than they have electrons. These ions are separated by about 0.24 nm. Suppose a free electron is located 0.48 nm above the midpoint of the sodium chloride molecule. What are the magnitude and the direction of the electrostatic force the molecule exerts on it?

21.43 Calculate the magnitude of the electrostatic force the two up quarks inside a proton exert on each other if they are separated by a distance of 0.900 fm.

21.44 A -4.00-μC charge lies 20.0 cm to the right of a 2.00-μC charge on the x-axis. What is the force on the 2.00-μC charge?

•**21.45** Two initially uncharged identical metal spheres, 1 and 2, are connected by an insulating spring (unstretched length $L_0 = 1.00\ \text{m}$, spring constant $K = 25.0\ \text{N/m}$), as shown in the figure. Charges $+q$ and $-q$ are then placed on the spheres, and the spring contracts to length $L = 0.635\ \text{m}$. Recall that the force exerted by a spring is $F_\text{s} = k\Delta x$, where Δx is the change in the spring's length from its equilibrium length. Determine the charge

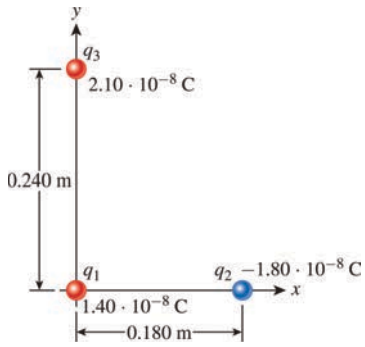
q. If the spring is coated with metal to make it conducting, what is the new length of the spring?



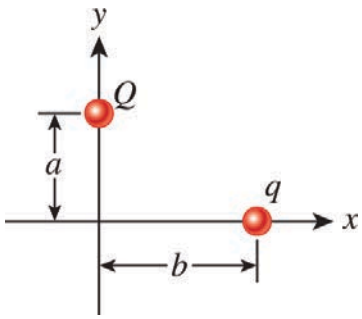
•21.46 A point charge $+3q$ is located at the origin, and a point charge $-q$ is located on the x-axis at $D = 0.500$ m. At what location on the x-axis will a third charge, q_0, experience no net force from the other two charges?

•21.47 Identical point charges Q are placed at each of the four corners of a rectangle measuring 2.00 m by 3.00 m. If $Q = 32.0\,\mu\text{C}$, what is the magnitude of the electrostatic force on any one of the charges?

•21.48 Charge $q_1 = 1.04 \cdot 10^{-8}\text{C}$ is placed at the origin. Charges $q_2 = -1.80 \cdot 10^{-8}\text{C}$ and $q_3 = -2.10 \cdot 10^{-8}\text{C}$ are placed at points (0.180 m , 0.000 m) and (0.000 m , 0.240 m), respectively, as shown in the figure. Determine the net electrostatic force (magnitude and direction) on charge q_3.



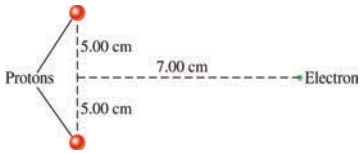
•21.49 A positive charge Q is on the y-axis at a distance a from the origin, and another positive charge q is on the x-axis at a distance b from the origin.



a) For what value(s) of b is the x-component of the force on q a minimum?

b) For what value(s) of b is the x-component of the force on q a maximum?

•**21.50** Find the magnitude and direction of the electrostatic force acting on the electron in the figure.



•**21.51** In a region of two-dimensional space, there are three fixed charges: $+1.00$ mC at (0,0), -2.00 mC at (17.0 mm, -5.00 mm), and $+3.00$ mC at (-2.00 mm, 11.0 mm). What is the net force on the -2.00-mC charge?

•**21.52** Two cylindrical glass beads each of mass $m = 10.0$ mg are set on their flat ends on a horizontal insulating surface separated by a distance $d = 2.00$ cm. The coefficient of static friction between the beads and the surface is $\mu_s = 0.200$. The beads are then given identical charges (magnitude and sign). What is the minimum charge needed to start the beads moving?

•**21.53** A small ball with a mass of 30.0 g and a charge of -0.200 μC is suspended from the ceiling by a string. The ball hangs at a distance of 5.00 cm above an insulating floor. If a second small ball with a mass of 50.0 g and a charge of 0.400 μC is rolled directly beneath the first ball, will the second ball leave the floor? What is the tension in the string when the second ball is directly beneath the first ball?

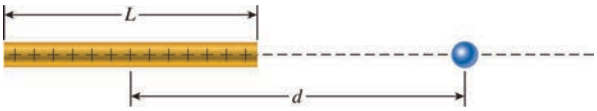
•21.54 A $+3.00$-mC charge and a -4.00-mC charge are fixed in position and separated by 5.00 m.

a) Where can a $+7.00$-mC charge be placed so that the net force on it is zero?

b) Where can a -7.00-mC charge be placed so that the net force on it is zero?

•21.55 Four point charges, q, are fixed to the four corners of a square that is 10.0 cm on a side. An electron is suspended above a point at which its weight is balanced by the electrostatic force due to the four electrons, at a distance of 15.0 nm above the center of the square. What is the magnitude of the fixed charges? Express the charge both in coulombs and as a multiple of the electron's charge.

••21.56 The figure shows a uniformly charged thin rod of length L that has total charge Q. Find an expression for the magnitude of the electrostatic force acting on an electron positioned on the axis of the rod at a distance d from the midpoint of the rod.



••21.57 A negative charge, $-q$, is fixed at the coordinate (0,0). It is exerting an attractive force on a positive charge, $+q$,, that is initially at coordinate (x,0). As a result, the positive charge accelerates toward the negative charge. Use the binomial expansion $(1+x)^n \approx 1+nx$, for $x \ll 1$, to show that when the positive charge moves a distance $\delta \ll x$ closer to the negative charge, the force that the negative charge exerts on it increases by $\Delta F = 2kq^2\delta/x^3$.

••21.58 Two negative charges ($-q$ and $-q$) of equal magnitude are fixed at coordinates ($-q$,0) and (d,0). A positive charge of the same magnitude, q, and with mass m is placed at coordinate (0,0), midway between the two negative charges. If the positive charge is

moved a distance $\delta \ll d$ in the positive y-direction and then released, the resulting motion will be that of a harmonic oscillator —the positive charge will oscillate between coordinates (0,δ) and $(0, -\delta)$. Find the net force acting on the positive charge when it moves to (0,δ) and use the binomial expansion $(1 + x)^n \approx 1 + nx$, for $x \ll 1$, to find an expression for the frequency of the resulting oscillation. (*Hint*: Keep only terms that are linear in δ.)

Section 21.6

21.59 Suppose the Earth and the Moon carried positive charges of equal magnitude. How large would the charge need to be to produce an electrostatic repulsion equal to 1.00% of the gravitational attraction between the two bodies?

21.60 The similarity of form of Newton's law of gravitation and Coulomb's Law caused some to speculate that the force of gravity is related to the electrostatic force. Suppose that gravitation is entirely electrical in nature—that an excess charge Q on the Earth and an equal and opposite excess charge $-Q$ on the Moon are responsible for the gravitational force that causes the observed orbital motion of the Moon about the Earth. What is the required size of Q to reproduce the observed magnitude of the gravitational force?

•**21.61** In the Bohr model of the hydrogen atom, the electron moves around the one-proton nucleus on circular orbits of well-determined radii, given by $r_n = n^2 a_B$, where $n = 1, 2, 3, \ldots$ is an integer that defines the orbit and $a_B = 5.29 \cdot 10^{-11}\text{m}$ is the radius of the first (minimum) orbit, called the *Bohr radius*. Calculate the force of electrostatic interaction between the electron and the proton in the hydrogen atom for the first four orbits. Compare the strength of this interaction to the gravitational interaction between the proton and the electron.

•**21.62** Some of the earliest atomic models held that the orbital velocity of an electron in an atom could be correlated with the radius of the atom. If the radius of the hydrogen atom is $5.29 \cdot 10^{-11}$ m and the electrostatic force is responsible for the circular motion of the electron, what is the kinetic energy of this orbital electron?

21.63 For the atom described in Problem 21.62, what is the ratio of the gravitational force between electron and proton to the electrostatic force? How does this ratio change if the radius of the atom is doubled?

•**21.64** In general, astronomical objects are not exactly electrically neutral. Suppose the Earth and the Moon each carry a charge of

$-1.00 \cdot 10^6$C (this is approximately correct; a more precise value is identified in Chapter 22).

a) Compare the resulting electrostatic repulsion with the gravitational attraction between the Moon and the Earth. Look up any necessary data.

b) What effects does this electrostatic force have on the size, shape, and stability of the Moon's orbit around the Earth?

Additional Exercises

21.65 Eight 1.00-μC charges are arrayed along the y-axis located every 2.00 cm starting at $y = 0$ and extending to $y = 14.0$ cm. Find the force on the charge at $y = 4.00$ cm.

21.66 In a simplified Bohr model of the hydrogen atom, an electron is assumed to be traveling in a circular orbit of radius of about $5.29 \cdot 10^{-11}$ m around a proton. Calculate the speed of the electron in that orbit.

21.67 The nucleus of a carbon-14 atom (mass = 14 amu) has diameter of 3.01 fm. It has 6 protons and a charge of $+6e$.

a) What is the force on a proton located at 3.00 fm from the surface of this nucleus? Assume that the nucleus is a point charge.

b) What is the proton's acceleration?

21.68 Two charged objects experience a mutual repulsive force of 0.100 N. If the charge of one of the objects is reduced by half and the distance separating the objects is doubled, what is the new force?

21.69 A particle (charge $= +19.0\ \mu\text{C}$) is located on the x-axis at $x = -10.0$ cm. and a second particle (charge $= -57.0\ \mu\text{C}$) is placed on the x-axis at $x = +20.0$ cm. What is the magnitude of the total electrostatic force on a third particle (charge $= -3.80\ \mu\text{C}$) placed at the origin ($x = 0$)?

21.70 Three point charges are positioned on the x-axis: $+64.0\ \mu$ at $x = 0.00$ cm, $+80.0\ \mu\text{C}$ at $x = 25.0$ cm, and $-160.0\ \mu\text{C}$ at $x = 50.0$ cm. What is the magnitude of the electrostatic force acting on the $+64.0\ \mu\text{C}$ charge?

21.71 From collisions with cosmic rays and from the solar wind, the Earth has a net electric charge of approximately $-6.8 \cdot 10^5\text{C}$. Find the charge that must be given to a 1.0-g object for it to be electrostatically levitated close to the Earth's surface.

21.72 Your sister wants to participate in the yearly science fair at her high school and asks you to suggest some exciting project. You suggest that she experiment with your recently created electron

extractor to suspend her cat in the air. You tell her to buy a copper plate and bolt it to the ceiling in her room and then use your electron extractor to transfer electrons from the plate to the cat. If the cat weighs 7.00 kg and is suspended 2.00 m below the ceiling, how many electrons have to be extracted from the cat? Assume that the cat and the metal plate are point charges.

•**21.73** A 10.0-g mass is suspended 5.00 cm above a nonconducting flat plate, directly above an embedded charge of q (in coulombs). If the mass has the same charge, q, how much must q be so that the mass levitates (just floats, neither rising nor falling)? If the charge q is produced by adding electrons to the mass, by how much will the mass be changed?

•**21.74** Four point charges are placed at the following xy-coordinates:

$Q_1 = -1.00\ \text{mC}$, at $(-3.00\ \text{cm}, 0.00\ \text{cm})$

$Q_2 = -1.00\ \text{mC}$, at $(+3.00\ \text{cm}, 0.00\ \text{cm})$

$Q_3 = +1.024\ \text{mC}$, at $(0.00\ \text{cm}, 0.00\ \text{cm})$

$Q_4 = +2.00\ \text{mC}$, at $(0.00\ \text{cm}, -4.00\ \text{cm})$

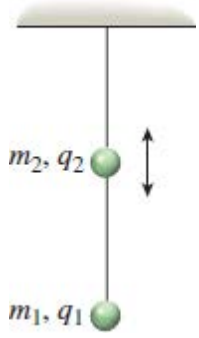
Calculate the net force on charge Q_4 due to charges Q_1,Q_2, and Q_3.

•**21.75** Three 5.00-g Styrofoam balls of radius 2.00 cm are coated with carbon black to make them conducting and then are tied to 1.00-m-long threads and suspended freely from a common point. Each ball is given the same charge, q. At equilibrium, the balls form an equilateral triangle with sides of length 25.0 cm in the horizontal plane. Determine q.

•**21.76** Two point charges lie on the x-axis. If one point charge is 6.00 μC and lies at the origin and the other is $-2.00\ \mu\text{C}$ and lies at 20.0 cm, at what position must a third charge be placed to be in equilibrium?

•**21.77** Two beads with charges $q_1 = q_2 = +2.67\ \mu\text{C}$ are on an insulating string that hangs straight down from the ceiling as shown in the figure. The lower bead is fixed in place on the end of the string and has a mass $m_1 = 0.280\ \text{kg}$. The second bead slides

without friction on the string. At a distance $d = 0.360$ m between the centers of the beads, the force of the Earth's gravity on m_2 is balanced by the electrostatic force between the two beads. What is the mass, m_2, of the second bead? (*Hint:* You can neglect the gravitational interaction between the two beads.)

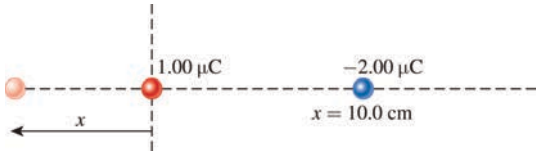


•21.78 Find the net force on a $+2.00$-C charge at the origin of an xy-coordinate system if there is a $+5.00$-C charge at (3.00 m ,0.00) and a -3.00-C charge at (0.00, 4.00 m).

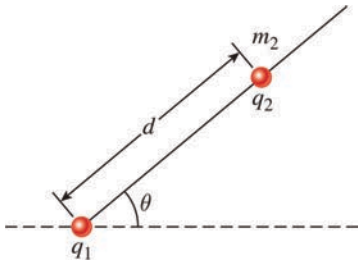
•21.79 Two spheres, each of mass $M = 2.33$ g, are attached by pieces of string of length $L = 45.0$ cm to a common point. The strings initially hang straight down, with the spheres just touching one another. An equal amount of charge, q, is placed on each sphere. The resulting forces on the spheres cause each string to hang at an angle of $\theta = 10.0^\circ$ from the vertical. Determine q, the amount of charge on each sphere.

•21.80 A point charge $q_1 = 100.$ nC is at the origin of an xy-coordinate system, a point charge $q_2 = -80.0$ nC is on the x-axis at $x = 2.00$ m, and a point charge $q_3 = -60.0$ nC is on the y-axis at $y = -2.00$ m. Determine the net force (magnitude and direction) on q_1.

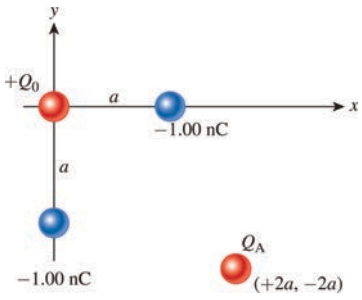
•21.81 A positive charge $q_1 = 1.00$ μC is fixed at the origin, and a second charge $q_2 = -2.00$ μC is fixed at $x = 10.0$ cm. Where along the x-axis should a third charge be positioned so that it experiences no force?



•**21.82** A bead with charge $q_1 = 1.27\ \mu\text{C}$ is fixed in place at the end of a wire that makes an angle of $\theta = 51.3^\circ$ with the horizontal. A second bead with mass $m_2 = 3.77$ g and a charge of 6.79 μC slides without friction on the wire. What is the distance d at which the force of the Earth's gravity on m_2 is balanced by the electrostatic force between the two beads? Neglect the gravitational interaction between the two beads.

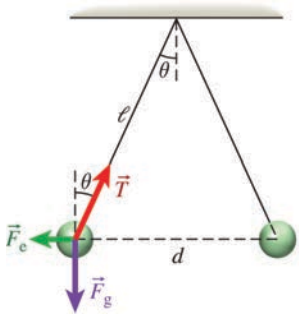


•**21.83** In the figure, the net electrostatic force on charge Q_A is zero. If $Q_\text{A} = +1.00$ nC, determine the magnitude of Q_0.



MULTI-VERSION EXERCISES

21.84 Two balls have the same mass, 0.9680 kg, and the same charge, 29.59 μC. They hang from the ceiling on strings of identical length, ℓ, as shown in the figure. If the angle of the strings with respect to the vertical is 29.79°, what is the length of the strings?



21.85 Two balls have the same mass and the same charge, 15.71 μC. They hang from the ceiling on strings of identical length, $\ell = 1.223$ m, as shown in the figure. The angle of the strings with respect to the vertical is 21.07°. What is the mass of each ball?

21.86 Two balls have the same mass, 0.9935 kg, and the same charge. They hang from the ceiling on strings of identical length, $\ell = 1.235$ m, as shown in the figure. The angle of the strings with respect to the vertical is 22.35°. What is the charge on each ball?

21.87 As shown in the figure, point charge q_1 is 3.979 μC and is located at $x_1 = -5.689$ m, and point charge q_2 is 8.669 μC and is located at $x_2 = 14.13$ m. What is the x-coordinate of the point at which the net force on a point charge of 5.000 μC will be zero?

21.88 As shown in the figure, point charge q_1 is 4.325 μC and is located at x_1, and point charge q_2 is 7.757 μC and is located at $x_2 = 14.33$ m. The x-coordinate of the point where the net force on

a point charge of $-3.000\ \mu\text{C}$ is zero is 2.358 m. What is the value of x_1?

21.89 As shown in the figure, point charge q_1 is 4.671 μC and is located at $x_1 = -3.573$ m, and point charge q_2 is 6.845 μC and is located at x_2. The x-coordinate of the point where the net force on a point charge of $-1.000\ \mu\text{C}$ is zero is 4.625 m. What is the value of x_2?

The great white shark is one of the most feared predators on Earth (Figure 22.1). It has several senses that have evolved for hunting prey; for example, it can smell tiny amounts of blood from as far away as 5 km (3 mi). Perhaps more amazing, it has developed special organs (called the *ampullae of Lorenzini*) that can detect the tiny electric fields generated by the movement of muscles in an organism, whether a fish, a seal, or a human. However, just what are electric fields? In addition, how are they related to electric charges?

FIGURE 22.1 A great white shark can detect tiny electric fields generated by its prey.

Marty Snyderman/Stephen Frink Collection/Alamy Stock Photo

The concept of vector fields is one of the most useful and productive ideas in all of physics. This chapter explains what an electric field is and how it is connected to electrostatic charges and forces and then examines how to determine the electric field due to some given distribution of charge. This study leads us to one of the most important laws of electricity—Gauss's Law—which provides a relationship between electric fields and electrostatic charge. However, Gauss's Law has practical application only when the charge distribution has enough geometric symmetry to simplify the calculation, and even then, some other concepts related to electric fields are necessary in order to apply the equations. We'll examine another kind of field—magnetic fields—in Chapters 27 through 29. Then, Chapter 31 will show how Gauss's Law fits into a unified description of electric and magnetic fields—one of the finest

achievements in physics, from both a practical and an esthetic point of view.

WHAT WE WILL LEARN

- An electric field represents the electric force at different points in space.
- Electric field lines represent the net force vectors exerted on a unit positive electric charge. They originate on positive charges and terminate on negative charges.
- The electric field of a point charge is radial, proportional to the charge, and inversely proportional to the square of the distance from the charge.
- An electric dipole consists of a positive charge and a negative charge of equal magnitude.
- The electric flux is the electric field component normal to an area times the area.
- Gauss's Law states that the electric flux through a closed surface is proportional to the net electric charge enclosed within the surface. This law provides simple ways to solve seemingly complicated electric field problems.
- The electric field inside a conductor is zero.
- The magnitude of the electric field due to a uniformly charged, infinitely long wire varies as the inverse of the perpendicular distance from the wire.
- The electric field due to an infinite sheet of charge does not depend on the distance from the sheet.
- The electric field outside a spherical distribution of charge is the same as the field of a point charge with the same total charge located at the sphere's center.

22.1 Definition of an Electric Field

In Chapter 21, we discussed the force between two or more point charges. When determining the net force exerted by other charges on a particular charge at some point in space, we obtain different directions for this force, depending on the sign of the charge that is the reference point. In addition, the net force is also proportional to the magnitude of the reference charge. The techniques used in Chapter 21 require us to redo the calculation for the net force each time we consider a different charge.

Dealing with this situation requires the concept of a **field,** which can be used to describe certain forces. An **electric field,** $E(r)$, is defined at any point in space, $\vec{r}$, as the net electric force on a charge, divided by that charge:

$$\vec{E}\left(\vec{r}\right) = \frac{\vec{F}\left(\vec{r}\right)}{q}. \qquad \textbf{(22.1)}$$

The units of the electric field are newtons per coulomb $(\mathrm{N/C})$. This simple definition eliminates the cumbersome dependence of the electric force on the particular charge being used to measure the force. We can quickly determine the net force on any charge by using $\vec{F}\left(\vec{r}\right) = q\vec{E}\left(\vec{r}\right)$, which is a trivial rearrangement of equation 22.1.

The electric force on a charge at a point is parallel (or antiparallel, depending on the sign of the charge in question) to the electric field at that point and proportional to the magnitude of the charge. The magnitude of the force is given by $F = |q|E$. The direction of the force on a positive charge is along $\vec{E}\left(\vec{r}\right)$; the

direction of the force on a negative charge is in the direction opposite to $\vec{E}\left(\vec{r}\right)$.

If several sources of electric fields are present at the same time, such as several point charges, the electric field at any given point is determined by the superposition of the electric fields from all sources. This superposition follows directly from the superposition of forces introduced in our study of mechanics and discussed in Chapter 21 for electrostatic forces. The **superposition principle** for the total electric field, $\vec{E}_{\mathrm{t}}$, at any point in space with coordinate $\vec{r}$, due to *n* electric field sources can be stated as

$$\vec{E}_t\left(\vec{r}\right) = \vec{E}_1\left(\vec{r}\right) = \vec{E}_2\left(\vec{r}\right) + \cdots + \vec{E}_n\left(\vec{r}\right). \quad \textbf{(22.2)}$$

22.2 Field Lines

An electric field can (and in most applications does) change as a function of the spatial coordinate. The changing direction and strength of the electric field can be visualized by means of **electric field lines.** These graphically represent the net vector force exerted on a unit positive test charge. The representation applies separately for each point in space where the test charge might be placed. The direction of the field line at each point is the same as the direction of the force at that point, and the density of field lines is proportional to the magnitude of the force.

Electric field lines can be compared to the streamlines of wind directions, shown in Figure 22.2. These streamlines represent the force of the wind on objects at given locations, just as the electric field lines represent the electric force at specific points. A hot-air balloon can be used as a test particle for determining these wind streamlines. For example, a hot-air balloon launched in Dallas, Texas, would float from north to south in the situation depicted in Figure 22.2. Where the wind streamlines are close together, the speed of the wind is higher, so the balloon would move faster.

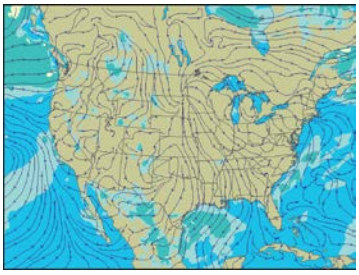

FIGURE 22.2
Streamlines of wind directions at the surface in the United States on March 23, 2008.

National Weather Service

To draw an electric field line, we imagine placing a tiny positive charge at each point in the electric field. This charge is small enough that it does not affect the surrounding field. A small charge like this is sometimes called a **test charge.** We calculate the resultant force on the charge, and the direction of the force gives the direction of the field line. For example, Figure 22.3a shows a point in an electric field. In Figure 22.3b, a charge $+q$ is placed at point P, on an electric field line. The force on the charge is in the same direction as the electric field. In Figure 22.3c, a charge $-q$ is placed at point P, and the resulting force is in the direction opposite to the electric field. In Figure 22.3d, a charge $+2q$ is placed at point P, and the resulting force on the charge is in the direction of the electric field, with twice the magnitude of the force on the charge $+q$. We will follow the convention of depicting a positive charge as red and a negative charge as blue.

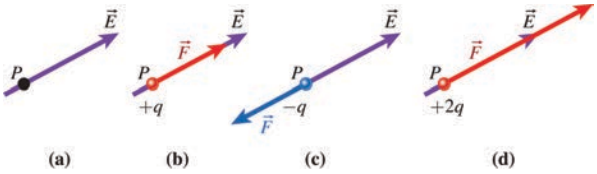

FIGURE 22.3 The force resulting from placing a charge in an electric field. (a) A point *P* on an electric field line. (b) A positive charge $+q$ placed at point P. (*c*) A negative charge $-q$ placed at point *P*. (d) A positive charge $+2q$ placed at point *P*.

In a nonuniform electric field, the electric force at a given point is tangent to the electric field lines at that point, as illustrated in Figure 22.4. The force on a positive charge is in the direction of the electric field, and the force on a negative charge is in the direction opposite to the electric field.

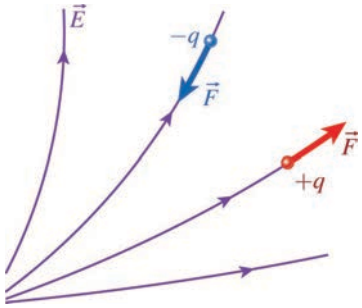

FIGURE 22.4 A nonuniform electric field. A positive charge $+q$ and a negative charge $-q$ placed in the field experience forces as shown. Each force is tangent to the electric field line.

Electric field lines point away from sources of positive charge and toward sources of negative charge. Each field line starts at a charge and ends at another charge. Electric field lines always originate on positive charges and terminate on negative charges.

Electric fields exist in three dimensions (Figure 22.5); however, this chapter usually presents two-dimensional depictions of electric fields for simplicity.

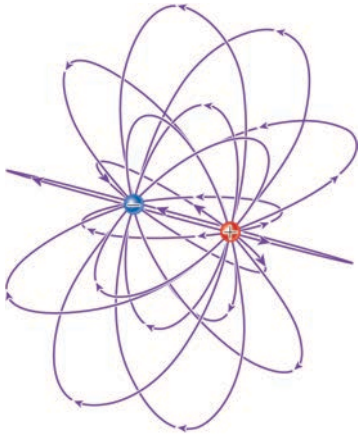

FIGURE 22.5
Three-dimensional representation of electric field lines from two point charges with opposite signs.

Point Charge

The electric field lines arising from an isolated point charge are shown in Figure 22.6. The field lines emanate in radial directions from the point charge. If the point charge is positive (Figure 22.6a), the field lines point outward, away from the charge; if the point charge is negative, the field lines point inward, toward the charge (Figure 22.6b). For an isolated positive point charge, the electric field lines originate at the charge and terminate on negative charges at infinity, and for a negative point charge, the electric field lines originate at positive charges at infinity and terminate at the charge. Note that the electric field lines are closer together near the point charge and farther apart away from the point charge, indicating that the electric field becomes weaker with increasing distance from the charge. We'll examine the magnitude of the field quantitatively in Section 22.3.

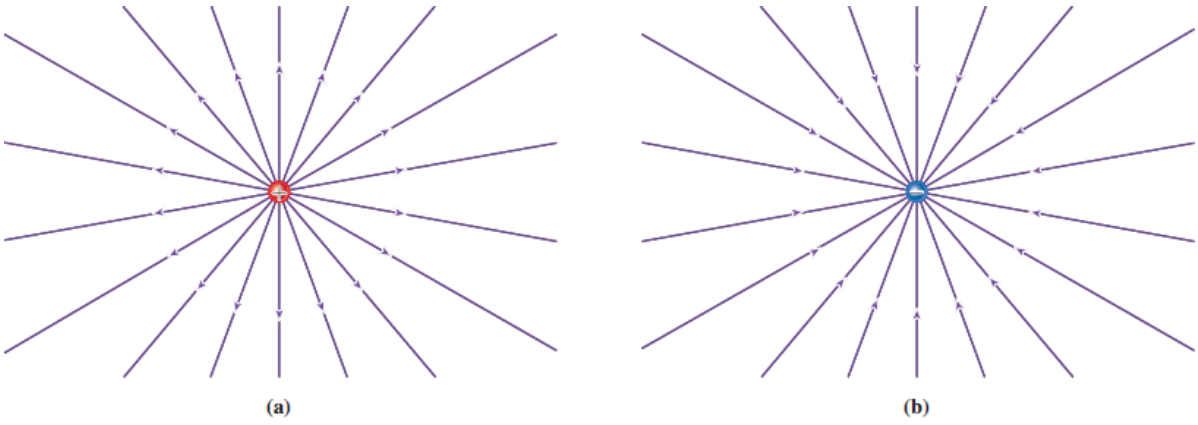

FIGURE 22.6 Electric field lines (a) from a single positive point charge and (b) to a single negative point charge.

Two Point Charges of Opposite Sign

We can use the superposition principle to determine the electric field from two point charges. Figure 22.7 shows the electric field lines for two oppositely charged point charges with the same magnitude. At each point in the plane, the electric field from the positive charge and the electric field from the negative charge add as vectors to give the magnitude and the direction of the resulting electric field. (Figure 22.5 shows the same field lines in three dimensions.)

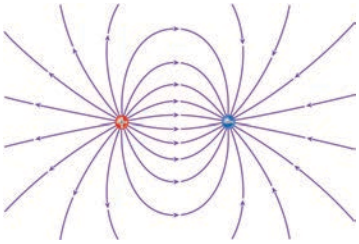

FIGURE 22.7
Electric field lines from two oppositely charged point charges. Each charge has the same magnitude.

As noted earlier, the electric field lines originate on the positive charge and terminate on the negative charge. At a point very close to either charge, the field lines are similar to those for a single point charge, since the effect of the more distant charge is small. Near the charges, the electric field lines are close together, indicating that the field is stronger in those regions. The fact that the field lines between the two charges connect indicates that an attractive force exists between the two charges.

Two Point Charges with the Same Sign

We can also apply the principle of superposition to two point charges with the same sign. Figure 22.8 shows the electric field lines for two point charges with the same sign and same magnitude. If both charges are positive (as in Figure 22.8), the electric field lines originate at the charges and terminate at infinity. If both charges are negative, the field lines originate at infinity and terminate at the charges. For two charges of the same sign, the field lines do not connect the two charges. Rather, the field lines terminate on opposite charges at infinity. The fact that the field lines never terminate on the other charge signifies that the charges repel each other.

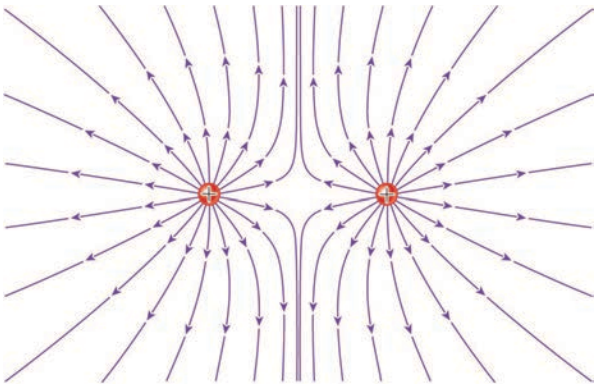

FIGURE 22.8 Electric field lines from two positive point charges with the same magnitude.

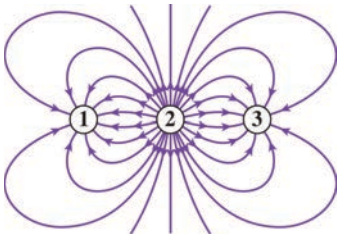
General Observations

The three simplest possible cases that we just examined lead to two general rules that apply to all field lines of all charge configurations:

1. *Field lines originate at positive charges and terminate at negative charges.*
2. *Field lines never cross.* This result is a consequence of the fact that the lines represent the electric field, which in turn is proportional to the net force that acts on a charge placed at a particular point. Field lines that crossed would imply that the net force points in two different directions at the same point, which is impossible.

Concept Check 22.1

Which of the charges in the figure is (are) positive?



a) 1

b) 2

c) 3

d) 1 and 3

e) All three charges are positive.

Concept Check 22.2

Assuming that there are no charges in the four regions shown in the figure, which of the patterns could represent an electric field?

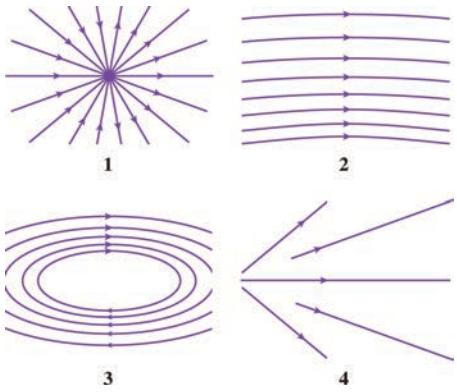
a) only 1

b) only 2

c) 2 and 3

d) 1 and 4

e) None of the patterns represent an electric field.



22.3 Electric Field due to Point Charges

The magnitude of the electric force on a point charge q_0 due to another point charge, q, is given by

$$F = \frac{1}{4\pi\epsilon_0}\frac{|qq_0|}{r^2}. \tag{22.3}$$

Taking q_0 to be a small test charge, we can express the magnitude of the electric field at the point where q_0 is and due to the point charge q as

$$E = \left|\frac{F}{q_0}\right| = \frac{1}{4\pi\epsilon_0}\frac{|q|}{r^2}, \tag{22.4}$$

where r is the distance from the test charge to the point charge. The direction of this electric field is radial. The field points outward for a positive point charge and inward for a negative point charge.

An electric field is a vector quantity, and thus the components of the field must be added separately. Example 22.1 demonstrates the addition of electric fields created by three point charges.

EXAMPLE 22.1 Three Charges

Figure 22.9 shows three fixed point charges: $q_1 = +1.50\ \mu\text{C}$, $q_2 = +2.50\ \mu\text{C}$, and $q_3 = -3.50\ \mu\text{C}$. Charge q_1 is located at $(0,a)$, q_2 is located at $(0,0)$, and q_3 is located at $(b,0)$, where $a = 8.00$ m and $b = 6.00$ m

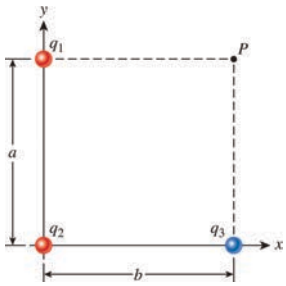


FIGURE 22.9 Locations of three point charges.

PROBLEM 1

What electric field, $\vec{E}$, do these three charges produce at the point $P = (b, a)$?

SOLUTION

We must sum the electric fields from the three charges using equation 22.2. We proceed by summing component by component, starting with the field due to q_1 :

$$\vec{E}_1 = E_{1,x}\hat{x} + E_{1,y}\hat{y}.$$

The field due to q_1 acts only in the x-direction at point (b,a), because q_1 has the same y-coordinate as P. Thus, $\vec{E}_1 = E_{1,x}\hat{x}$.

We can determine $E_{1,x}$ using equation 22.4:

$$E_{1,x} = \frac{kq_1}{b^2}.$$

Note that the sign of $E_{1,x}$ is the same as the sign of q_1 Similarly, the field due to q_3 acts only in the y-direction at point (b,a). Thus, $\vec{E}_3 = E_{3,y}\hat{y}$. where

$$E_{3,y} = \frac{kq_3}{a^2}.$$

As shown in Figure 22.10, the electric field due to q_2 at P is given by

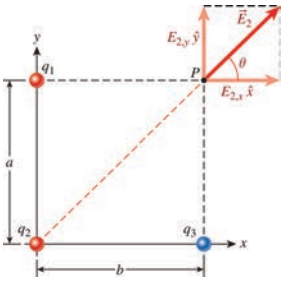

FIGURE 22.10 Electric field due to q_2 and its *x*- and *y*-components at point *P*.

$$\vec{E}_2 = E_{2,x}\hat{x} + E_{2,y}\hat{y}.$$

Note that $\vec{E}_2$, the electric field due to q_2 at point P, points directly away from q_2 because $q_2 > 0$. (It would point directly toward q_2 if this charge were negative.) The magnitude of this electric field is given by

$$E_2 = \frac{k\,|q_2|}{a^2 + b^2}.$$

The component $E_{2,x}$ is given by $E_2 \cos\theta$, where $\theta = \tan^{-1}(a/b)$, and the component $E_{2,y}$ is given by $E_2 \sin\theta$.

Adding the components, the total electric field at point P is

$$\begin{aligned}\vec{E} &= (E_{1,x} + E_{2,x})\hat{x} + (E_{2,y} + E_{3,y})\hat{y} \\ &= \underbrace{\left(\frac{kq_1}{b^2}, +, \frac{kq_2\,\cos\theta}{a^2 + b^2}\right)}_{E_x}\hat{x} + \underbrace{\left(\frac{kq_2\,\sin\theta}{a^2 + b^2}, +, \frac{kq_3}{a^2}\right)}_{E_y}\hat{y}.\end{aligned}$$

With the given values for a and b, we find $\theta = \tan^{-1}(8/6) = 53.1^\circ$, and $a^2 + b^2 = (8.00\ \mathrm{m})^2 + (6.00\ \mathrm{m})^2 = 100\ \mathrm{m}^2$. We can then calculate the x-component of the total electric field as

$$E_x = \left(8.99 \cdot 10^9\ \mathrm{N\,m^2/C^2}\right)\left(\frac{1.50 \cdot 10^{-6}\ \mathrm{C}}{(6.00\ \mathrm{m})^2} + \frac{\left(2.50 \cdot 10^{-}\right.}{1}\right.$$

The y-component is

$$E_y = \left(8.99 \cdot 10^9\ \mathrm{N\,m^2/C^2}\right)\left(\frac{\left(2.50 \cdot 10^{-6}\ \mathrm{C}\right)(\sin 53.1^\circ)}{100\ \mathrm{m^2}}\right.$$

The magnitude of the field is

$$E = \sqrt{E_x^2 + E_y^2} = \sqrt{(509\ \mathrm{N/C})^2 + (-312\ \mathrm{N/C})^2} = 597$$

The direction of the field at point P is

$$\varphi = \tan^{-1}\left(\frac{E_y}{E_x}\right) = \tan^{-1}\left(\frac{-312\ \mathrm{N/C}}{509\ \mathrm{N/C}}\right) = -31.5^\circ,$$

which means that the electric field points to the right and downward.

Note that even though the charges in this example are in microcoulombs and the distances are in meters, the electric fields are still large, showing that a microcoulomb is a large amount of charge.

22.4 Electric Field due to a Dipole

A system of two equal (in magnitude) but oppositely charged point particles is called an **electric dipole.** The electric field from an electric dipole is given by the vector sum of the electric fields from the two charges. Figure 22.7 shows the electric field lines in two dimensions for an electric dipole.

The superposition principle allows us to determine the electric field due to two point charges through vector addition of the electric fields of the two charges. Let's consider the special case of the electric field due to a dipole along the axis of the dipole, defined as the line connecting the charges. This main symmetry axis of the dipole is assumed to be oriented along the x-axis (Figure 22.11).

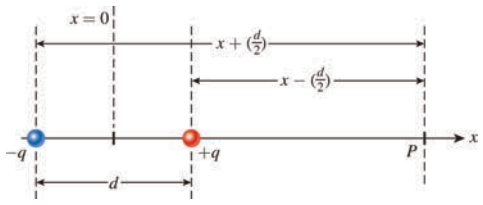

FIGURE 22.11 Calculation of the electric field from an electric dipole.

The electric field, $\vec{E}$, at point P on the dipole axis is the sum of the field due to $+q$, denoted as $\vec{E}_+$, and the field due to $-q$, denoted as $\vec{E}_-$:

$$\vec{E} = \vec{E}_+ + \vec{E}_-.$$

Using equation 22.4, we can express the magnitude of the dipole's electric field along the x-axis, for $x > d/2$, as

$$E = \frac{1}{4\pi\varepsilon_0}\frac{q}{r_+^2} + \frac{1}{4\pi\varepsilon_0}\frac{-q}{r_-^2},$$

where r_+ is the distance between P and $+q$ and $r_-$is the distance between P and $-q$. Absolute value bars are not needed in this equation, because the first term on the right-hand side is positive and is greater than the second (negative) term. The electric field at all points on the x-axis (except at $x = \pm d/2$, where the two charges are located) is given by

$$\vec{E} = E_x\hat{x} = \frac{1}{4\pi\epsilon_0}\frac{q(x-d/2)}{r_+^3}\hat{x} + \frac{1}{4\pi\epsilon_0}\frac{-q(x+d/2)}{r_-^3}\hat{x}. \quad (2$$

Now we examine the magnitude of $\vec{E}$ and restrict the value of x to $x > d/2$, where $E = E_x > 0$. Then we have

$$E = \frac{1}{4\pi\epsilon_0}\frac{q}{\left(x-\frac{1}{2}d\right)^2} - \frac{1}{4\pi\epsilon_0}\frac{q}{\left(x+\frac{1}{2}d\right)^2}.$$

With some rearrangement and keeping in mind that we want to obtain an expression that has the same form as the electric field from a point charge, we write the preceding equation as

$$E = \frac{q}{4\pi\epsilon_0 x^2}\left[\left(1-\frac{d}{2x}\right)^{-2} - \left(1+\frac{d}{2x}\right)^{-2}\right].$$

To find an expression for the electric field at a large distance from the dipole, we can make the approximation $x \gg d$ and use the binomial expansion. (Since $x \gg d$, we can drop terms containing the square of d/x and higher powers.) We obtain

$$E \approx \frac{q}{4\pi\epsilon_0 x^2}\left[\left(1+\frac{b}{x}-\cdots\right)-\left(1-\frac{d}{x}+\cdots\right)\right] = \frac{q}{4\pi\epsilon_0 x^2}$$

which can be rewritten as

$$E \approx \frac{qd}{2\pi\epsilon_0 x^3}. \qquad \textbf{(22.6)}$$

Equation 22.6 can be simplified by defining a vector quantity called the **electric dipole moment,** $\vec{p}$. The direction of this dipole moment is from the negative charge to the positive charge, which is opposite to the direction of the electric field lines. The magnitude, p, of the electric dipole moment is given by

$$p = qd, \qquad \textbf{(22.7)}$$

where q is the magnitude of either of the charges and d is the distance separating the two charges. With this definition, the expression for the magnitude of the electric field due to the dipole along the positive x-axis at a distance that is large compared with the separation between the two charges is

$$E = \frac{p}{2\pi\epsilon_0 |x|^3}. \qquad \textbf{(22.8)}$$

Although not shown explicitly here, equation 22.8 is also valid for $x = \ll -d$. Also, an examination of equation 22.5 for $\vec{E}$ shows that

$E_x > 0$ on either side of the dipole. In contrast to the field due to a point charge, which is inversely proportional to the square of the distance, the field due to a dipole is inversely proportional to the cube of the distance, according to equation 22.8.

EXAMPLE 22.2 Water Molecule

The water molecule, H_2O is arguably the most important one for life. It has a nonzero dipole moment, which is the basic reason why many organic molecules are able to bind to water. This dipole moment also allows water to be an excellent solvent for many inorganic and organic compounds.

Each water molecule consists of two atoms of hydrogen and one atom of oxygen, as shown in Figure 22.12a. The charge distribution of each of the individual atoms is approximately spherical. The oxygen atom tends to pull the negatively charged electrons toward itself, giving the hydrogen atoms slight positive charges. The three atoms are arranged so that the lines connecting the centers of the hydrogen atoms with the center of the oxygen atom have an angle of 105° between them (see Figure 22.12a).

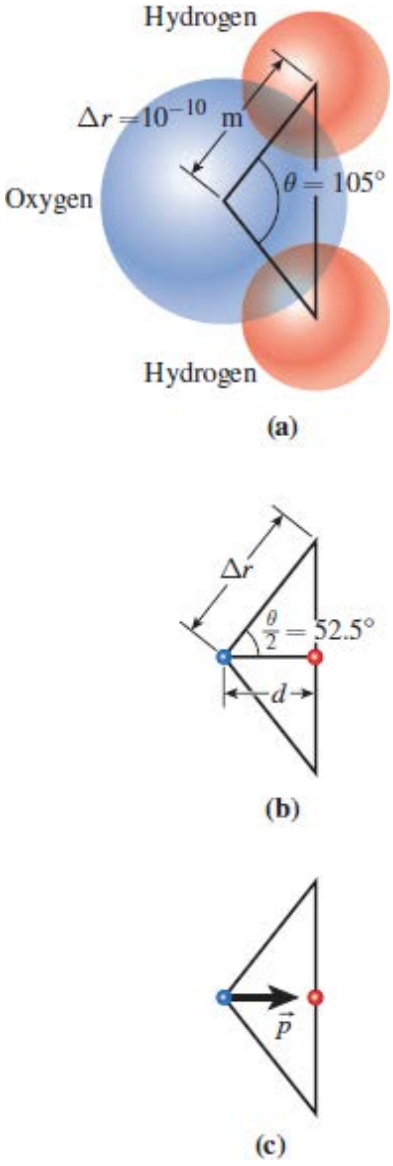

FIGURE 22.12 (a) Schematic drawing showing the geometry of a water molecule, H_2O with atoms as spheres. (b) Diagram showing the effective positive (red dot on the right) and negative (blue dot on the left) charge

centers. (c) Dipole moment assuming pointlike charges.

PROBLEM

Suppose we approximate a water molecule by two positive charges at the locations of the two hydrogen nuclei (protons) and two negative charges at the location of the oxygen nucleus, with all charges of equal magnitude. What is the resulting electric dipole moment of water?

SOLUTION

The center of charge of the two positive charges, analogous to the center of mass of two masses, is located exactly halfway between the centers of the hydrogen atoms, as shown in Figure 22.12b. With the hydrogen-oxygen distance of $\Delta r = 10^{-10}\text{m}$, as indicated in Figure 22.12a, the distance between the positive and negative charge centers is

$$d = \Delta r \cos\left(\frac{\theta}{2}\right) = \left(10^{-10}\text{m}\right)\left(\cos 52.5^\circ\right) = 0.6 \cdot 10^{-10}\ \text{m}$$

This distance times the transferred charge, $q = 2e$, is the magnitude of the dipole moment of water:

$$p = 2ed = \left(3.2 \cdot 10^{-19}\text{C}\right)\left(0.6 \cdot 10^{-10}\text{m}\right) = 2.10^{-29}\text{C m}.$$

This result of an extremely oversimplified calculation actually comes close, within a factor of 3, to the measured value of $6.2 \cdot 10^{-30}\text{C m}$. The fact that the real dipole moment of water is smaller than this calculated result is an indication that the two electrons of the hydrogen atoms are not pulled all the way to the oxygen but, on average, only one-third of the way.

Concept Check 22.3

An electrically neutral dipole is placed in an external electric field as shown in the figure. In which situation(s) is the net *force* on the dipole zero?

22.5 General Charge Distributions

We have determined the electric fields of a single point charge and of two point charges (an electric dipole). What if we want to determine the electric field due to many charges? Each individual charge creates an electric field, as described by equation 22.4, and because of the superposition principle, all of these electric fields can be added to find the net field at any point in space. But we have already seen in Example 22.1 that the addition of electric field vectors can be cumbersome for a collection of only three point charges. If we had to apply this method to, say, trillions of point charges, the task would be unmanageable even if we could use a supercomputer. Since real-world applications usually involve a very large number of charges, it is clear that we need a way to simplify the calculations. This can be accomplished by using an integral, if the large number of charges are arranged in space in some regular distribution. Of particular interest are two-dimensional distributions, where charges are located on the surface of a metallic object, and one-dimensional distributions, where charges are arranged along a wire. As we will see, integration can be a surprisingly simple way to solve problems involving such charge distributions, which would be very hard to analyze by the method of direct summation.

To prepare for the integration procedure, we divide the charge into differential elements of charge, dq, and find the electric field resulting from each differential charge element as if it were a point charge. If the charge is distributed along a one-dimensional object (a line), the differential charge may be expressed in terms of a charge per unit length times a differential length, or λdx. If the charge is distributed over a surface (a two-dimensional object), dq is expressed in terms of a charge per unit area times a differential area, or σdA. And, finally, if the charge is distributed over a three-dimensional volume, then dq is written as the product of a charge per unit volume and a differential volume, or ρdV. That is,

$$\left.\begin{aligned} dq &= \lambda dx \\ dq &= \sigma dA \\ dq &= \rho dV \end{aligned}\right\} \text{ for a charge distribution } \begin{cases} \text{along a line;} \\ \text{over a surface;} \\ \text{throughout a vo} \end{cases}$$

The magnitude of the electric field resulting from the charge distribution is then obtained from the differential charge:

$$dE = k\frac{dq}{r^2}. \tag{22.10}$$

In the following example, we find the electric field due to a finite line of charge.

EXAMPLE 22.3 Finite Line of Charge

To find the electric field along a line bisecting a finite length of wire with linear charge density λ, we integrate the contributions to the electric field from all the charge in the wire. We assume that the wire lies along the x-axis (Figure 22.13).

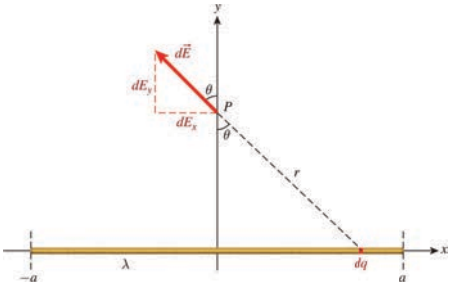

FIGURE 22.13
Calculating the electric field due to all the charge in a long wire by integrating the contributions to the electric field over the length of the wire.

Page 691

We also assume that the wire is positioned with its midpoint at $x = 0$, one end at $x = a$, and the other end at $x = -a$. The symmetry of the situation then allows us to conclude that there cannot be any electric force parallel to the wire (in the x-direction) along the line bisecting the wire. Along this line, the electric field can be only in the y-direction. We can then calculate the electric field due to all the charge for $x \geq 0$ and multiply the result by 2 to get the electric field for the whole wire.

We consider a differential charge, dq, on the x-axis, as shown in Figure 22.13. The magnitude of the electric field, dE, at a point (0,y) due to this charge is given by equation 22.10,

$$dE = k\frac{dq}{r^2},$$

where $r = \sqrt{x^2 + y^2}$ is the distance from dq to point P. The component of the electric field perpendicular to the wire (in the y-direction) is then given by

$$dE_y = k\frac{dq}{r^2}\cos\,\theta,$$

where θ is the angle between the electric field produced by dq and the y-axis (see Figure 22.13). The angle θ is related to r and y because $\cos\,\theta = y/r$.

We can relate the differential charge to the differential distance along the x-axis through the linear charge density, λ : $dq = \lambda dx$. The electric field at a distance y from the long wire is then

$$E_y = 2\int_0^a dE_y = 2\int_0^a k\frac{dq}{r^2}\cos\,\theta = 2k\int_0^a \frac{\lambda dx}{r^2}\frac{y}{r} = 2k\lambda y\int_0$$

Evaluation of the integral on the right-hand side (with the aid of an integral table or a software package like Mathematica or Maple) gives us

$$\int_0^a \frac{dx}{\left(x^2 + y^2\right)^{3/2}} = \left[\frac{1}{y^2}\frac{x}{\sqrt{x^2 + y^2}}\right]_0^a = \frac{1}{y^2}\frac{a}{\sqrt{y^2 + a^2}}.$$

Thus, the electric field at a distance y along a line bisecting the wire is given by

$$E_y = 2k\lambda y \frac{1}{y^2} \frac{a}{\sqrt{y^2 + a^2}} = \frac{2k\lambda}{y} \frac{a}{\sqrt{y^2 + a^2}}.$$

Finally, when $a \to \infty$, that is, the wire becomes infinitely long, $a/\sqrt{y^2 + a^2} \to 1$, and we have for an infinitely long wire

$$E_y = \frac{2k\lambda}{y}.$$

In other words, the electric field decreases in inverse proportion to the distance from the wire.

Now let's tackle a problem with a slightly more complicated geometry, finding the electric field due to a ring of charge along the axis of the ring.

SOLVED PROBLEM 22.1 Ring of Charge

PROBLEM

Consider a charged ring with radius $R = 0.250$ m (Figure 22.14). The ring has uniform linear charge density, and the total charge on the ring is $Q = +5.00$ μC. What is the electric field at a distance $b = 0.500$ m along the axis of the ring?

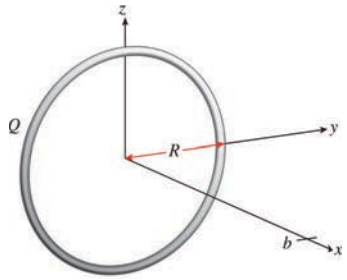

FIGURE 22.14
Charged ring with radius *R* and total charge *Q*.

SOLUTION

THINK

The charge is evenly distributed around the ring. The electric field at position $x = b$ can be calculated by integrating the differential electric field due to a differential electric charge. By symmetry, the components of the electric field perpendicular to the axis of the ring integrate to zero, because the electric fields of charge elements on opposite sides of the axis cancel one another out. The resulting electric field is parallel to the axis of the circle.

SKETCH

Figure 22.15 shows the geometry for the electric field along the axis of the ring of charge.

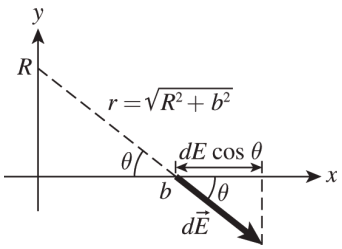

FIGURE 22.15
The geometry for the electric field along the axis of a ring of charge.

RESEARCH

The differential electric field, dE, at $x = b$ is due to a differential charge dq located at $y = R$ (see Figure 22.15). The distance from the point $(x = b, y = 0)$ to the point $(x = 0, y = R)$ is

$$r = \sqrt{R^2 + b^2}.$$

Again, the magnitude of $d\vec{E}$ is given by equation 22.10:

$$dE = k\frac{dq}{r^2}.$$

The magnitude of the component of $d\vec{E}$ parallel to the x-axis is given by

$$dE_x = dE \cos \theta = dE\frac{b}{r}.$$

SIMPLIFY

We can find the total electric field by integrating its x-components over all the charge on the ring:

$$E_x = \int_{\text{ring}} dE_x = \int_{\text{ring}} \frac{b}{r} k \frac{dq}{r^2}.$$

We need to integrate around the circumference of the ring of charge. We can relate the differential charge to the differential arc length, *ds*, as follows:

$$dq = \frac{Q}{2\pi R} ds.$$

We can then express the integral over the entire ring of charge as an integral around the arc length of a circle:

$$E_x = \int_0^{2\pi R} k \left(\frac{Q}{2\pi R} ds \right) \frac{b}{r^3} = \left(\frac{kQb}{2\pi R r^3} \right) \int_0^{2\pi R} ds = kQ \frac{b}{r^3}$$

CALCULATE

Putting in the numerical values, we get

$$E_x = \frac{kQb}{\left(R^2 + b^2\right)^{3/2}} = \frac{\left(8.99 \cdot 10^9 \text{N m}^2/\text{C}^2\right)\left(5.00 \cdot 10^{-6}\text{C}\right.}{\left[(0.250\ \text{m})^2 + (0.500\ \text{m})^2\right.}$$

ROUND

We report our result to three significant figures:

$$E_x = 1.29 \cdot 10^5\ \text{N/C}.$$

DOUBLE-CHECK

We can check the validity of the formula we derived for the electric field by using a large distance from the ring of charge, such that $b \gg R$. In this case,

$$E_x = \frac{kQb}{\left(R^2 + b^2\right)^{3/2}} \overset{b \gg R}{\Longrightarrow} E_x = \frac{kQb}{b^3} = k\frac{Q}{b^2},$$

which is the expression for the electric field due to a point charge Q at a distance b. We can also check the formula with $b = 0$.

$$E_x = \frac{kQb}{\left(R^2 + b^2\right)^{3/2}} \overset{b=0}{\Longrightarrow} E_x = 0,$$

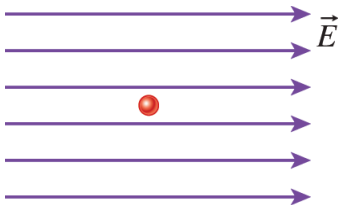
which is what we would expect at the center of a ring of charge. Thus, our result seems reasonable.

22.6 Force due to an Electric Field

The force $\vec{F}$ exerted by an electric field $\vec{E}$ on a point charge q is given by $\vec{F} = q\vec{E}$, a simple restatement of the definition of the electric field in equation 22.1. Thus, the force exerted by the electric field on a positive charge acts in the same direction as the electric field. The force vector is always tangent to the electric field lines and points in the direction of the electric field if $q > 0$.

Concept Check 22.5

A small positively charged object is placed at rest in a uniform electric field as shown in the figure. When the object is released, it will



a) not move.

b) begin to move with a constant speed.

c) begin to move with a constant acceleration.

d) begin to move with an increasing acceleration.

e) move back and forth in simple harmonic motion.

Concept Check 22.6

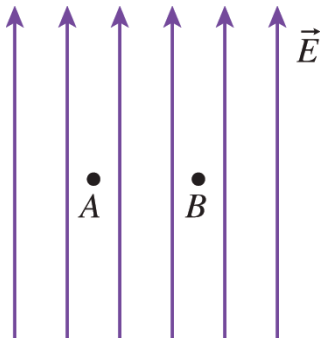
A small positively charged object could be placed in a uniform electric field at position *A* or position *B* in the figure. How do the electric forces on the object at the two positions compare?

a) The magnitude of the electric force on the object is greater at position *A*.

b) The magnitude of the electric force on the object is greater at position *B*.

c) There is no electric force on the object at either position *A* or position *B*.

d) The electric force on the object at position *A* has the same magnitude as the force on the object at position *B* but is in the opposite direction.



e) The electric force on the object at position *A* is the same nonzero electric force as that on the object at position *B*.

The force at various locations on a positive charge due to the electric field in three dimensions is shown in Figure 22.16 for the case of two oppositely charged particles. (This is the same field as in Figure 22.5, but with some representative force vectors added.) You can see that the force on the positive charge is always tangent to the field lines and points in the same direction as the electric

field. The force on the negative charge would point in the opposite direction.

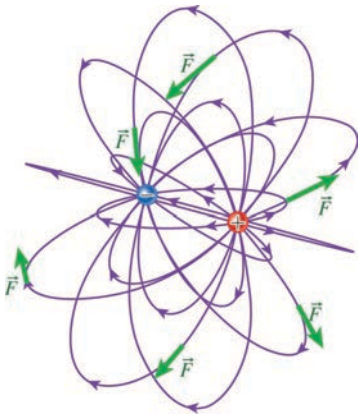


FIGURE 22.16
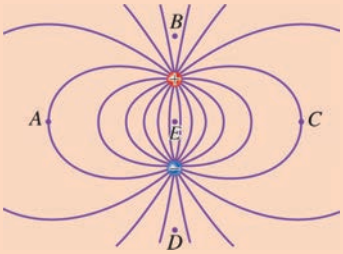
Direction of the force that an electric field produced by two opposite point charges exerts on a positive charge at various points in space.

Self-Test Opportunity 22.1

The figure shows a two-dimensional view of electric field lines due to two opposite charges. What is the direction of the electric field at the five points *A, B, C, D,* and *E*? At which of the five points is the magnitude of the electric field the largest?



EXAMPLE 22.4 Time Projection Chamber

Nuclear physicists study new forms of matter by colliding gold nuclei at very high energies. In particle physics, new elementary particles are created and studied by colliding protons and antiprotons at the highest energies. These collisions create many particles that stream away from the interaction point at high speeds. A simple particle detector is not sufficient to identify these particles. A device that helps physicists study these collisions is a time projection chamber (TPC), found in most large particle detectors.

Page 694

One example of a TPC is the STAR TPC of the Relativistic Heavy Ion Collider at Brookhaven National Laboratory on Long Island, New York. The STAR TPC consists of a large cylinder filled with a gas (90% argon, 10% methane) that allows free electrons to move within it without being captured by the gas atoms or molecules.

Figure 22.17 shows the results of a collision of two gold nuclei that occurred in the STAR TPC. In such a collision, thousands of charged particles are created that pass through the gas inside the TPC. As these charged particles pass through the gas, they ionize the atoms of the gas, releasing free electrons. A constant electric field of magnitude $13,500\text{N/C}$ is applied between the center of the TPC and the caps on the ends of the cylinder, and the field exerts an electric force on the freed electrons. Because the electrons have a negative charge, the electric field exerts a force in the direction opposite to the electric field. The electrons attempt to accelerate in the direction of the electric force, but they interact with the electrons of the molecules of the gas and begin to drift toward the caps with a constant speed of $5\ \text{cm}/\mu\text{s}\ = 5.10^4\text{m/s} \approx 100{,}000\ \text{mph}$.

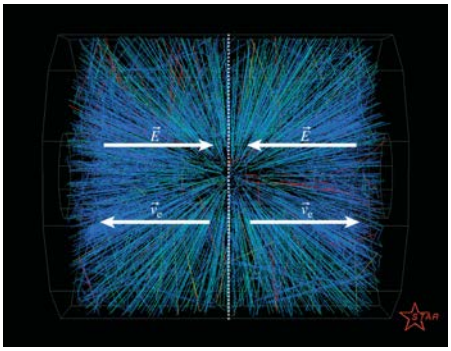


FIGURE 22.17 An event in the STAR TPC in which two gold nuclei have collided at very high energies at the point in the center of the image. Each colored line represents the track left behind by a subatomic particle produced in the collision.

Brookhaven National Laboratory

In this TPC event, each end cap of the cylinder has 87,384 detectors that can measure the charge as a function of the drift time of the electrons from the point where they were freed. Each detector has a specific (x,y) position. From measurements of the arrival time of the charge and the known drift speed of the electrons, the z-components of their positions can be calculated. Thus, the STAR TPC can produce a complete three-dimensional representation of the ionization track of each charged particle. These tracks are shown in Figure 22.17, where the colors represent the amount of ionization produced by each track.

SOLVED PROBLEM 22.2 Electron Moving over a Charged Plate

PROBLEM

An electron with a kinetic energy of $2.00\,\text{keV}\left(1\,\text{eV} = 1.602.10^{-19}\,\text{J}\right)$ is fired horizontally across a horizontally oriented charged conducting plate with a surface charge density of $+4.00 \cdot 10^{-6}\text{C/m}^2$. Taking the positive direction to be upward (away from the plate), what is the vertical deflection of the electron after it has traveled a horizontal distance of 4.00 cm?

SOLUTION

THINK

The initial velocity of the electron is horizontal. During its motion, the electron experiences a constant attractive force from the positively charged plate, which causes a constant acceleration downward. We can calculate the time it takes the electron to travel 4.00 cm in the horizontal direction and use this time to calculate the vertical deflection of the electron.

SKETCH

Figure 22.18 shows the electron with initial velocity $\overrightarrow{v_0}$ in the horizontal direction. The initial position of the electron is taken to be at $x_0 = 0$ and $y = y_0$.

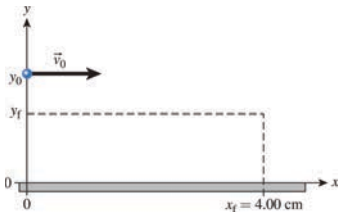

FIGURE 22.18 An electron moving to the right with initial velocity $\vec{v_0}$ over a charged conducting plate.

RESEARCH

The time the electron takes to travel the given distance is

$$t = x_f / v_0, \qquad \textbf{(i)}$$

where x_f is the final horizontal position and v_0 is the initial speed of the electron. While the electron is in motion, it experiences a force from the charged conducting plate. This force is directed downward (toward the plate) and has a magnitude given by

$$F = qE = e\frac{\sigma}{\epsilon_0}, \qquad \textbf{(ii)}$$

where σ is the charge density on the conducting plate and e is the charge of an electron. This force causes a constant acceleration in the downward direction whose magnitude is given by $a = F/m$, where m is the mass of the electron. Using the expression for the force from equation (ii), we can express the magnitude of this acceleration as

$$a = \frac{F}{m} = \frac{e\sigma}{m\epsilon_0}. \qquad \textbf{(iii)}$$

Note that this acceleration is constant. Thus, the vertical position of the electron as a function of time is given by

$$y_f = y_0 - \frac{1}{2}at^2 \Rightarrow y_f - y_0 = -\frac{1}{2}at^2. \qquad \textbf{(iV)}$$

Finally, we can relate the electron's initial kinetic energy to its initial velocity through

$$K = \frac{1}{2}mv_0^2 \Rightarrow v_0^2 = \frac{2k}{m}. \qquad \textbf{(V)}$$

SIMPLIFY

We substitute the expressions for the time and the acceleration from equations (i) and (iii) into equation (iv) and obtain

$$y_f - y_0 = -\frac{1}{2}at^2 = -\frac{1}{2}\left(\frac{e\sigma}{m\epsilon_0}\right)\left(\frac{x_\mathrm{f}}{v_0}\right)^2 = -\frac{e}{2r}$$

Now substituting the expression for the square of the initial speed from equation (v) into the right-hand side of equation (vi) gives us

$$y_\mathrm{f} - y_0 = -\frac{e\sigma x_\mathrm{f}^2}{2m\epsilon_0\left(\dfrac{2K}{m}\right)} = -\frac{e\sigma x_\mathrm{f}^2}{4\epsilon_0 K}. \qquad \textbf{(vii)}$$

CALCULATE

We first convert the kinetic energy of the electron from electron-volts to joules:

$$K = (2.00\,\mathrm{keV})\frac{1.602\cdot 10^{-19}\mathrm{J}}{1\,\mathrm{eV}} = 3.204\cdot 10^{-16}\mathrm{J}.$$

Putting the numerical values into equation (vii), we get

$$y_\mathrm{f} - y_0 = -\frac{e\sigma x_\mathrm{f}^2}{4\epsilon_0 K} = -\frac{\left(1.602\cdot 10^{-19}\mathrm{C}\right)\left(4.00\cdot 10^{-6}\mathrm{C/m}\right.}{4\left(8.85\cdot 10^{-12}\mathrm{C}^2/(\mathrm{N\,m}^2)\right)\left(3.0\right.}$$

ROUND

We report our result to three significant figures:

$$y_f - y_0 = -0.0904\,\mathrm{m} = -9.04\,\mathrm{cm}.$$

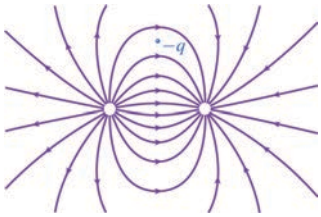
DOUBLE-CHECK

The vertical deflection that we calculated is about twice the distance that the electron travels in the x-direction, which seems reasonable, at least in the sense of being of the same order of magnitude. Also, equation (vii) for the deflection has several features that should be present. First, the trajectory is parabolic, which we expect for a constant force and thus constant acceleration (see Chapter 3). Second, for zero surface charge density, we obtain zero deflection. Third, for very high kinetic energy, there is negligible deflection, which is also intuitively what we expect.

Concept Check 22.7

A negative charge $-q$ is placed in a nonuniform electric field as shown in the figure. What is the direction of the electric force on this negative charge?

a) →



b) ↑

c) ←

d) ↓

e) The force is zero.

Dipole in an Electric Field

A point charge in an electric field experiences a force, given by equation 22.1. The electric force is always tangent to the electric field line passing through the point. The effect of an electric field on a dipole can be described in terms of the vector electric field, $\vec{E}$, and the vector electric dipole moment, $\vec{P}$, without detailed knowledge of the charges making up the electric dipole.

To examine the behavior of an electric dipole, let's consider two charges, $+q$ and $-q$, separated by a distance d in a constant uniform electric field, $\vec{E}$, (Figure 22.19). (Note that we are now considering the forces acting on a dipole placed in an external field, as opposed to considering the field caused by the dipole, which we did in Section 22.4, and we also assume that the dipole field is small compared to $\vec{E}$, [so its effect on the uniform field can be ignored].) The electric field exerts an upward force on the positive charge and a downward force on the negative charge. Both forces have the magnitude qE In Chapter 10, we saw that this situation gives rise to a torque, $\vec{\tau}$, given by $\vec{\tau} = \vec{r} \times \vec{F}$, where $\vec{r}$ is the moment arm and $\vec{F}$ is the force. The magnitude of the torque is $\tau = rF \sin \theta$.

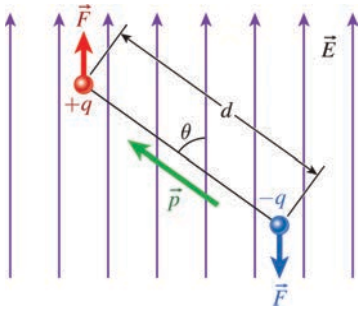


FIGURE 22.19
Electric dipole in an electric field.

As always, we can calculate the torque about any pivot point, so we can pick the location of the negative charge. Then, only the force on the positive charge contributes to the torque, and the length of the position vector is $r = d$, that is, the length of the dipole. Since, as already stated, $F = qE$, the expression for the torque on an electric dipole in an external electric field can be written as

$$\tau = qEd \sin \theta.$$

Remembering that the electric dipole moment is defined as $p = qd$, we obtain the magnitude of the torque:

$$\tau = pE \sin \theta. \qquad \textbf{(22.11)}$$

Because the torque is a vector and must be perpendicular to both the electric dipole moment and the electric field, the relationship in equation 22.11 can be written as a vector product:

$$\overrightarrow{\tau} = \overrightarrow{p} \times \overrightarrow{E}. \qquad \textbf{(22.12)}$$

As with all vector products, the direction of the torque is given by a right-hand rule. As shown in Figure 22.20, the thumb indicates the direction of the first term of the vector product, in this case $\overrightarrow{p}$ and the index finger indicates the direction of the second term, $\overrightarrow{E}$ The result of the vector product, $\overrightarrow{\tau}$, is then directed along the middle finger and is perpendicular to each of the two terms.

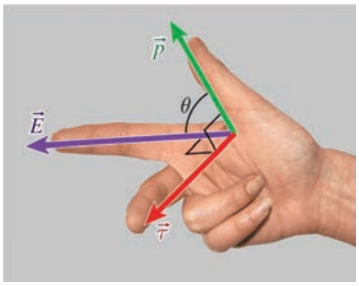

FIGURE 22.20
Right-hand rule for the vector product of the electric dipole moment and the electric field, producing the torque vector.

Mark Dierker/McGraw Hill

Self-Test Opportunity 22.2

Use the center of mass of the dipole as the pivot point, and show that you again obtain the expression $\tau = qEd\sin\theta$ for the torque.

SOLVED PROBLEM 22.3 Electric Dipole in an Electric Field

PROBLEM

An electric dipole with dipole moment of magnitude $p = 1.40 \cdot 10^{-12}$ C m is placed in a uniform electric field of magnitude $E = 498\,\mathrm{N/C}$ (Figure 22.21a).

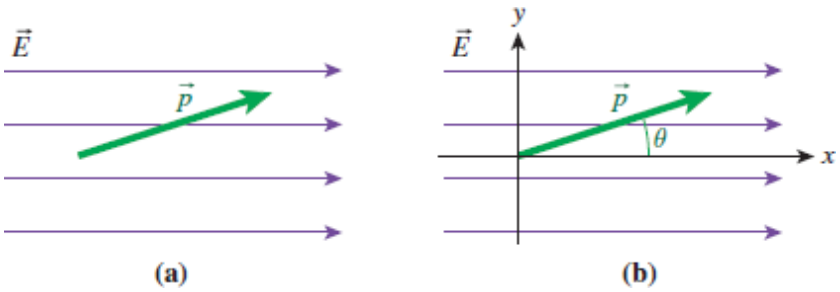

FIGURE 22.21 (a) An electric dipole in a uniform electric field. (b) The electric field oriented in the x-direction and the dipole moment in the *xy*-plane.

At some instant (in time) the angle between the electric dipole moment and the electric field is $\theta = 14.5^\circ$. What are the Cartesian components of the torque on the dipole?

SOLUTION

THINK

The torque on the dipole is equal to the vector product of the electric field and the electric dipole moment.

SKETCH

We assume that the electric field lines point in the *x*-direction and the electric dipole moment is in the *xy*-plane (Figure 22.21b). The *z*-direction is perpendicular to the plane of the page.

RESEARCH

The torque on the electric dipole due to the electric field is given by

$$\vec{\tau} = \vec{p} \times \vec{E}.$$

Since the dipole is located in the xy-plane, the Cartesian components of the electric dipole moment are

$$\vec{p} = (p_x, p_y, 0).$$

Since the electric field is acting in the x-direction, its Cartesian components are

$$\vec{E} = (E_x, 0, 0) = (E, 0, 0).$$

SIMPLIFY

From the definition of the vector product, we express the Cartesian components of the torque as

$$\vec{\tau} = (p_y E_z - p_z E_y)\hat{x} + (p_z E_x - p_x E_z)\hat{y} + (p_x E_y - p_y E_x)$$

In this particular case, with E_y, E_z, and p_z all equal to zero, we have

$$\vec{\tau} = -p_y E_x \hat{z}.$$

The y-component of the dipole moment is $p_y = p \sin\theta$, and the x-component of the electric field is simply $E_x = E$. The magnitude of the torque is then

$$\tau = (p \sin\theta)E = pE \sin\theta,$$

and the direction of the torque is in the negative z-direction.

CALCULATE

We insert the given numerical data and get

$$\tau = pE \sin\theta = \left(1.40 \cdot 10^{-12}\text{C m}\right)(498\text{N/C})(\sin 14.5^\circ) =$$

ROUND

We report our result to three significant figures:

$$\tau = 1.75 \cdot 10^{-10}\ \text{N m}.$$

DOUBLE-CHECK

From equation 22.11, we know that the magnitude of the torque is

$$\tau = pE \sin\theta,$$

which is the result we obtained using the explicit vector product. Applying the right-hand rule illustrated in Figure 22.20, we can determine the direction of the torque: With the right thumb representing the electric dipole moment and the right index finger representing the electric field, the right middle finger points into the page, which agrees with the result we found using the vector product. Thus, our result is correct.

Example 22.2 looked at the dipole moment of the water molecule. If water molecules are exposed to an external electric field, they experience a torque and thus begin to rotate. If the direction of the external electric field changes very rapidly, the water molecules perform rotational oscillations, which create heat. This is the principle of operation of a microwave oven. Microwave ovens use a frequency of 2.45 GHz for the oscillating electric field. (How an electric field is made to oscillate in time will be covered in Chapter 31 on electromagnetic waves.)

Electric fields also play a key role in human physiology, but these fields are time-varying and not static, like those studied in this chapter. (They will be covered in later chapters.) The evolution

over time of electric fields in the human heart is measured by an electrocardiogram (ECG) (to be discussed, along with the functioning of pacemaker implants, in Chapter 26 on circuits). The human brain also generates continuously changing electrical fields through the activity of the neurons. These fields can be measured invasively by inserting electrodes through the skull and into the brain or by placing electrodes onto the surface of the exposed brain, usually during brain surgery. This technique is called electrocorticography (ECoG). An intense area of current research focuses on measuring and imaging brain electric fields noninvasively by attaching electrodes to the outside of the skull. However, since the skull itself dampens the electric fields, these techniques require great instrumental sensitivity and are still in their infancy. Perhaps the most exciting (or scary, depending on your point of view) research developments are in brain-computer interfaces. In this emerging field, electrical activity in the brain is used directly to control computers, and external stimuli are used to create electric fields inside the brain. Researchers in this area are motivated by the goal of helping people overcome physical disabilities, such as blindness or paralysis.

22.7 Electric Flux

Electric field calculations, like those in Example 22.3, can require quite a bit of work. However, in many common situations, particularly those with some geometric symmetry, a powerful technique for determining electric fields without having to explicitly calculate integrals can be used. This technique is based on *Gauss's Law,* one of the fundamental relations concerning electric fields. It will allow us to solve seemingly very complicated problems involving electric fields in an amazingly straightforward and simple fashion. However, to use Gauss's Law requires understanding of a concept called *electric flux*.

Imagine holding a ring with inside area A in a stream of water flowing with velocity $\vec{v}$, as shown in Figure 22.22. The area vector, $\vec{A}$, of the ring is defined as a vector with magnitude A pointing in a direction perpendicular to the plane of the ring. In Figure 22.22a, the area vector of the ring is parallel to the flow velocity, and the flow velocity is perpendicular to the plane of the ring. The product Av gives the amount of water passing through the ring per unit time (see Chapter 13), where v is the magnitude of the flow velocity. If the plane of the ring is tilted with respect to the direction of the flowing water (Figure 22.22b), the amount of water flowing through the ring is given by $Av \cos\theta$, where θ is the angle between the area vector of the ring and the direction of the velocity of the flowing water. The amount of water flowing through the ring is called the *flux,* $\Phi = Av\cos\theta = \vec{A} \bullet \vec{v}$. Since flux is a measure of volume per unit time, its units are cubic meters per second $\left(\mathrm{m}^3/\mathrm{s}\right)$.

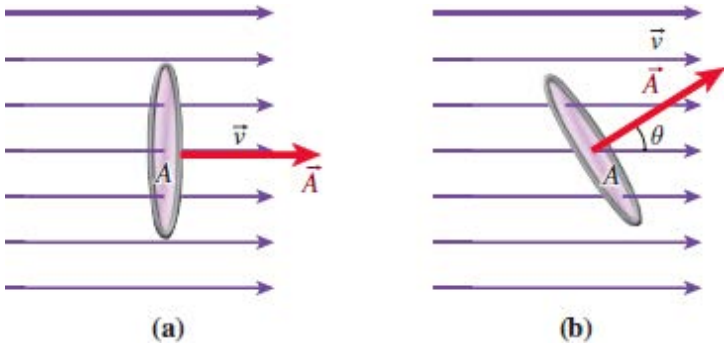

FIGURE 22.22 Water flowing with velocity of magnitude v through a ring of area A. (a) The area vector is parallel to the flow velocity. (b) The area vector is at an angle θ to the flow velocity.

An electric field is analogous to flowing water. Consider a uniform electric field of magnitude E passing through a given area A (Figure 22.23). Again, the area vector is $\vec{A}$, with a direction normal to the surface of the area and a magnitude A. The angle θ is the angle between the vector electric field and the area vector, as shown in Figure 22.23. The electric field passing through a given area A is called the **electric flux** and is given by

$$\Phi = EA \cos \theta. \qquad \textbf{(22.13)}$$

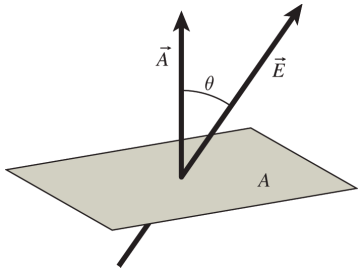

FIGURE 22.23 A uniform electric field $\vec{E}$ passing through an area $\vec{A}$.

In simple terms, the electric flux is proportional to the number of electric field lines passing through the area. We'll assume that the electric field is given by $\vec{E}\left(\vec{r}\right)$ and that the area is a closed surface, rather than the open surface of a simple ring in flowing water. In this closed-surface case, the total, or net, electric flux is given by an integral of the electric field over the closed surface:

$$\Phi = \oiint \vec{E} \bullet d\vec{A}, \qquad \textbf{(22.14)}$$

where $\vec{E}$ is the electric field at each differential area element $d\vec{A}$ of the closed surface. The direction of $d\vec{A}$ is outward from the closed surface. In equation 22.14, the loop on the integrals means that the integration is over a closed surface, and the two integral signs signify an integration over two variables. (*Note:* Some books use different notation for the integral over a closed surface, $\iint_S dA$ or just $\int_S dA$, but these refer to the same integration procedure as is represented in equation 22.14.) The differential area element $d\vec{A}$ must be described by two spatial variables, such as x and y in Cartesian coordinates or θ and ϕ in spherical coordinates.

Figure 22.24 shows a nonuniform electric field, $\vec{E}$, passing through a differential area element, $d\vec{A}$, A portion of the closed surface is also shown. The angle between the electric field and the differential area element is θ.

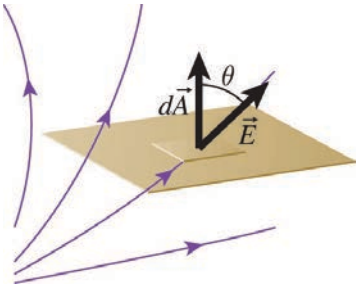

FIGURE 22.24 A nonuniform electric field, $\overrightarrow{E}$, passing through a differential area, $d\overrightarrow{A}$.

EXAMPLE 22.5 Electric Flux through a Cube

Figure 22.25 shows a cube that has faces of area A in a uniform electric field, $\vec{E}$, that is perpendicular to the plane of one face of the cube.

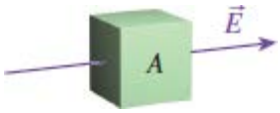

FIGURE 22.25 A cube with faces of area A in a uniform electric field, $\vec{E}$,

PROBLEM

What is the net electric flux passing though the cube?

SOLUTION

The electric field in Figure 22.25 is perpendicular to the plane of one of the cube's six faces and therefore is also perpendicular to the opposite face. The area vectors of these two faces, $\vec{A}_1$ and $\vec{A}_2$ are shown in Figure 22.26a. The net electric flux passing through these two faces is

$$\Phi_{12} = \Phi_1 + \Phi_2 = \vec{E} \bullet \vec{A}_1 + \vec{E} \bullet \vec{A}_2 = -EA_1 + EA_2 = 0$$

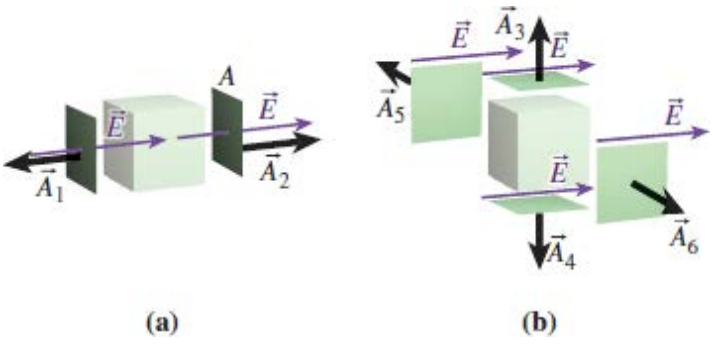

FIGURE 22.26 (a) The two faces of the cube that are perpendicular to the electric field. The area vectors are parallel and antiparallel to the electric field. (b) The four faces of the cube that are parallel to the electric field. The area vectors are perpendicular to the electric field.

The negative sign arises for the flux through face 1 because the electric field and the area vector, $\vec{A}_1$ are in opposite directions. The area vectors of the remaining four faces are all perpendicular to the electric field, as shown in Figure 22.26b. The net electric flux passing through these four faces is

$$\Phi_{3456} = \Phi_3 + \Phi_4 + \Phi_5 + \Phi_6 = \vec{E} \bullet \vec{A}_3 + \vec{E} \bullet \vec{A}_4 + \vec{E} \bullet \vec{A}$$

All the scalar products are zero because the area vectors of these four faces are perpendicular to the electric field. Thus, the net electric flux passing through the cube is

$$\Phi = \Phi_{12} + \Phi_{3456} = 0.$$

22.8 Gauss's Law

To begin our discussion of Gauss's Law, let's imagine a box in the shape of a cube (Figure 22.27a), which is constructed of a material that does not affect electric fields. A positive test charge brought close to any surface of the box will experience no force. Now suppose a positive charge is inside the box and the positive test charge is brought close to the surface of the box (Figure 22.27b). The positive test charge experiences an outward force due to the positive charge inside the box. If the test charge is close to any surface of the box, it experiences the outward force. If twice as much positive charge is inside the box, the positive test charge experiences twice the outward force when brought close to any surface of the box.

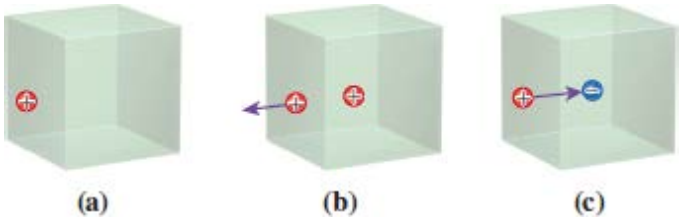

FIGURE 22.27 Three imaginary boxes constructed of material that does not affect electric fields. A positive test charge is brought up to the box from the left toward: (a) an empty box; (b) a box with a positive charge inside; (c) a box with a negative charge inside.

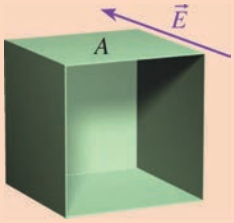
Self-Test Opportunity 22.3

The figure shows a cube with faces of area A and one face missing. This five-sided cubical object is in a uniform electric field, $\vec{E}$, perpendicular to one face. What is the net electric flux passing through the object?



Now suppose there is a negative charge inside the box (Figure 22.27c). When the positive test charge is brought close to one surface of the box, the charge experiences an inward force. If the positive test charge is close to any surface of the box, it experiences an inward force. Doubling the negative charge in the box doubles the inward force on the test charge when it is close to any surface of the box.

In analogy with flowing water, the electric field lines seem to be flowing out of the box containing positive charge and into the box containing negative charge.

Now let's imagine an empty box in a uniform electric field (Figure 22.28). If a positive test charge is brought close to side 1, it experiences an inward force. If the charge is close to side 2, it experiences an outward force. The electric field is parallel to the other four sides, so the positive test charge does not experience any inward or outward force when brought close to those sides. Thus, in analogy with flowing water, the net amount of electric field that seems to be flowing in and out of the box is zero.

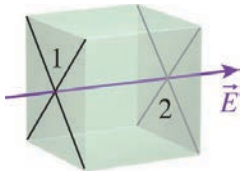


FIGURE 22.28
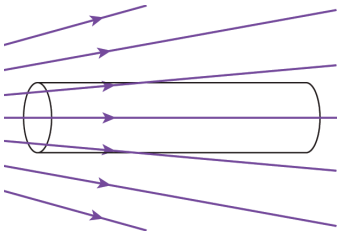
Imaginary empty box in a uniform electric field.

Concept Check 22.8

A cylinder made of an insulating material is placed in an electric field as shown in the figure. The net electric flux passing through the surface of the cylinder is



a) positive.
b) negative.
c) zero.

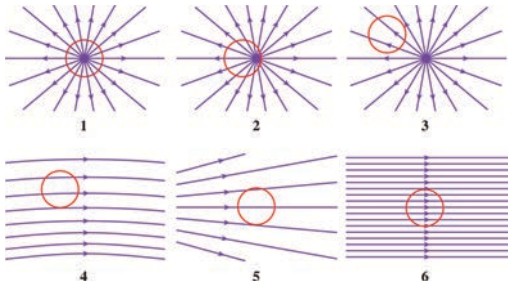
Whenever a charge is inside the box, the electric field lines seem to be flowing in or out of the box. When there is no charge in the box, the net flow of electric field lines in or out of the box is zero. These observations and the definition of electric flux, which quantifies the concept of the flow of the electric field lines, lead to **Gauss's Law:**

$$\Phi = \frac{q}{\epsilon_0}. \qquad \textbf{(22.15)}$$

Here q is the net charge inside a closed surface, called a **Gaussian surface.** The closed surface could be a box like that we have been discussing or any arbitrarily shaped closed surface. Usually, the shape of the Gaussian surface is chosen so as to reflect the symmetries of the problem situation.

Concept Check 22.9

The lines in the figure are electric field lines, and the circle is a Gaussian surface. For which case(s) is (are) the total electric flux nonzero?



a) 1 only
b) 2 only
c) 4, 5, and 6
d) 6 only
e) 1 and 2

An alternative formulation of Gauss's Law incorporates the definition of the electric flux (equation 22.14):

$$\oiint \vec{E} \bullet d\vec{A} = \frac{q}{\epsilon_0}. \qquad \textbf{(22.16)}$$

According to equation 22.16, Gauss's Law states that the surface integral of the electric field components perpendicular to the area

times the area is proportional to the net charge within the closed surface. This expression may look daunting, but it simplifies considerably in many cases and allows us to perform very quickly calculations that would otherwise be quite complicated.

Gauss's Law and Coulomb's Law

We can derive Gauss's Law from Coulomb's Law. To do this, we start with a positive point charge, q. The electric field due to this charge is radial and pointing outward, as we saw in Section 22.3. According to Coulomb's Law (Section 21.5), the magnitude of the electric field from this charge is

$$E = \frac{1}{4\pi\epsilon_0}\frac{q}{r^2}.$$

We now find the electric flux passing through a closed surface resulting from this point charge. For the Gaussian surface, we choose a spherical surface with radius r, with the charge at the center of the sphere, as shown in Figure 22.29. The electric field due to the positive point charge intersects each differential element of the surface of the Gaussian sphere perpendicularly. Therefore, at each point of this Gaussian surface, the electric field vector, $\vec{E}$, and the differential surface area vector, $d\vec{A}$, are parallel. The surface area vector will always point outward from the spherical Gaussian surface, but the electric field vector can point outward or inward depending on the sign of the charge. For a positive charge, the scalar product of the electric field and the surface area element is $\vec{E} \bullet d\vec{A} = E\,dA\cos 0^\circ = E\,dA$. The electric flux in this case, according to equation 22.14, is

$$\Phi = \oiint \vec{E} \bullet d\vec{A} = \oiint E\,dA.$$

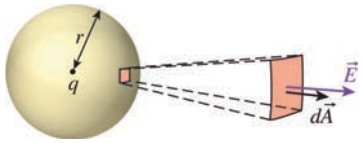


FIGURE 22.29 A spherical Gaussian surface with radius *r* surrounding a charge *q*. A closeup view of a differential surface element with area *dA* is shown.

Because the electric field has the same magnitude anywhere in space at a distance r from the point charge q, we can take E outside the integral:

$$\Phi = \oiint E\, dA = E \oiint dA.$$

Now what we have left to evaluate is the integral of the differential area over a spherical surface, which is given by $\oiint dA = 4\pi r^2$. Therefore, we have found from Coulomb's Law for the case of a point charge

$$\Phi = (E)(\oiint\ dA) = \left(\frac{1}{4\pi\epsilon_0}\frac{q}{r^2}\right)(4\pi r^2) = \frac{q}{\epsilon_0},$$

which is the same as the expression for Gauss's Law in equation 22.15. We have shown that Gauss's Law can be derived from Coulomb's Law for a positive point charge, but it can also be shown that Gauss's Law holds for any distribution of charge inside a closed surface.

Self-Test Opportunity 22.4

What changes in the preceding derivation of Gauss's Law if a negative point charge is used?

Shielding

Two important consequences of Gauss's Law are evident:

1. The electrostatic field inside any isolated conductor is always zero.
2. Cavities inside conductors are shielded from electric fields.

To examine these consequences, let's suppose a net electric field exists at some moment at some point inside an isolated conductor; see Figure 22.30a. But every conductor has free electrons inside it (blue circles in Figure 22.30b), which can move rapidly in response to any net external electric field, leaving behind positively charged ions (red circles in Figure 22.30b). The charges will move to the outer surface of the conductor, leaving no net accumulation of charge inside the volume of the conductor. These charges will in turn create an electric field inside the conductor (yellow arrows in Figure 22.30b), and they will move around until the electric field produced by them exactly cancels the external electric field. The net electric field thus becomes zero everywhere inside the conductor (Figure 22.30c).

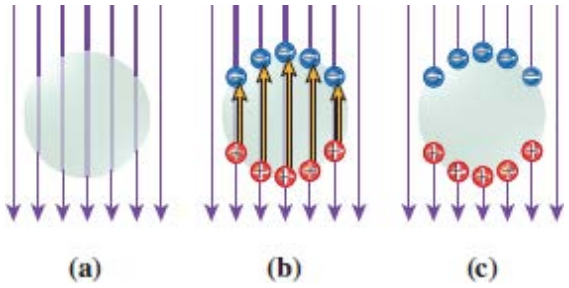

FIGURE 22.30
Shielding of an external electric field (purple vertical arrows) from the inside of a conductor.

If a cavity is scooped out of a conducting body, the net charge and thus the electric field inside this cavity is always zero, no

matter how strongly the conductor is charged or how strong an external electric field acts on it. To prove this, we assume a closed Gaussian surface surrounds the cavity, completely inside the conductor. From the preceding discussion (see Figure 22.30), we know that at each point of this surface, the field is zero. Therefore, the net flux over this surface is also zero. By Gauss's Law, it then follows that this surface encloses zero net charge. If there were equal amounts of positive and negative charge on the cavity surface (and thus no net charge), this charge would not be stationary, as the positive and negative charges would be attracted to each other and would be free to move around the cavity surface to cancel each other. Therefore, any cavity inside a conductor is totally shielded from any external electric field. This effect is sometimes called **electrostatic shielding.**

Concept Check 22.10

A hollow, conducting sphere is initially given an evenly distributed negative charge. A positive charge $+q$ is brought near the sphere and placed at rest as shown in the figure. What is the direction of the electric field inside the hollow sphere?

a) ➞

b) ↑

c) ←

d) ↓

e) The field is zero.

A convincing demonstration of this shielding is provided by placing a plastic container filled with Styrofoam peanuts on top of a Van de Graaff generator, which serves as the source of strong electric field (Figure 22.31a). Charging the generator results in a large net charge accumulation on the dome, producing a strong electric field in the vicinity. Because of this field, the charges in the Styrofoam peanuts separate slightly, and the peanuts acquire small dipole moments. If the field were uniform, there would be no force on these dipoles. However, the nonuniform electric field does exert a force, even though the peanuts are electrically neutral. The peanuts thus fly out of the container. If the same Styrofoam peanuts are placed inside an open metal can, they do not fly out when the generator is charged (Figure 22.31b). The electric field easily penetrates the walls of the plastic container and reaches the Styrofoam peanuts, whereas, in accord with Gauss's Law, the conducting metal can provide shielding inside and prevents the Styrofoam peanuts from acquiring dipole moments.

FIGURE 22.31 Styrofoam peanuts are put inside a container that is placed on top of a Van de Graaff generator, which is then charged. (a) The peanuts fly out of a nonconducting plastic container. (b) The peanuts remain within a metal can.

W. Bauer and G. D. Westfall

The conductor surrounding the cavity does not have to be a solid piece of metal; even a wire mesh is sufficient to provide shielding. This can be demonstrated most impressively by seating a person inside a cage and then hitting the cage with a lightning-like electrical discharge (Figure 22.32). The person inside the cage is unhurt, even if he or she touches the metal of the cage *from the inside*. (It is important to realize that severe injuries can result if any body parts stick out of the cage, for example, if hands are wrapped around the bars of the cage!) This cage is called a *Faraday cage*, after British physicist Michael Faraday (1791–1867), who invented it.

FIGURE 22.32 A person inside a Faraday cage is unharmed by a large voltage applied outside the cage, which produces a huge spark. This demonstration is performed several times daily at the Deutsches Museum in Munich, Germany.

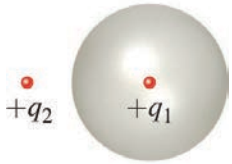
Michigan State University

A Faraday cage has important consequences, probably the most relevant of which is the fact that your car protects you from being hit by lightning while inside it—unless you drive a convertible. The sheet metal and steel frame that surround the passenger

compartment provide the necessary shielding. (But as fiberglass, plastic, and carbon fiber begin to replace sheet metal in auto bodies, this shielding is not assured any more.)

Concept Check 22.11

A hollow, conducting sphere is initially uncharged. A positive charge, $+q_1$, is placed inside the sphere, as shown in the figure. Then, a second positive charge, $+q_2$, is placed near the sphere but outside it. Which of the following statements describes the net electric force on each charge?



a) There is a net electric force on $+q_2$, but not on $+q_1$,

b) There is a net electric force on $+q_1$, but not on $+q_2$,

c) Both charges are acted on by a net electric force with the same magnitude and in the same direction.

d) Both charges are acted on by a net electric force with the same magnitude but in opposite directions.

e) There is no net electric force on either charge.

22.9 Special Symmetries

In this section we'll determine the electric field due to charged objects of different shapes. In Section 22.5, the charge distributions for different geometries were defined; see equation 22.9. Table 22.1 lists the symbols for these charge distributions and their units.

Page 703

Table 22.1 Symbols for Charge Distributions

Symbol	Name	Unit
λ	Charge per length	$\mathrm{C/m}$
σ	Charge per area	$\mathrm{C/m^2}$
ρ	Charge per volume	$\mathrm{C/m^3}$

Cylindrical Symmetry

Using Gauss's Law, we can calculate the magnitude of the electric field due to a long straight conducting wire with uniform charge per unit length $\lambda > 0$. We first imagine a Gaussian surface in the form of a right cylinder with radius r and length L surrounding the wire so that the wire is along the axis of the cylinder (Figure 22.33). We can apply Gauss's Law to this Gaussian surface. From symmetry, we know that the electric field produced by the wire must be radial and perpendicular to the wire. What invoking symmetry means deserves further explanation because such arguments are very common.

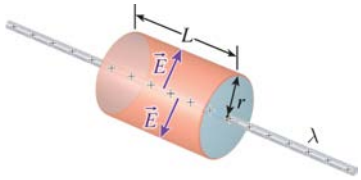


FIGURE 22.33
Long wire with charge per unit length λ surrounded by a Gaussian surface in the form of a right cylinder with radius r and length L. Representative electric field vectors are shown inside the cylinder.

First, we imagine rotating the wire about an axis along its length. This rotation would include all charges on the wire and their electric fields. However, the wire would still look the same after a rotation through any angle. The electric field created by the charge on the wire would therefore also be the same. From this argument, we conclude that the electric field cannot depend on the rotation angle around the wire. This conclusion is general: If an

object has *rotational symmetry,* its electric field cannot depend on the rotation angle.

Second, if the wire is very long, it will look the same no matter where along its length it is viewed. If the wire is unchanged, its electric field is also unchanged. This observation means that there is no dependence on the coordinate along the wire. This symmetry is called *translational symmetry*. Since there is no preferred direction in space along the wire, there can be no electric field component parallel to the wire.

Concept Check 22.12

A total of $1.45 \cdot 10^6$ excess electrons are placed on an initially electrically neutral wire of length 1.13 m. What is the magnitude of the electric field at a point at a perpendicular distance of 0.401 m away from the center of wire? (*Hint*: Assume that 1.13 m is close enough to "infinitely long.")

a) $9.21 \cdot 10^{-3}$ N/C

b) $2.92 \cdot 10^{-1}$ N/C

c) $6.77 \cdot 10^{1}$ N/C

d) $8.12 \cdot 10^{2}$ N/C

e) $3.31 \cdot 10^{3}$ N/C

Returning to the Gaussian surface, we can see that the contribution to the integral in Gauss's Law (equation 22.16) from the ends of the cylinder is zero because the electric field is parallel to these surfaces and is thus perpendicular to the normal vectors from the surface. The electric field is perpendicular to the wall of the cylinder everywhere, so we have

$$\oiint \vec{E} \bullet d\vec{A} = EA = E(2\pi rL) = \frac{q}{\epsilon_0} = \frac{\lambda L}{\epsilon_0},$$

where $2\pi rL$ is the area of the wall of the cylinder. Solving this equation, we find the magnitude of the electric field due to a uniformly charged long straight wire:

$$E = \frac{\lambda}{2\pi\epsilon_0 r} = \frac{2k\lambda}{r}, \qquad \textbf{(22.17)}$$

where r is the perpendicular distance to the wire. For $\lambda < 0$, equation 22.17 still applies, but the electric field points inward instead of outward. Note that this is the same result we obtained in Example 22.3 for the electric field due to a wire of infinite length—but attained here in a much simpler way!

You begin to see the great computational power contained in Gauss's Law, which can be used to calculate the electric field resulting from all kinds of charge distributions, both discrete and continuous. However, it is practical to use Gauss's Law only in situations where you can exploit some symmetry; otherwise, it is too difficult to calculate the flux.

Self-Test Opportunity 22.5

By how much does the answer to Concept Check 22.12 change if the assumption that the wire can be treated as being infinitely long is not made? (*Hint:* See Example 22.3.)

It is instructive to compare the dependence of the electric field on the distance from a point charge and the distance from a long straight wire. For the point charge, the electric field falls off with the square of the distance, much faster than does the electric field due to the long wire, which decreases in inverse proportion to the distance.

Planar Symmetry

Assume a flat thin, infinite, nonconducting sheet of positive charge (Figure 22.34), with uniform charge per unit area $\sigma > 0$. Let's find the electric field a distance r from the surface of this infinite plane of charge.

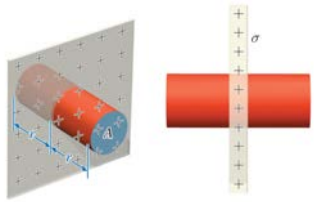

FIGURE 22.34
Infinite, flat, nonconducting sheet with charge density σ. Cutting through the plane perpendicularly is a Gaussian surface in the form of a right cylinder with cross-sectional area A parallel to the plane and height r above and below the plane.

To do this, we choose a Gaussian surface in the form of a closed right cylinder with cross-sectional area A and length $2r$, which cuts through the plane perpendicularly, as shown in Figure 22.34. Because the plane is infinite and the charge is positive, the electric field must be perpendicular to the ends of the cylinder and parallel to the cylinder wall. Using Gauss's Law, we obtain

$$\oiint \vec{E} \bullet d\vec{A} = (EA + EA) = \frac{q}{\epsilon_0} = \frac{\sigma A}{\epsilon_0},$$

where σA is the charge enclosed in the cylinder. Thus, the magnitude of the electric field due to an infinite plane of charge is

$$E = \frac{\sigma}{2\epsilon_0}. \qquad \textbf{(22.18)}$$

If $\sigma < 0$, then equation 22.18 still holds, but the electric field points toward the plane instead of away from it.

For an infinite conducting sheet with charge density $\sigma > 0$ on each surface, we can find the electric field by choosing a Gaussian surface in the form of a right cylinder. However, for this case, one end of the cylinder is embedded inside the conductor (Figure 22.35). The electric field inside the conductor is zero; therefore, there is no flux through the end of the cylinder enclosed in the conductor. The electric field outside the conductor must be perpendicular to the surface and therefore parallel to the wall of the cylinder and perpendicular to the end of the cylinder that is outside the conductor. Thus, the flux through the Gaussian surface is EA. The enclosed charge is given by σA, so Gauss's Law becomes

$$\oiint \vec{E} \bullet d\vec{A} = EA = \frac{\sigma A}{\epsilon_0}.$$

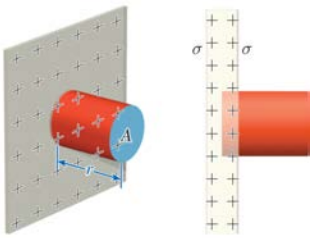

FIGURE 22.35
Infinite conducting plane with charge density σ on each surface and a Gaussian surface in the form of a right cylinder embedded in one side.

Thus, the magnitude of the electric field just outside the surface of a flat charged conductor is

$$E = \frac{\sigma}{\epsilon_0}. \qquad \textbf{(22.19)}$$

Spherical Symmetry

To find the electric field due to a spherically symmetrical distribution of charge, we consider a thin spherical shell with charge $q > 0$ and radius r_s (Figure 22.36).

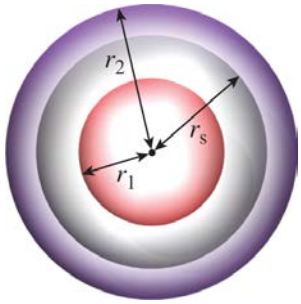

FIGURE 22.36
Spherical shell of charge with radius r_s along with a Gaussian surface with radius $r_2 > r_s$ and a second Gaussian surface with radius $r_1 < r_s$.

Here we use a spherical Gaussian surface with $r_2 > r_s$ that is concentric with the charged sphere. Applying Gauss's Law, we get

$$\oiint \vec{E} \bullet d\vec{A} = E\left(4\pi r_2^2\right) = \frac{q}{\epsilon_0}.$$

We can solve for the magnitude of the electric field, E, which is

$$E = \frac{1}{4\epsilon_0}\frac{q}{r_2^2}.$$

If $q < 0$, the field points radially inward instead of radially outward from the spherical surfaces. For another spherical Gaussian surface, with $r_1 < r_s$, that is also concentric with the charged spherical shell, we obtain

$$\oiint \vec{E} \bullet d\vec{A} = E\left(4\pi r_1^2\right) = 0.$$

Thus, the electric field outside a spherical shell of charge behaves as if the charge were a point charge located at the center of the sphere, whereas the electric field is zero inside the spherical shell of charge.

Now let's find the electric field due to charge that is equally distributed throughout a spherical volume, with uniform charge density $\rho > 0$ (Figure 22.37). The radius of the sphere is r. We use a Gaussian surface in the form of a sphere with radius $r_1 < r$. From the symmetry of the charge distribution, we know that the electric field resulting from the charge is perpendicular to the Gaussian surface. Thus, we can write

$$\oiint \vec{E} \bullet d\vec{A} = E\left(4\pi r_1^2\right) = \frac{q}{\epsilon_0} = \frac{\rho}{\epsilon_0}\left(\frac{4}{3}\pi r_1^3\right),$$

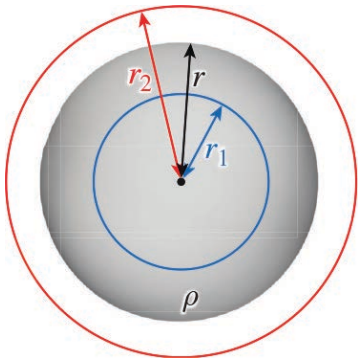

FIGURE 22.37
Spherical distribution of charge with uniform charge per unit volume ρ and radius r. Two spherical Gaussian surfaces are also shown, one with radius $r_1 < r$ and one with radius $r_2 > r$.

where $4\pi r_1^2$ is the area of the spherical Gaussian surface and $\frac{4}{3}\pi \mathrm{r}_1^3$ is the volume enclosed by the Gaussian surface. From the preceding equation, we obtain the electric field at a radius r_1 inside a uniform distribution of charge:

$$E = \frac{\rho r_1}{3\epsilon_0}. \tag{22.20}$$

The total charge on the sphere can be called q_t, and it equals the total volume of the spherical charge distribution times the charge density:

$$q_\mathrm{t} = \rho\frac{4}{3}\pi r^3.$$

The charge enclosed by the Gaussian surface then is

$$q = \frac{\text{volume inside } r_1}{\text{volume of charge distribution}} q_\mathrm{t} = \frac{\frac{4}{3}\pi r_1^3}{\frac{4}{3}\pi r^3} q_\mathrm{t} = \frac{r_1^3}{r^3} q_\mathrm{t}.$$

With this the expression for the enclosed charge, we can rewrite Gauss's Law for this case as

$$\oiint \vec{E} \bullet d\vec{A} = E\left(4\pi r_1^2\right) = \frac{q_\mathrm{t}}{\epsilon_0}\frac{r_1^3}{r^3},$$

which gives us

$$E = \frac{q_\mathrm{t} r_1}{4\pi\epsilon_0 r^3} = \frac{k q_\mathrm{t} r_1}{r^3}. \tag{22.21}$$

If we consider a Gaussian surface with a radius larger than the radius of the charge distribution, $r_2 > r$, we can apply Gauss's Law as follows:

$$\oiint \vec{E} \bullet d\vec{A} = E\left(4\pi r_2^2\right) = \frac{q_t}{\epsilon_0},$$

or

$$E = \frac{q_t}{4\pi\epsilon_0 r_2^2} = \frac{kq_t}{r_2^2}. \qquad \textbf{(22.22)}$$

Self-Test Opportunity 22.6

Consider a sphere of radius *R* with charge *q* uniformly distributed throughout the volume of the sphere. What is the magnitude of the electric field at a point 2*R* away from the center of the sphere?

Thus, the electric field outside a uniform spherical distribution of charge is the same as the field due to a point charge of the same magnitude located at the center of the sphere.

SOLVED PROBLEM 22.4 Nonuniform Spherical Charge Distribution

A spherically symmetrical but nonuniform charge distribution is given by

$$\rho(r) = \begin{cases} \rho_0\left(1 - \dfrac{r}{R}\right) & \text{for } r \leq R \\ 0 & \text{for } r > R, \end{cases}$$

where $\rho_0 = 10.0\ \mu\text{C/m}^3$ and $R = 0.250\ \text{m}$.

PROBLEM

What is the electric field produced by this charge distribution at $r_1 = 0.125\ \text{m}$ and at $r_2 = 0.500\ \text{m}$?

SOLUTION

THINK

We can use Gauss's Law to determine the electric field as a function of radius if we employ a spherical Gaussian surface. The radius $r_1 = 0.125\ \text{m}$ is located inside the charge distribution. The charge enclosed inside the spherical surface at $r = r_1$ is given by an integral of the charge density from $r = 0$ to $r = r_1$. Outside the spherical charge distribution, the electric field is the same as that of a point charge whose magnitude is equal to the total charge of the spherical distribution.

SKETCH

The charge density, ρ, as a function of radius, r, is plotted in Figure 22.38.

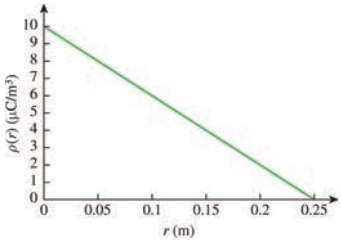

FIGURE 22.38
Charge density as a function of radius for a nonuniform spherical charge distribution.

RESEARCH

Gauss's Law (equation 22.16) tells us that $\oiint \vec{E} \bullet d\vec{A} = q/\epsilon_0$. Inside the nonuniform spherical charge distribution at a radius $r_1 < R$, Gauss's Law becomes

$$\epsilon_0 E\left(4\pi r_1^2\right) = \int_0^{V_1} \rho(r)dV = \int_0^{r_1} \rho_0\left(1 - \frac{r}{R}\right)\left(4\pi r^2\right)dr. \text{ (i}$$

Carrying out the integral on the right-hand side of equation (i), we obtain

$$\int_0^{r_1} \rho_0\left(1 - \frac{r}{R}\right)\left(4\pi r^2\right)dr = 4\pi\rho_0 \int_0^{r_1} \left(r^2 - \frac{r^3}{R}\right)dr = 4$$

SIMPLIFY

The electric field due to the charge inside $r_1 \leq R$ is then given by

$$E = \frac{4\pi\rho_0\left(\frac{r_1^3}{3} - \frac{r_1^4}{4R}\right)}{\epsilon_0\left(4\pi r_1^2\right)} = \frac{\rho_0}{\epsilon_0}\left(\frac{r_1}{3} - \frac{r_1^2}{4R}\right). \quad \textbf{(iii)}$$

In order to calculate the electric field due to the charge inside $r_2 > R$, we need the total charge contained in the spherical charge distribution. We can obtain the total charge using equation (ii) with $r_1 = R$:

$$q_\mathrm{t} = 4\pi\rho_0\left(\frac{R^3}{3} - \frac{R^4}{4R}\right) = 4\pi\rho_0\left(\frac{R^3}{3} - \frac{R^3}{4}\right) = 4\pi\rho_0\frac{R}{1}$$

The electric field outside the spherical charge distribution $(r_2 > R)$ is then

$$E = \frac{1}{4\pi\epsilon_0}\frac{q_\mathrm{t}}{r_2^2} = \frac{1}{4\pi\epsilon_0}\frac{\frac{1}{3}\pi\rho_0 R^3}{r_2^2} = \frac{\rho_0 R^3}{12\epsilon_0 r_2^2}. \quad \textbf{(iv)}$$

CALCULATE

The electric field at $r_1 = 0.125\ \mathrm{m}$ is

$$E = \frac{\rho_0}{\epsilon_0}\left(\frac{r_1}{3} - \frac{r_1^2}{4R}\right) = \frac{10.0\ \mu\mathrm{C/m^3}}{8.85 \cdot 10^{-12}\mathrm{C^2/N\ m^2}}\left[\frac{0.125\ \mathrm{m}}{3}\right.$$

The electric field at $r_2 = 0.500\ \text{m}$ is

$$E = \frac{\rho_0 R^3}{12\epsilon_0 r_2^2} = \frac{\left(10.0\ \mu\text{C/m}^3\right)(0.250\ \text{m})^3}{12\left(8.85 \cdot 10^{-12}\text{C}^2/\text{N m}^2\right)(0.500\ \text{m})^2} =$$

ROUND

We report our results to three significant figures. The electric field at $r_1 = 0.125\ \text{m}$ is

$$E = 2.94 \cdot 10^4\ \text{N/C}.$$

The electric field at $r_2 = 0.500\ \text{m}$ is

$$E = 5.89 \cdot 10^3\ \text{N/C}.$$

DOUBLE-CHECK

The electric field at $r_1 = R$ can be calculated using equation (iii):

$$E = \frac{\rho_0}{\epsilon_0}\left(\frac{R}{3} - \frac{R^2}{4R}\right) = \frac{\rho_0 R}{12\epsilon_0} = \frac{\left(10.0\ \mu\text{C/m}^3\right)(0.250\ \text{r}}{12\left(8.85 \cdot 10^{-12}\text{C}^2/\text{N m}\right.}$$

We can also use equation (iv) to find the electric field outside the spherical charge distribution but very close to the surface, where $r_2 \approx R$:

$$E = \frac{\rho_0 R^3}{12\epsilon_0 R^2} = \frac{\rho_0 R}{12\epsilon_0},$$

which is the same result we obtained using our result for $r_1 \leq R$. The calculated electric field at the surface of the charge distribution is lower than that at $r_1 = 0.125$, which may seem counterintuitive. An idea of the dependence of the magnitude of E on r is provided by the plot in Figure 22.39, which was created using equations (iii) and (iv).

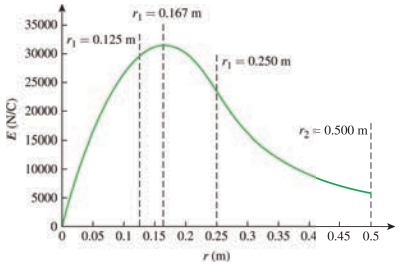

FIGURE 22.39 The electric field due to a nonuniform spherical distribution of charge as a function of the distance from the center of the sphere.

You can see that a maximum occurs in the electric field and that our result for $r_1 = 0.125$ m is less than this maximum value. We can calculate the radius at which the maximum occurs by differentiating equation (iii) with respect to r_1, setting the result equal to zero, and solving for r_1:

$$\frac{dE}{dr_1} = \frac{\rho_0}{\epsilon_0}\left(\frac{1}{3} - \frac{r_1}{2R}\right) = 0 \Rightarrow$$
$$\frac{1}{3} = \frac{r_1}{2R} \Rightarrow r_1 = \frac{2}{3}R.$$

Thus, we expect a maximum in the electric field at $r_1 = \frac{2}{3}R = 0.167$ m. The plot in Figure 22.39 does indeed show a maximum at that radius. It also shows the value of E at $r = 0.250$ to be smaller than that at $r = 0.125$ as we found in our calculation. Thus, our answers seem reasonable.

Concept Check 22.13

Suppose an uncharged solid-steel ball, for example, one of the steel balls used in an old-fashioned pinball machine, is resting on a perfect insulator. Some small amount of negative charge (say, a few hundred electrons) is placed at the north pole of the ball. If you could check the distribution of the charge after a few seconds, what would you detect?

a) All of the added charge has vanished, and the ball is again electrically neutral.

b) All of the added charge has moved to the center of the ball.

c) All of the added charge is distributed uniformly over the surface of the ball.

d) The added charge is still located at or very near the north pole of the ball.

e) The added charge is performing a simple harmonic oscillation on a straight line between the south and north poles of the ball.

Concept Check 22.14

Suppose an uncharged hollow sphere made of a perfect insulator, for example a Ping-Pong ball, is resting on a perfect insulator. Some small amount of negative charge (say, a few hundred electrons) is placed at the north pole of the sphere. If you could check the distribution of the charge after a few seconds, what would you detect?

a) All of the added charge has vanished, and the sphere is again electrically neutral.

b) All of the added charge has moved to the center of the sphere.

c) All of the added charge is distributed uniformly over the surface of the sphere.

d) The added charge is still located at or very near the north pole of the sphere.

e) The added charge is performing a simple harmonic oscillation on a straight line between the south and north poles of the sphere.

Sharp Points and Lightning Rods

We have already seen that the electric field is perpendicular to the surface of a conductor. (To repeat, if there were a field component parallel to the conductor, then the charges inside the conductor would move until they reached equilibrium, which means no force or electric field component in the direction of motion, that is, along the surface of the conductor.) Figure 22.40a shows the distribution of charges on the surface of the end of a pointed conductor. Note that the charges are closer together at the sharp tip, where the curvature is largest. Near that sharp tip on the end of the conductor, the electric field looks much more like that due to a point charge, with the field lines spreading out radially (Figure 22.40b). Since the field lines are closer together near a sharp point on a conductor, the field is stronger near the sharp tip than on the flat part of the conductor.

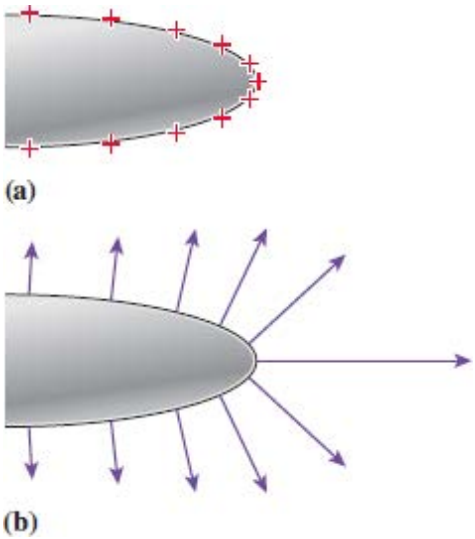

FIGURE 22.40 A sharp end of a conductor (with large curvature): (a) distribution of charges; (b) electric field at the surface of the conductor.

Benjamin Franklin proposed metal rods with sharp points as lightning rods (Figure 22.41). He reasoned that the sharp points would dissipate the electric charge built up in a storm, preventing the discharge of lightning. When Franklin installed such lightning rods, they were struck by lightning instead of the buildings to which they were attached. However, recent findings indicate that lightning rods used to protect structures from lightning should have blunt, rounded ends. When charged during thunderstorm conditions, a lightning rod with a sharp point creates a strong electric field that locally ionizes the air, producing a condition that actually causes lightning. Conversely, round-ended lightning rods are just as effective in protecting structures from lightning and do not increase lightning strikes. Any lightning rod should be carefully grounded to carry charge from a lightning strike away from the structure on which the lightning rod is mounted.

FIGURE 22.41 A lightning rod with a sharp point installed on the top of a building.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- The electric force, $\vec{F}\left(\vec{r}\right)$, on a charge, q, due to an electric field, $\vec{E}\left(\vec{r}\right)$, is given by $\vec{F}\left(\vec{r}\right) = q\vec{E}\left(\vec{r}\right)$.
- The electric field at any point is equal to the sum of the electric fields from all sources: $\vec{E}_{\mathrm{t}}\left(\vec{r}\right) = \vec{E}_1\left(\vec{r}\right) + \vec{E}_2\left(\vec{r}\right) + \cdots + \vec{E}_n\left(\vec{r}\right)$.
- The magnitude of the electric field due to a point charge q at a distance r is given by $E(r) = \dfrac{1}{4\pi\epsilon_0}\dfrac{|q|}{r^2} = \dfrac{k\,|q|}{r^2}$. The electric field points radially away from a positive point charge and radially toward a negative charge.
- A system of two equal (in magnitude) but oppositely charged point particles is an electric dipole. The magnitude, p, of the electric dipole moment is given by $p = \mathrm{qd}$, where q is the magnitude of either of the charges and d is the distance separating them. The electric dipole moment is a vector pointing from the negative toward the positive charge. On the dipole axis, the dipole produces an electric field of magnitude $E = \dfrac{p}{2\pi\epsilon_0|x|^3}$, where $|x| \gg d$.
- Gauss's Law states that the electric flux over an entire closed surface is equal to the enclosed charge divided by ϵ_0: $\oiint \vec{E} \bullet d\vec{A} = \dfrac{q}{\epsilon_0}$.
- The differential electrical field is given by $\mathrm{dE} = k\dfrac{\mathrm{dq}}{r^2}$, and the differential charge is

$$\left.\begin{aligned} dq &= \lambda \mathrm{dx} \\ dq &= \sigma \mathrm{dA} \\ dq &= \rho \mathrm{dV} \end{aligned}\right\} \text{ for a charge distribution } \begin{cases} \text{along a line} \\ \text{over a surfa} \\ \text{throughout} \end{cases}$$

- The magnitude of the electric field at a distance r from a long straight wire with uniform linear charge density $\lambda > 0$ is given by $E = \dfrac{\lambda}{2\pi\epsilon_0 r} = \dfrac{2k\lambda}{r}$.
- The magnitude of the electric field produced by an infinite nonconducting plane that has uniform charge density $\sigma > 0$ is $E = \dfrac{1}{2}\sigma/\epsilon_0$.
- The magnitude of the electric field produced by an infinite conducting plane that has uniform charge density $\sigma > 0$ on each side is $E = \sigma/\epsilon_0$.
- The electric field inside a closed conductor is zero.
- The electric field outside a charged spherical conductor is the same as that due to a point charge of the same magnitude located at the center of the sphere.

ANSWERS TO SELF-TEST OPPORTUNITIES

22.1 The direction of the electric field is downward at points *A*, *C*, and *E* and upward at points *B* and *D*. (There is an electric field at point *E*, even though there is no line drawn there; the field lines are only sample representations of the electric field, which also exists between the field lines.) The field is largest in magnitude at point *E*, which can be inferred from the fact that it is located where the field lines have the highest density.

22.2 The two forces acting on the two charges in the electric field create a torque on the electric dipole around its center of mass, given by

$$\tau = (\text{force}_+)(\text{moment arm}_+)(\sin\theta) + (\text{force}_-)(\text{moment arm}$$

The length of the moment arm in both cases is $\frac{1}{2}d$, and the magnitude of the force is $F = qE$ for both charges. Thus, the torque on the electric dipole is

$$\tau = qE\left(\frac{d}{2}\sin\theta\right) + qE\left(\frac{d}{2}\sin\theta\right) = qEd\,\sin\theta.$$

Page 709

22.3 The net electric flux passing though the object is EA. Remember, the object is not a closed surface; otherwise, the result would be zero.

22.4 The sign of the scalar product changes, because the electric field points radially inward: $\vec{E} \cdot \vec{dA} = EdA\,\cos 180^\circ = -EdA$. But the magnitude of the electric field due to the negative charge is

$E = \dfrac{1}{4\pi\epsilon_0}\dfrac{-q}{r^2}$. The two minus signs cancel, giving the same results for Coulomb's and Gauss's Laws for a point charge, independent of the sign of the charge.

22.5 For a wire of infinite length, $E_y = \dfrac{2k\lambda}{y}$; for a wire of finite length, $E_y = \dfrac{2k\lambda}{y}\dfrac{a}{\sqrt{y^2+a^2}}$. With the values given in Concept Check 22.12, $\dfrac{a}{\sqrt{y^2+a^2}} = \dfrac{0.565}{\sqrt{0.401^2+0.565^2}} = 0.815$. Thus, the "infinitely long" approximation is off by ~18%.

22.6 The charged sphere acts like a point charge, so the electric field at $2R$ is

$$E = k\frac{q}{(2R)^2} = k\frac{q}{4R^2}.$$

PROBLEM-SOLVING GUIDELINES

1. Be sure to distinguish between the point where an electric field is being generated and the point where the electric field is being determined.

2. Some of the same guidelines for dealing with electrostatic charges and forces also apply to electric fields: Use symmetry to simplify your calculations; remember that the field is composed of vectors and thus you have to use vector operations instead of simple addition, multiplication, and so on; convert units to meters and coulombs for consistency with the given values of constants.

3. Remember to use the correct form of the charge density for field calculations: λ for linear charge density, σ for surface charge density, and ρ for volume charge density.

4. The key to using Gauss's Law is to choose the right shape for the Gaussian surface to exploit the symmetry of the problem situation. Cubical, cylindrical, and spherical Gaussian surfaces are typically useful.

5. Often, you can break a Gaussian surface into surface elements that are either perpendicular to or parallel to the electric field lines. If the field lines are perpendicular to the surface, the electric flux is simply the field strength times the area, EA, or $-EA$ if the field points inward instead of outward. If the field lines are parallel to the surface, the flux through that surface is zero. The total flux is the sum of the flux through each surface element of the Gaussian surface. Remember that zero flux through a Gaussian surface does not necessarily mean that the electric field is zero.

Multiple-Choice Questions

22.1 In order to use Gauss's Law to calculate the electric field created by a known distribution of charge, which of the following *must* be true?

a) The charge distribution must be in a nonconducting medium.

b) The charge distribution must be in a conducting medium.

c) The charge distribution must have spherical or cylindrical symmetry.

d) The charge distribution must be uniform.

e) The charge distribution must have a high degree of symmetry that allows assumptions about the symmetry of its electric field to be made.

22.2 An electric dipole consists of two equal and opposite charges situated a small distance from each other. When the dipole is placed in a uniform electric field, which of the following statements is (are) true?

a) The dipole will not experience any net force from the electric field; since the charges are equal and have opposite signs, the individual effects will cancel out.

b) There will be no net force and no net torque acting on the dipole.

c) There will be a net force but no net torque acting on the dipole.

d) There will be no net force, but there will (in general) be a net torque acting on dipole.

22.3 A point charge, $+Q$, is located on the x-axis at $x = a$, and a second point charge, $-Q$, is located on the x-axis at $x = -a$. A Gaussian surface with radius $r = 2a$ is centered at the origin. The flux through this Gaussian surface is

a) zero.

b) greater than zero.

c) less than zero.

d) none of the above.

22.4 A charge of $+2q$ is placed at the center of an uncharged conducting shell. What will be the charges on the inner and outer surfaces of the shell, respectively?

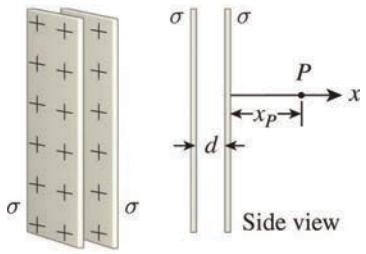
a) $-2q, +2q$

b) $-q, +q$

c) $-2q, -2q$

d) $-2q, +4q$

22.5 Two infinite nonconducting plates are parallel to each other, with a distance $d = 10.0$ cm between them, as shown in the figure. Each plate carries a uniform charge distribution of $\sigma = 4.5\ \mu\text{C/m}^2$. What is the electric field, $\vec{E}$, at point P (with $x_p = 20.0$ cm)?



a) $0\ \text{N/C}$

b) $2.54\hat{x}\ \text{N/C}$

c) $\left(-5.08 \cdot 10^5\right)\hat{x}\ \text{N/C}$

d) $\left(5.08 \cdot 10^5\right)\hat{x}\ \text{N/C}$

e) $\left(-1.02 \cdot 10^6\right)\hat{x}\ \text{N/C}$

f) $\left(1.02 \cdot 10^6\right)\hat{x}\ \text{N/C}$

22.6 At which of the following locations is the electric field the strongest?

a) a point 1 m from a 1-C point charge

b) a point 1 m (perpendicular distance) from the center of a 1-m-long wire with 1 C of charge distributed on it

c) a point 1 m (perpendicular distance) from the center of a 1-m^2 sheet of charge with 1 C of charge distributed on it

d) a point 1 m from the surface of a charged spherical shell with a radius of 1 m

e) a point 1 m from the surface of a charged spherical shell with a radius of 0.5 m and a charge of 1 C

22.7 The electric flux through a spherical Gaussian surface of radius R centered on a charge Q is $1200\ \mathrm{N/(C\ m^2)}$. What is the electric flux through a cubic Gaussian surface of side R centered on the same charge Q?

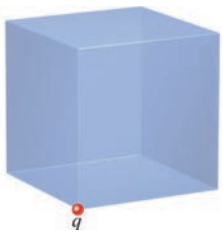
a) less than $1200\ \mathrm{N/(C\ m^2)}$

b) more than $1200\ \mathrm{N/(C\ m^2)}$

c) equal to $1200\ \mathrm{N/(C\ m^2)}$

d) cannot be determined from the information given

22.8 A single positive point charge, q, is at one corner of a cube with sides of length L, as shown in the figure. The net electric flux through the three adjacent sides is zero. The net electric flux through *each* of the other three sides is



a) $q/3\epsilon_0$.

b) $q/6\epsilon_0$.

c) $q/24\epsilon_0$.

d) $q/8\epsilon_0$.

22.9 Three -9-mC point charges are located at (0,0), (3 m,3 m), and $(3\ \text{m}, -3\ \text{m})$. What is the magnitude of the electric field at (3 m,0)?

a) $0.9 \cdot 10^7 \text{N/C}$

b) $1.2 \cdot 10^7 \text{N/C}$

c) $1.8 \cdot 10^7 \text{N/C}$

d) $2.4 \cdot 10^7 \text{N/C}$

e) $3.6 \cdot 10^7 \text{N/C}$

f) $5.4 \cdot 10^7 \text{N/C}$

g) $10.8 \cdot 10^7 \text{N/C}$

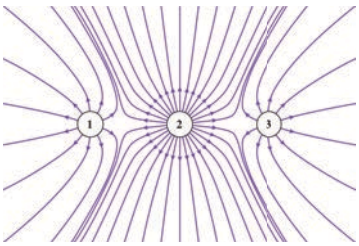
22.10 Which of the following statements is (are) true?

a) There will be *no* change in the charge on the inner surface of a hollow conducting sphere if additional charge is placed on the outer surface.

b) There will be some change in the charge on the inner surface of a hollow conducting sphere if additional charge is placed on the outer surface.

c) There will be *no* change in the charge on the inner surface of a hollow conducting sphere if additional charge is placed at the center of the sphere.

d) There will be some change in the charge on the inner surface of a hollow conducting sphere if additional charge is placed at the center of the sphere.



22.11 What are the signs of the charges in the configuration shown in the figure?

a) Charges 1, 2, and 3 are negative.

b) Charges 1, 2, and 3 are positive.

c) Charges 1 and 3 are positive, and 2 is negative.

d) Charges 1 and 3 are negative, and 2 is positive.

e) All that can be said is that the charges have the same sign.

22.12 Which of the following statements is (are) true?

a) Electric field lines point inward toward negative charges.

b) Electric field lines form circles around positive charges.

c) Electric field lines may cross.

d) Electric field lines point outward from positive charges.

e) A positive point charge released from rest will initially accelerate along a tangent to the electric field line at that point.

CONCEPTUAL QUESTIONS

22.13 Many people have been sitting in a car when it was struck by lightning. Why were they able to survive such an experience?

22.14 Why is it a bad idea to stand under a tree in a thunderstorm? What should one do instead to avoid getting struck by lightning?

22.15 Why do electric field lines never cross?

22.16 How is it possible that the flux through a closed surface does not depend on where inside the surface the charge is located (that is, the charge can be moved around inside the surface with no effect whatsoever on the flux)? If the charge is moved from just inside to just outside the surface, the flux changes discontinuously to zero, according to Gauss's Law. Does this really happen? Explain.

22.17 A solid conducting sphere of radius r_1 has a total charge of $+3Q$. It is placed inside (and concentric with) a conducting spherical shell of inner radius r_2 and outer radius r_3. Find the electric field in these regions: $r < r_1$, $r_1 < r < r_2$, $r_2 < r < r_3$, and $r > r_3$,

22.18 A thin rod has end points at $x = \pm 100$ cm. There is a total charge Q uniformly distributed along the rod.

a) What is the electric field very close to the midpoint of the rod?

b) What is the electric field a few centimeters (perpendicularly) from the midpoint of the rod?

c) What is the electric field very far (perpendicularly) from the midpoint of the rod?

22.19 A dipole is completely enclosed by a spherical surface. Describe how the total electric flux through this surface varies with the strength of the dipole.

22.20 Repeat Example 22.3, assuming that the charge distribution is $-\lambda$ for $-a < x < 0$ and $+\lambda$ for $0 < x < a$.

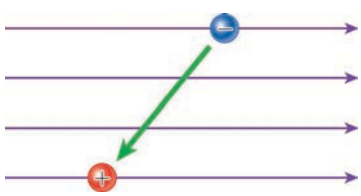
22.21 A negative charge is placed on a solid prolate spheroidal conductor (shown in cross section in the figure). Sketch the distribution of the charge on the conductor and the electric field lines due to the charge.

Page 711

22.22 *Saint Elmo's fire* is an eerie glow that appears at the tips of masts and yardarms of sailing ships in stormy weather and at the tips and edges of the wings of aircraft in flight. St. Elmo's fire is an electrical phenomenon. Explain it, concisely.

22.23 A charge placed on a conductor of any shape forms a layer on the outer surface of the conductor. Mutual repulsion of the individual charge elements creates an outward pressure on this layer, called *electrostatic stress*. Treating the infinitesimal charge elements like tiles of a mosaic, calculate the magnitude of this electrostatic stress in terms of the surface charge density, σ. Note that σ need not be uniform over the surface.

22.24 An electric dipole is placed in a uniform electric field as shown in the figure. What motion will the dipole have in the electric field? Which way will it move? Which way will it rotate?



EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

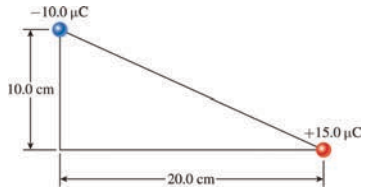
Section 22.3

22.25 A point charge, $q = 4.00 \cdot 10^{-9}\text{C}$, is placed on the x-axis at the origin. What is the electric field produced at $x = 25.0$ cm?

22.26 A $+1.60$-nC point charge is placed at one corner of a square (1.00 m on a side), and a -2.40-nC charge is placed on the corner diagonally opposite. What is the magnitude of the electric field at either of the other two corners?

22.27 A $+48.00$-nC point charge is placed on the x-axis at $x = 4.000$ m, and a -24.00-nC point charge is placed on the y-axis at $y = -6.000$ m. What is the direction of the electric field at the origin?

•**22.28** Two point charges are placed at two of the corners of a triangle as shown in the figure. Find the magnitude and the direction of the electric field at the third corner of the triangle.

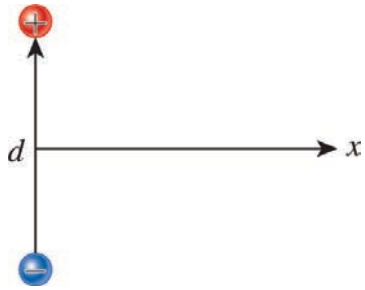


•**22.29** A $+5.00$-C charge is located at the origin. A -3.00-C charge is placed at $x = 1.00$ m. At what finite distance(s) along the x-axis will the electric field be equal to zero?

•**22.30** Three charges are on the y-axis. Two of the charges, each $-q$, are located $y = \pm d$, and the third charge, $+2q$, is located at $y = 0$. Derive an expression for the electric field at a point P on the x-axis.

Section 22.4

22.31 For the electric dipole shown in the figure, express the magnitude of the resulting electric field as a function of the perpendicular distance x from the center of the dipole axis. Comment on what the magnitude is when $x \gg d$.



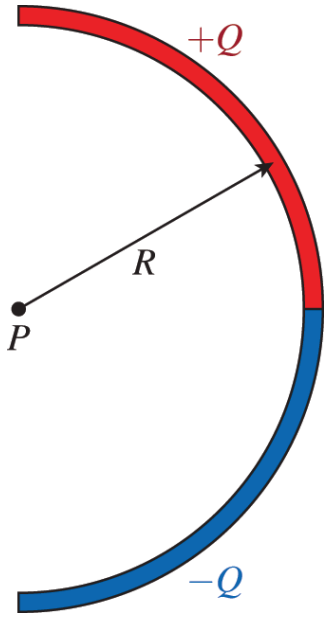
•**22.32** Consider an electric dipole on the x-axis and centered at the origin. At a distance h along the positive x-axis, the magnitude of electric field due to the electric dipole is given by $k(2qd)/h^3$. Find a distance perpendicular to the x-axis and measured from the origin at which the magnitude of the electric field is the same.

Section 22.5

•**22.33** A small metal ball with a mass of 4.00 g and a charge of 5.00 mC is located at a distance of 0.700 m above the ground in an electric field of 12.0 N/C directed to the east. The ball is then released from rest. What is the velocity of the ball after it has moved downward a vertical distance of 0.300 m?

•**22.34** A charge per unit length $+\lambda$ is uniformly distributed along the positive y-axis from $y = 0$ to $y = +a$. A charge per unit length $-\lambda$ is uniformly distributed along the negative y-axis from $y = 0$ to $y = -a$. Write an expression for the electric field (magnitude and direction) at a point on the x-axis a distance x from the origin.

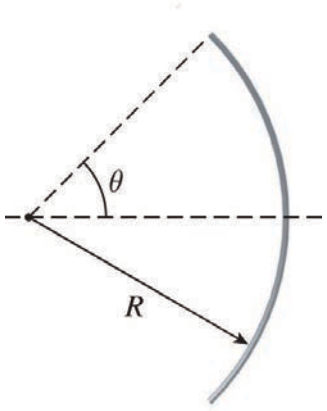
•**22.35** A thin glass rod is bent into a semicircle of radius R. A charge $+Q$ is uniformly distributed along the upper half, and a charge $-Q$ is uniformly distributed along the lower half as shown in the figure. Find the magnitude and direction of the electric field $\vec{E}$ (in component form) at point P, the center of the semicircle.



•**22.36** Two uniformly charged insulating rods are bent in a semicircular shape with radius $r = 10.0$ cm. If they are positioned so that they form a circle but do not touch and if they have opposite charges of $+1.00$ μC and -1.00 μC, find the magnitude and the direction of the electric field at the center of the composite circular charge configuration.

•**22.37** A uniformly charged rod of length L with total charge Q lies along the y-axis, from $y = 0$ to $y = L$. Find an expression for the electric field at the point (d,0) (that is, the point at $x = d$ on the x-axis).

•• **22.38** A charge Q is distributed evenly on a wire bent into an arc of radius R, as shown in the figure. What is the electric field at the center of the arc as a function of the angle θ? Sketch a graph of the electric field as a function of θ for $0 < \theta < 180^\circ$.



•• **22.39** A thin, flat washer is a disk with an outer diameter of 10.0 cm and a hole of diameter 4.00 cm in the center. The washer has a uniform charge distribution and a total charge of 7.00 nC. What is the electric field on the axis of the washer at a distance of 30.0 cm from the center of the washer?

Section 22.6

22.40 Research suggests that the electric fields in some thunderstorm clouds can be on the order of 10.0 kN/C. Calculate the magnitude of the electric force acting on a particle with two excess electrons in the presence of a 10.0-kN/C field.

22.41 An electric dipole has opposite charges of $5.00 \cdot 10^{-15}\text{C}$ separated by a distance of 0.400 mm. It is oriented at 60.0° with respect to a uniform electric field of magnitude $2.00 \cdot 10^{3}\text{N/C}$. Determine the magnitude of the torque exerted on the dipole by the electric field.

22.42 Electric dipole moments of molecules are often measured in debyes (D), where $1\text{D} = 3.34 \cdot 10^{-30}\text{C m}$. For instance, the dipole moment of hydrogen chloride gas molecules is 1.05 D. Calculate the maximum torque such a molecule can experience in the presence of an electric field of magnitude 160.0 N/C.

22.43 An electron is observed traveling at a speed of $27.5 \cdot 10^{6}\text{m/s}$ parallel to an electric field of magnitude 11,400 N/C. How far will the electron travel before coming to a stop?

22.44 Two charges, $+e$ and $-e$, are a distance of 0.680 nm apart in an electric field, E, that has a magnitude of 4.40 kN/C and is directed at an angle of 45.0° with respect to the dipole axis. Calculate the dipole moment and thus the torque on the dipole in the electric field.

•22.45 A body of mass M, carrying charge Q, falls from rest from a height h (above the ground) near the surface of the Earth, where the gravitational acceleration is g and there is an electric field with a constant component E in the vertical direction.

a) Find an expression for the speed, v, of the body when it reaches the ground, in terms of M, Q, h, g, and E.

b) The expression from part (a) is not meaningful for certain values of M, g, Q, and E. Explain what happens in such cases.

•**22.46** A water molecule, which is electrically neutral but has a dipole moment of magnitude $p = 6.20 \cdot 10^{-30}\text{Cm}$, is 1.00 cm away from a point charge $q = +1.00\ \mu\text{C}$. The dipole will align with the electric field due to the charge. It will also experience a net force, since the field is not uniform.

a) Calculate the magnitude of the net force. (*Hint:* You do not need to know the precise size of the molecule, only that it is much smaller than 1 cm.)

b) Is the molecule attracted to or repelled by the point charge? Explain.

•**22.47** A total of $3.05 \cdot 10^6$ electrons are placed on an initially uncharged wire of length 1.33 m.

a) What is the magnitude of the electric field a perpendicular distance of 0.401 m away from the midpoint of the wire?

b) What is the magnitude of the acceleration of a proton placed at that point in space?

c) In which direction does the electric field force point in this case?

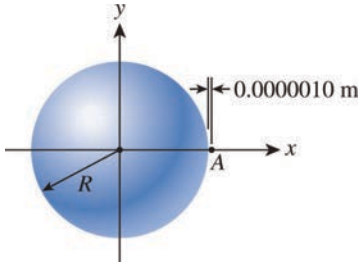
Sections 22.7 and 22.8

22.48 Four charges are placed in three-dimensional space. The charges have magnitudes $+3q$, $-q$, $+2q$, and $-7q$. If a Gaussian surface encloses all the charges, what will be the electric flux through that surface?

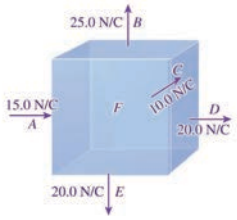
22.49 The six faces of a cubical box each measure 20.0 cm by 20.0 cm, and the faces are numbered such that faces 1 and 6 are opposite to each other, as are faces 2 and 5, and faces 3 and 4. The flux through each face is given in the table. Find the net charge inside the cube.

Face	Flux $\left(\mathrm{Nm^2/C}\right)$
1	-70.0
2	-300.0
3	-300.0
4	+300.0
5	-400.0
6	-500.0

22.50 A conducting solid sphere $\left(R = 0.15\ \mathrm{m}, q = 6.1 \cdot 10^{-6}\mathrm{C}\right)$ is shown in the figure. Using Gauss's Law and two different Gaussian surfaces, determine the electric field (magnitude and direction) at point *A*, which is 0.0000010 m outside the conducting sphere. (*Hint:* One Gaussian surface is a sphere, and the other is a small right cylinder.)



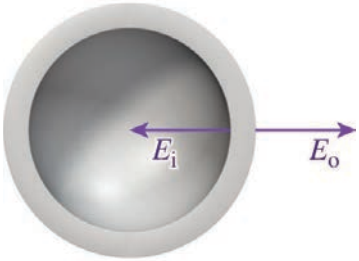
22.51 Electric fields of varying magnitudes are directed either inward or outward at right angles on the faces of a cube, as shown in the figure. What is the strength and direction of the field on the face *F*?



22.52 Consider a hollow spherical conductor with total charge $+5e$. The outer and inner radii are a and b, respectively. (a) Calculate the charge on the sphere's inner and outer surfaces if a charge of $-3e$ is placed at the center of the sphere. (b) What is the total net charge of the sphere?

•22.53 A spherical aluminized Mylar balloon carries a charge Q on its surface. You are measuring the electric field at a distance R from the balloon's center. The balloon is slowly inflated, and its radius approaches but never reaches R. What happens to the electric field you measure as the balloon increases in radius? Explain.

•22.54 A hollow conducting spherical shell has an inner radius of 8.00 cm and an outer radius of 10.0 cm. The electric field at the inner surface of the shell, $E_{i,}$ has a magnitude of 80.0 N/C and points toward the center of the sphere, and the electric field at the outer surface, E_o, has a magnitude of 80.0 N/C and points away from the center of the sphere (see the figure). Determine the magnitude of the charge on the inner surface and on the outer surface of the spherical shell.



•**22.55** A -6.00-nC point charge is located at the center of a conducting spherical shell. The shell has an inner radius of 2.00 m, an outer radius of 4.00 m, and a charge of $+7.00$ nC.

a) What is the electric field at $r = 1.00$ m?

b) What is the electric field at $r = 3.00$ m?

c) What is the electric field at $r = 5.00$ m?

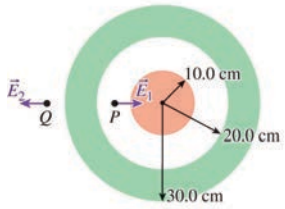
d) What is the surface charge distribution, σ, on the outside surface of the shell?

Section 22.9

22.56 A solid, nonconducting sphere of radius a has total charge Q and a uniform charge distribution. Using Gauss's Law, determine the electric field (as a vector) in the regions $r < a$ and $r > a$ in terms of Q.

22.57 There is an electric field of magnitude 150.0 N/C, directed downward, near the surface of the Earth. What is the net electric charge on the Earth? You can treat the Earth as a spherical conductor of radius 6371 km.

22.58 A hollow metal sphere has inner and outer radii of 20.0 cm and 30.0 cm, respectively. As shown in the figure, a solid metal sphere of radius 10.0 cm is located at the center of the hollow sphere. The electric field at a point P, a distance of 15.0 cm from the center, is found to be $E_1 = 1.00 \cdot 10^4 \text{N/C}$, directed radially inward. At point Q, a distance of 35.0 cm from the center, the electric field is found to be $E_2 = 1.00 \cdot 10^4 \text{N/C}$, directed radially outward. Determine the total charge on (a) the surface of the inner sphere, (b) the inner surface of the hollow sphere, and (c) the outer surface of the hollow sphere.



22.59 Two parallel, infinite, nonconducting plates are 10.0 cm apart and have charge distributions of $+1.00\ \mu\text{C/m}^2$ and $-1.00\ \mu\text{C/m}^2$. What is the force on an electron in the space between the plates? What is the force on an electron located outside the two plates near the surface of one of the two plates?

22.60 An infinitely long charged wire produces an electric field of magnitude $1.23 \cdot 10^3 \mathrm{N/C}$ at a distance of 50.0 cm perpendicular to the wire. The direction of the electric field is toward the wire.

a) What is the charge distribution?

b) How many electrons per unit length are on the wire?

•**22.61** A solid sphere of radius R has a nonuniform charge distribution $\rho = Ar^2$, where A is a constant. Determine the total charge, Q, within the volume of the sphere.

•**22.62** Two parallel, uniformly charged, infinitely long wires are 6.00 cm apart and carry opposite charges with a linear charge density of $\lambda = 1.00\ \mu\mathrm{C/m}$. What are the magnitude and the direction of the electric field at a point midway between the two wires and 40.0 cm above the plane containing them?

•**22.63** A sphere centered at the origin has a volume charge distribution of $120.\mathrm{nC/cm^3}$ and a radius of 12.0 cm. The sphere is centered inside a conducting spherical shell with an inner radius of 30.0 cm and an outer radius of 50.0 cm. The charge on the spherical shell is $-2.00\ \mathrm{mC}$. What are the magnitude and the direction of the electric field at each of the following distances from the origin?

a) at $r = 10.0$ cm

b) at $r = 20.0$ cm

c) at $r = 40.0$ cm

d) at $r = 80.0$ cm

•**22.64** A thin, hollow, metal cylinder of radius R has a surface charge distribution σ. A long, thin wire with a linear charge density $\lambda/2$ runs through the center of the cylinder. Find an expression for the electric field and determine the direction of the field at each of the following locations:

a) $r \leq R$

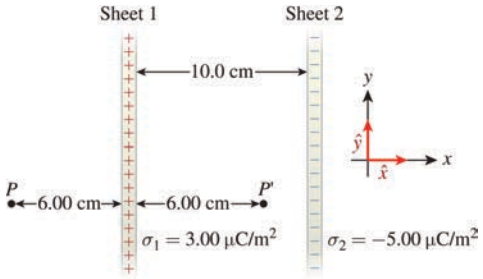
b) $r \geq R$

•**22.65** Two infinite sheets of charge are separated by 10.0 cm as shown in the figure. Sheet 1 has a surface charge distribution of

$\sigma_1 = 3.00\ \mu\text{C/m}^2$ and sheet 2 has a surface charge distribution of $\sigma_2 = -5.00\ \mu\text{C/m}^2$. Find the total electric field (magnitude and direction) at each of the following locations:

a) at point *P*, 6.00 cm to the left of sheet 1

b) at point *P'*, 6.00 cm to the right of sheet 1



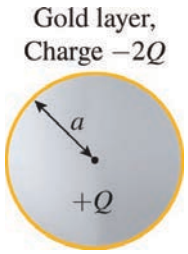
•**22.66** A conducting solid sphere of radius 20.0 cm is located with its center at the origin of a three-dimensional coordinate system. A charge of 0.271 nC is placed on the sphere.

a) What is the magnitude of the electric field at point $(x, y, z) = (23.1\text{ cm}, 1.10\text{ cm}, 0.00\text{ cm})$?

b) What is the angle of this electric field with the *x*-axis at this point?

c) What is the magnitude of the electric field at point $(x, y, z) = (4.10\text{ cm}, 1.10\text{ cm}, 0.00\text{ cm})$?

•• **22.67** A solid nonconducting sphere of radius *a* has a total charge +*Q* uniformly distributed throughout its volume. The surface of the sphere is coated with a very thin (negligible thickness) conducting layer of gold. A total charge of $-2Q$ is placed on this conducting layer. Use Gauss's Law to do the following.



a) Find the electric field *E*(*r*) for $r < a$ (inside the sphere, up to and excluding the gold layer).

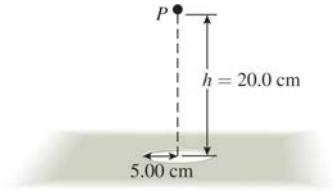
b) Find the electric field $E(r)$ for $r > a$ (outside the coated sphere, beyond the sphere and the gold layer).

c) Sketch the graph of $E(r)$ versus r. Comment on the continuity or discontinuity of the electric field, and relate this to the surface charge distribution on the gold layer.

•• **22.68** A solid nonconducting sphere has a volume charge distribution given by $\rho(r) = (\beta/r)\sin(\pi r/2R)$. Find the total charge contained in the spherical volume and the electric field in the regions $r < R$ and $r > R$. Show that the two expressions for the electric field equal each other at $r = R$.

•• **22.69** A very long cylindrical rod of nonconducting material with a 3.00-cm radius is given a uniformly distributed positive charge of 6.00 nC per centimeter of its length. Then a cylindrical cavity is drilled all the way through the rod, of radius 1 cm, with its axis located 1.50 cm from the axis of the rod. That is, if, at some cross section of the rod, x- and y-axes are placed so that the center of the rod is at $(x, y) = (0,0)$; then the center of the cylindrical cavity is at $(x, y) = (0,1.50)$. The creation of the cavity does not disturb the charge on the remainder of the rod that has not been drilled away; it just removes the charge from the region in the cavity. Find the electric field at the point $(x, y) = (2.00,1.00)$.

•• **22.70** What is the electric field at a point P, which is at a distance $h = 20.0$ cm above an infinite sheet of charge that has a charge distribution of $1.30\ \mathrm{C/m^2}$ and a hole of radius 5.00 cm whose center is directly below P, as shown in the figure? Plot the electric field as a function of h in terms of $\sigma/(2\epsilon_0)$.



Additional Exercises

22.71 A cube has an edge length of 1.00 m. An electric field acting on the cube from outside has a constant magnitude of 150 N/C and its direction is also constant but unspecified (not necessarily along any edges of the cube). What is the total charge within the cube?

22.72 A carbon monoxide (CO) molecule has a dipole moment of approximately $8.0 \cdot 10^{-30}$ Cm. If the carbon and oxygen atoms are separated by $1.2 \cdot 10^{-10}$ m, find the net charge on each atom and the maximum amount of torque the molecule would experience in an electric field of 500.0 N/C.

22.73 An infinitely long, solid cylinder of radius $R = 9.00$ cm, with a uniform charge per unit of volume of $\rho = 6.40 \cdot 10^{-8}\text{C/m}^3$, is centered about the y-axis. Find the magnitude of the electric field at a radius $r = 4.00$ cm from the center of this cylinder.

22.74 Find the magnitudes and the directions of the electric fields needed to counteract the weight of (a) an electron and (b) a proton at the Earth's surface.

22.75 A solid metal sphere of radius 8.00 cm, with a total charge of 10.0 μC, is surrounded by a metallic shell with a radius of 15.0 cm carrying a -5.00-μC charge. The sphere and the shell are both inside a larger metallic shell of inner radius 20.0 cm and outer radius 24.0 cm. The sphere and the two shells are concentric.

a) What is the charge on the inner wall of the larger shell?

b) If the electric field outside the larger shell is zero, what is the charge on the outer wall of the shell?

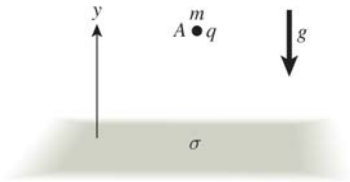
22.76 Two infinite, uniformly charged, flat, nonconducting surfaces are mutually perpendicular. One of the surfaces has a charge distribution of $+30.0\ \text{pC/m}^2$, and the other has a charge distribution of $-40.0\ \text{pC/m}^2$. What is the magnitude of the electric field at any point not on either surface?

22.77 There is an electric field of magnitude 150. N/C, directed vertically downward, near the surface of the Earth. Find the acceleration (magnitude and direction) of an electron released near the Earth's surface.

22.78 Suppose you have a large spherical balloon and you are able to measure the component E_n of the electric field normal to its surface. If you sum $E_n dA$ over the whole surface area of the balloon and obtain a magnitude of 10.0 N m^2/C, what is the electric charge enclosed by the balloon?

22.79 A 30.0-cm-long uniformly charged rod is sealed in a container. The total electric flux leaving the container is $1.46 \cdot 10^6$ N m^2/C. Determine the linear charge distribution on the rod.

•**22.80** A long conducting wire with charge distribution λ and radius r produces an electric field of 2.73 N/C just outside its surface. What is the magnitude of the electric field just outside the surface of another wire with charge distribution 0.810λ and radius $6.50r$?



•**22.81** An object with mass $m = 1.00$ g and charge q is placed at point A, which is 0.0500 m above an infinitely large, uniformly charged, nonconducting sheet $\left(\sigma = -3.50 \cdot 10^{-5} \text{C/m}^2\right)$, as shown in the figure. Gravity is acting downward $\left(g = 9.81 \text{ m/s}^2\right)$. Determine the number, N, of electrons that must be added to or removed from the object for the object to remain motionless above the charged plane.

•**22.82** A proton enters the gap between a pair of metal plates (an electrostatic separator) that produce a uniform, vertical electric field between them. Ignore the effect of gravity on the proton.

a) Assuming that the length of the plates is 15.0 cm and that the proton approaches the plates with a speed of 15.0 km/s, what electric field strength should the plates be designed to provide

so that the proton will be deflected vertically by $1.50 \cdot 10^{-3}$ rad?

b) What speed will the proton have after exiting the electric field?

c) Suppose the proton is one in a beam of protons that has been contaminated with positively charged kaons, particles whose mass is $494\ \mathrm{MeV}/c^2\left(8.81 \cdot 10^{-28}\mathrm{kg}\right)$, while the mass of the proton is $938\ \mathrm{MeV}/c^2\left(1.67 \cdot 10^{-27}\mathrm{kg}\right)$. The kaons have a charge of $+1e$, just like the protons. If the electrostatic separator is designed to give the protons a deflection of $1.20 \cdot 10^{-3}$ rad, what deflection will kaons with the same momentum as the protons experience?

•22.83 Consider a uniform nonconducting sphere with a surface charge density $\rho = 3.57 \cdot 10^{-6}\mathrm{C/m}^3$ and a radius $R = 1.72$ m. What is the magnitude of the electric field 0.530 m from the center of the sphere?

•• 22.84 A uniform sphere has a radius R and a total charge $+Q$, uniformly distributed throughout its volume. It is surrounded by a thick spherical shell carrying a total charge $-Q$, also uniformly distributed, and having an outer radius of $2R$. What is the electric field as a function of R?

•• 22.85 If a charge is held in place above a large, flat, grounded, conducting slab, such as a floor, it will experience a downward force toward the floor. In fact, the electric field in the room above the floor will be exactly the same as that produced by the original charge plus a "mirror image" charge, equal in magnitude and opposite in sign, as far below the floor as the original charge is above it. Of course, there is no charge below the floor; the effect is produced by the surface charge distribution induced on the floor by the original charge.

a) Describe or sketch the electric field lines in the room above the floor.

b) If the original charge is 1.00 μC at a distance of 50.0 cm above the floor, calculate the downward force on this charge.

c) Find the electric field at (just above) the floor, as a function of the horizontal distance from the point on the floor directly

under the original charge. Assume that the original charge is a point charge, $+q$, at a distance a above the floor. Ignore any effects of walls or ceiling.

d) Find the surface charge distribution $\sigma(\rho)$ induced on the floor.

e) Calculate the total surface charge induced on the floor.

22.86 A long, horizontal, conducting wire has the charge density $\lambda = 2.849 \cdot 10^{-12}\ \mathrm{C/m}$. A proton $\left(\text{mass} = 1.673 \cdot 10^{-27}\ \mathrm{kg}\right)$ is placed 0.6815 m above the wire and released. What is the magnitude of the initial acceleration of the proton?

22.87 A long, horizontal, conducting wire has the charge density λ. A proton $\left(\text{mass} = 1.673 \cdot 10^{-27}\ \mathrm{kg}\right)$ is placed 0.6897 m above the wire and released. The magnitude of the initial acceleration of the proton is $1.111 \cdot 10^{7}\ \mathrm{m/s^2}$. What is the charge density on the wire?

22.88 A long, horizontal, conducting wire has the charge density $\lambda = 6.055 \cdot 10^{-12}\ \mathrm{C/m}$. A proton $\left(\text{mass} = 1.673 \cdot 10^{-27}\ \mathrm{kg}\right)$ is placed a distance d above the wire and released. The magnitude of the initial acceleration of the proton is $1.494 \cdot 10^{7}\ \mathrm{m/s^2}$. What is the distance d?

22.89 There is a uniform charge distribution of $\lambda = 5.635 \cdot 10^{-8}\ \mathrm{C/m}$ along a thin wire of length $L = 22.13$ cm. The wire is then curved into a semicircle that is centered at the origin and has a radius of $R = L/\pi$. Find the magnitude of the electric field at the center of the semicircle.

22.90 There is a uniform charge distribution λ along a thin wire of length $L = 10.55$ cm. The wire is then curved into a semicircle that is centered at the origin and has a radius of $R = L/\pi$. The magnitude of the electric field at the center of the semicircle is $3.117 \cdot 10^{4}\ \mathrm{N/C}$. What is the value of λ?

22.91 There is a uniform charge distribution of $\lambda = 6.005 \cdot 10^{-8}\ \mathrm{C/m}$ along a thin wire of length L. The wire is then curved into a semicircle that is centered at the origin and has a radius of $R = L/\pi$. The magnitude of the electric field at the center of the semicircle is $2.425 \cdot 10^{4}\ \mathrm{N/C}$. What is the value of L?

Energy is vital to all kinds of systems, from our own bodies to the world economy. A large fraction of the devices we rely on—including pacemakers, televisions, computers, cell phones, hair dryers, and locomotives—use electric energy. It is therefore important to understand how electrically powered devices process and store this energy. We start by looking at electric energy and electric potential in order to understand the relationship between them and see how to calculate both. Figure 23.1 shows the result of calculating the electric potential due to four identical charges arranged at the corners of a tetrahedron. The electric potential is visualized as five nested surfaces representing points at which its magnitude is constant. The highest values of the potential occur closest to the charges, and the equipotential surfaces approximate spheres around each charge. The equipotential surfaces with the lowest values are farthest away from the charges and approximate spheres around the center of mass of the combined charges.

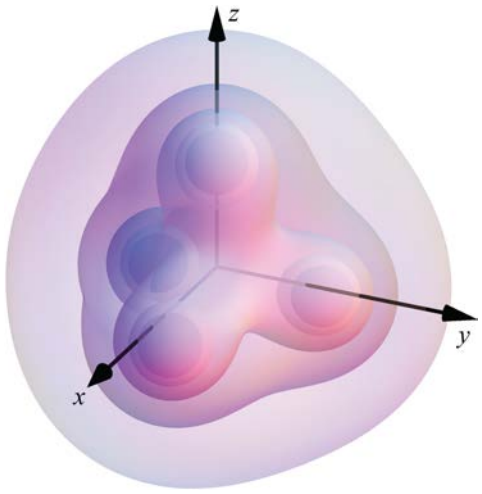

FIGURE 23.1 Five equipotential surfaces of a tetrahedral arrangement of four identical charges.

WHAT WE WILL LEARN

- Electric potential energy is analogous to gravitational potential energy.
- The change in electric potential energy is proportional to the work done by the electric field on a charge.
- The electric potential at a given point in space is a scalar.
- The electric potential, *V,* of a point charge, *q,* is inversely proportional to the distance from that point charge.
- The electric potential can be derived from the electric field by integrating the electric field over a displacement.
- The electric potential at a given point in space due to a distribution of point charges equals the algebraic sum of the electric potentials due to the individual charges.
- The electric field can be derived from the electric potential by differentiating the electric potential with respect to displacement.

23.1 Electric Potential Energy

Throughout this book, we have encountered various forms of energy and have seen how energy conservation affects different physical systems. We have also noted the importance of energy conversion in processes that are vital to daily life and the world economy. Now we turn our attention to electric energy, in particular, to the storage of electric potential energy in batteries. An electric field has many similarities to a gravitational field, including its mathematical formulation. We saw in Chapter 12 that the magnitude of the gravitational force is given by

$$F_{\mathrm{g}} = G\frac{m_1 m_2}{r^2},$$

where G is the universal gravitational constant, m_1 and m_2 are two masses, and r is the distance between the two masses. In Chapter 21, we saw that the magnitude of the electrostatic force is

$$F_{\mathrm{e}} = k\frac{|q_1 q_2|}{r^2}, \tag{23.1}$$

where k is Coulomb's constant, q_1 and q_2 are two electric charges, and r is the distance between the two charges. Both gravitational and electrostatic forces depend only on the inverse square of the distance between the objects, and it can be shown that all such forces are conservative. Therefore, the electric potential energy, U, can be defined in analogy with the gravitational potential energy.

In Chapter 6, we saw that for any conservative force, the change in potential energy due to some spatial rearrangement of a system is equal to the negative of the work done by the conservative force during this spatial rearrangement. For a system of two or more particles, the work done by an electric force, w_e, when the system configuration changes from an initial state to a final state, is given in terms of the change in **electric potential energy,** ΔU:

$$\Delta U = U_{\mathrm{f}} - U_{\mathrm{i}} = -W_{\mathrm{e}}, \tag{23.2}$$

where U_i is the initial electric potential energy and U_f is the final electric potential energy. Note that it does not matter *how* the system gets from the initial to the final state. The work is always the same, independent of the path taken. Chapter 6 noted that this path-independence of the work done by a force is a general feature of conservative forces.

As is the case for gravitational potential energy (see Chapter 12), a reference point for the electric potential energy must always be specified. It simplifies the equations and calculations if the zero point of the electric potential energy is assumed to be the configuration in which an infinitely large distance separates all the charges, which is exactly the same convention used for the gravitational potential energy. This assumption allows equation 23.2 for the change in electric potential energy to be rewritten as $\Delta U = U_{\mathrm{f}} - 0 = U$, or

$$U = -W_{e,\infty}. \qquad \textbf{(23.3)}$$

Even though the convention of zero potential energy at infinity is very useful and is universally accepted for a collection of point charges, in some physical situations there is a reason to select a reference potential energy at some point in space, which will not lead to a value of zero potential energy at infinite separation. Remember, all potential energies of conservative forces are fixed only within an arbitrary additive constant. So you need to pay attention to how this constant is chosen in a particular situation. One situation in which the potential energy at infinity is not set to zero is that involving a constant electric field.

Special Case: Charge in a Constant Electric Field

Let's consider a point charge, q, moving through a displacement, $\vec{d}$, in a constant electric field, $\vec{E}$, (Figure 23.2). The work done by a constant force $\vec{F}$, is $W = \vec{F} \bullet \vec{d}$. For this case, the constant force is created by a constant electric field, $\vec{F} = q\vec{E}$. Thus, the work done by the field on the charge is given by

$$W = q\vec{E} \bullet \vec{d} = qEd \cos\theta, \tag{23.4}$$

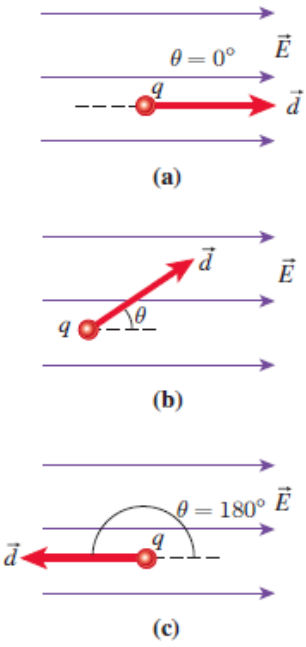

FIGURE 23.2 Work done by an electric field, $\vec{E}$ on a moving charge, q: (a) case where the displacement is in the same direction as the electric field, (b) general case, (c) case where the displacement is opposite to the direction of the electric field.

where θ is the angle between the electric force and the displacement. When the displacement is parallel to the electric field $(\theta = 0^\circ)$, the work done by the field on the charge is $W = qEd$. When the displacement is antiparallel to the electric field $(\theta = 180^\circ)$, the work done by the field is $W = -qEd$.

Because the change in electric potential energy is related to the work done on the charge by $\Delta U = -W$, if $q > 0$, the charge loses potential energy when the displacement is in the same direction as the electric field and gains potential energy when the displacement is in the direction opposite to the electric field.

Figure 23.3a shows a mass, *m,* near the surface of the Earth, where it can be considered to be in a constant gravitational field, which points downward. From Chapter 6, we know that when the mass moves toward the surface of the Earth a distance *h,* the change in the gravitational potential energy of the mass is

$$\Delta U = -W = -\vec{F}_{\text{g}} \cdot \vec{d} = -mgh.$$

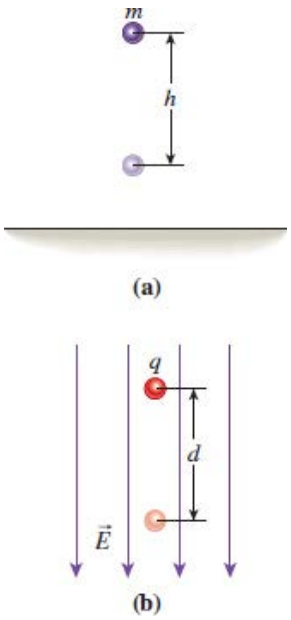

FIGURE 23.3 The analogy between gravitational potential energy and electric potential energy. (a) A mass falls in a gravitational field. (b) A positive charge moves in the same direction as an electric field.

It is intuitive that the mass has less potential energy if it is closer to the surface of the Earth. Figure 23.3b shows a positive charge, *q,* in a constant electric field. If the charge moves a distance, *d,* in the same direction as the electric field, the change in the electric potential energy is

$$\Delta U = -W = -q\vec{E} \bullet \vec{d} = -qEd.$$

Thus, the electric potential energy of a charge in an electric field is analogous to the gravitational potential energy of a mass in Earth's gravitational field near the surface of Earth. (But, of course, the important difference between the two interactions is that masses come in only one variety, and exert gravitational attraction for one another, whereas charges can attract or repel each other. Thus, ΔU can change sign, depending on the signs of the charges.)

Special Case: Dipole in a Constant Electric Field

Now let's consider an electric dipole with dipole moment $\vec{p}$ moving through a constant electric field (see Figure 23.4). In Chapter 22, we saw that an electric dipole consists of a positive charge and a negative charge, which have equal magnitudes, meaning that the dipole has zero net charge. Since, according to equation 23.4, the work done in moving an object through a constant electric field is proportional to the charge on that object, the net work done in moving an electric dipole through a constant electric field is zero.

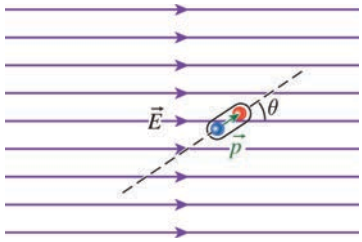

FIGURE 23.4 An electric dipole in a uniform electric field.

This fact may make it seem impossible to store potential energy in a system consisting of a dipole in a constant field. However, this is not the case. In Chapter 22, we saw that a dipole in a constant electric field experiences a torque, $\vec{\tau} = \vec{p} \times \vec{E}$, and so it is clear that the orientation of the dipole relative to the electric field is key. Let's see how the orientation of the dipole can result in the storage of potential energy.

In Chapter 10, we saw that the work done by a torque is given by $W = \int \vec{\tau}(\theta\prime) d\vec{\theta\prime}$. If we apply an external torque opposing the torque that the dipole experiences from the electric field, we can express the work done by this external torque as follows:

$$W = \int_{\theta_0}^{\theta} \vec{\tau}(\theta\prime) d\vec{\theta\prime} = \int_{\theta_0}^{\theta} -pE \sin\theta\prime \, d\theta\prime = -pE \int_{\theta_0}^{\theta} \sin\theta\prime \, d\theta\prime = pE(\cos\theta - c$$

With $W = -\Delta U = -(U - U_0) = U_0 - U$ (see Chapter 6), we then have the potential energy of an electric dipole in a constant electric field:

$$U = -pE\cos\theta = -\vec{p}\cdot\vec{E}, \tag{23.5}$$

where we have chosen the integration constant U_0 so that the potential energy is zero for $\theta = \pi/2$.

Equation 23.5 indicates that the potential energy has a minimum at $\theta = 0$, where the dipole moment is parallel to the electric field; see Figure 23.5. Remember that electric field lines point from positive to negative charges and that the dipole moment is defined to point from the negative to the positive charge. When the dipole moment and electric field vectors are parallel, the negative charge of the dipole is closest to the positive charge that is generating the external electric field, and it makes physical sense that that configuration has the lowest energy.

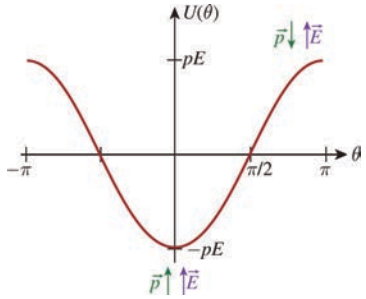

FIGURE 23.5 Potential energy as a function of the angle between an electric dipole and a constant external electric field.

23.2 Definition of Electric Potential

The potential energy of a charged particle, q, in an electric field depends on the magnitude of the charge as well as that of the electric field. A quantity that is independent of the charge on the particle is the **electric potential,** V, defined in terms of the electric potential energy as

$$V = \frac{U}{q}. \tag{23.6}$$

Because U is proportional to q, V is independent of q, which makes it a useful variable. The electric potential, V, characterizes an electrical property of a point in space even when no charge, q, is placed at that point. In contrast to the electric field, which is a vector, the electric potential is a scalar. It has a value everywhere in space, but has no direction. In Chapter 6, we saw that we can always add an arbitrary constant to the potential energy without changing any observable consequence and that only differences in potential energy are physically meaningful. Since the electric potential is proportional to the potential energy, the same is true for it. Stating a difference in electric potentials is unambiguous, but stating a value for the electric potential itself always implies a normalization condition, which is usually that the potential is zero at an infinite distance.

The difference in electric potential, ΔV, between an initial point and final point, $V_\mathrm{f} - V_\mathrm{i}$, can be expressed in terms of the electric potential energy at each point:

$$\Delta V = V_\mathrm{f} - V_\mathrm{i} = \frac{U_\mathrm{f}}{q} - \frac{U_\mathrm{i}}{q} = \frac{\Delta U}{q}. \tag{23.7}$$

Combining equations 23.2 and 23.7 yields a relationship between the change in electric potential and the work done by an electric field on a charge:

$$\Delta V = \frac{W_\mathrm{e}}{q}. \tag{23.8}$$

Taking the electric potential energy to be zero at infinity, as in equation 23.3, gives the electric potential at a point as

$$V = -\frac{W_{\mathrm{e},\infty}}{q}, \tag{23.9}$$

where $W_{\mathrm{e},\infty}$ is the work done by the electric field on the charge when it is brought in to the point from infinity. An electric potential can have a positive, a negative, or a zero value, but it has no direction.

The SI units for electric potential are joules/coulomb $(\mathrm{J/C})$. This combination has been named the **volt (V)** for Italian physicist Alessandro Volta (1745–1827) (note the use of the roman V for the unit, whereas the italicized *V* is used for the physical quantity of electric potential):

$$1\ \mathrm{V} \equiv \frac{1\ \mathrm{J}}{1\ \mathrm{C}}.$$

With this definition of the volt, the units for the magnitude of the electric field are

$$[E] = \frac{[F]}{[q]} = \frac{1\ \mathrm{N}}{1\ \mathrm{C}} = \left(\frac{1\ \mathrm{N}}{1\ \mathrm{C}}\right)\frac{1\ \mathrm{V}}{\left(\dfrac{1\ \mathrm{J}}{1\ \mathrm{C}}\right)}\left(\frac{1\ \mathrm{J}}{(1\ \mathrm{N})(1\ \mathrm{m})}\right) = \frac{1\ \mathrm{V}}{1\ \mathrm{m}}.$$

For the remainder of this book, the magnitude of an electric field will have units of $\mathrm{V/m}$, which is the standard convention, instead of $\mathrm{N/C}$. Note that an electric potential difference is often referred to as a “voltage,” particularly in circuit analysis, because it is measured in volts.

EXAMPLE 23.1 Energy Gain of a Proton

A proton is placed between two parallel conducting plates in a vacuum (Figure 23.6). The difference in electric potential between the two plates is 450 V. The proton is released from rest close to the positive plate.

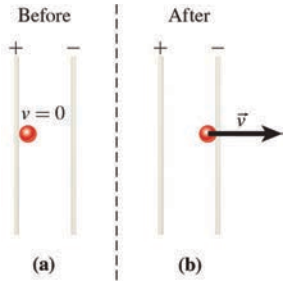

FIGURE 23.6 A proton between two charged parallel conducting plates in a vacuum. (a) The proton is released from rest. (b) The proton has moved from the positive plate to the negative plate, gaining kinetic energy.

PROBLEM

What is the kinetic energy of the proton when it reaches the negative plate?

SOLUTION

The difference in electric potential, ΔV, between the two plates is 450 V. We can relate this potential difference across the two plates to the change in electric potential energy, ΔU, of the proton using equation 23.7:

$$\Delta V = \frac{\Delta U}{q}.$$

Because of the conservation of total energy, all the electric potential energy lost by the proton in crossing between the two plates is turned into

kinetic energy due to the motion of the proton. We apply the law of conservation of energy, $\Delta K + \Delta U = 0$, where ΔU is the change in the proton's electric potential energy:

$$\Delta K = -\Delta U = -q\Delta V.$$

Because the proton started from rest, we can express its final kinetic energy as $K = -q\Delta V$. Therefore, the kinetic energy of the proton after crossing the gap between the two plates is

$$K = -\left(1.602 \cdot 10^{-19}\ \text{C}\right)(-450\ \text{V}) = 7.21 \cdot 10^{-17}\ \text{J}.$$

Concept Check 23.1

An electron is positioned and then released on the *x*-axis, where the electric potential has the value $-20\ \text{V}$. Which of the following statements describes the subsequent motion of the electron?

a) The electron will move to the left (negative *x*-direction) because it is negatively charged.

b) The electron will move to the right (positive *x*-direction) because it is negatively charged.

c) The electron will move to the left (negative *x*-direction) because the electric potential is negative.

d) The electron will move to the right (positive *x*-direction) because the electric potential is negative.

e) Not enough information is given to predict the motion of the electron.

Because the acceleration of charged particles across a potential difference is often used in the measurement of physical quantities, a common unit for the kinetic energy of a singly charged particle, such as a proton or an electron, is the **electron-volt (eV)**: 1 ev represents the energy gained by a proton $\left(q = 1.602 \cdot 10^{-19}\ \text{C}\right)$ accelerated across a potential difference of 1 V. The conversion between electron-volts and joules is

$$1\ \text{eV} = 1.602 \cdot 10^{-19}\ \text{J}.$$

The kinetic energy of the proton in Example 23.1 is then 450 eV, or 0.450 keV, which we could have obtained from the definition of the electron-volt

without performing any calculations.

Batteries

A common means of creating electric potential is a battery. We'll see in Chapters 24 and 25 how a battery uses chemical reactions to provide a source of (nearly) constant potential difference between its two terminals. An assortment of batteries is shown in Figure 23.7.

(a)

(b)

FIGURE 23.7 (a) Some representative batteries (clockwise from upper left): rechargeable AA nickel metal hydride (NiMH) batteries in their charger, disposable 1.5-V AAA batteries, a 12-V lantern battery, a D-size battery, a lithium ion laptop battery, and a watch battery; (b) 330-V battery for a gas-electric hybrid SUV, filling the entire floor of the trunk.

a-b: W. Bauer and G. D. Westfall

At its simplest, a battery consists of two half-cells, filled with a conducting electrolyte (originally a liquid but now almost always a solid); see Figure 23.8. The electrolyte is separated into two equal portions by a barrier, which prevents the bulk of the electrolyte from passing through but allows charged ions to pass through. The negatively charged ions (anions) move toward the anode, and the positively charged ions move toward the cathode. This creates

a potential difference between the two terminals of the battery. Thus, a battery is basically a device that converts chemical energy directly into electrical energy.

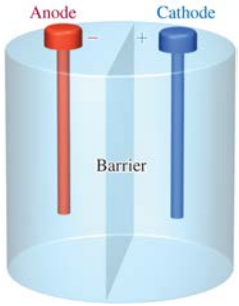

FIGURE 23.8 Schematic drawing of a battery.

Research on battery technology is of current importance, because many mobile applications require a great deal of energy, from cell phones to laptop computers, from electrical cars to military gear. The weight of the batteries needs to be as small as possible, they need to be rapidly rechargeable for hundreds of cycles, they need to deliver as constant a potential difference as possible, and they need to be available at an affordable price. Thus, such research provides many scientific and engineering challenges.

One example of relatively recent battery technology is the lithium ion cell, which is often used in applications such as laptop computer batteries. A lithium ion battery has a much higher energy density (energy content per unit volume) than conventional batteries. A typical lithium ion cell, has a potential difference of 3.6 V. They can be combined in series and in parallel into batteries of various potential differences. Shown in Figure 23.9 are three of the most common batteries with potential differences of 12 V, 18 V, and 56 V. Lithium ion batteries have several other advantages over conventional batteries. They can be recharged hundreds of times. They have no “memory” effect and thus do not need to be conditioned to hold their charge. They hold their charge on the shelf. They also have some disadvantages. For example, if a lithium ion battery is completely discharged, it can no longer be recharged. Heat degrades lithium ion batteries. If the batteries are discharged too quickly, the constituents can catch fire or explode. To deal with these problems, most commercial lithium ion battery packs have a small built-in electronic circuit that protects the battery pack. The circuit will not allow the battery to be overcharged or overly discharged; it will not allow charge to flow out of the battery so quickly that the battery will overheat. If the battery becomes too warm, the circuit disconnects the battery.

FIGURE 23.9 Lithium ion batteries of various sizes and voltages for power tools, plugged into their chargers.

Dr. Wolfgang Bauer/McGraw Hill

Currently, lithium ion batteries are being used in some electric-powered cars. The following example compares the energy carried by a battery-powered car and a gasoline-powered car.

EXAMPLE 23.2 Battery-Powered Cars and Trucks

Battery-powered cars produce no emissions and thus are an attractive alternative to gasoline powered cars. Some of these cars, such as the 2023 Chevrolet Silverado truck car shown in Figure 23.10, are powered by batteries constructed of lithium-ion cells. The Ultium battery pack of this truck has the capacity to hold up to 200 kWh of energy. A gasoline-powered Silverado typically has a 24-gallon tank, i.e. can hold 91 liters of gasoline, and gasoline has an energy content of 34.8 MJ/L.

FIGURE 23.10
Chevrolet Silverado EV

Paul Sancya/AP Images

PROBLEM

How does the available energy in a lithium-ion battery pack of this all-electric truck compare with the energy carried by its gasoline-powered sibling?

SOLUTION

Conversion of the 200 kWh battery energy into Joules results in

$$E_{\text{battery}} = (200\ \text{kWh})(3.6\ \text{MJ/kWh}) = 720\ \text{MJ}.$$

The 91 L of gasoline in the combustion engine powered Silverado have an energy content of

$$E_{\text{gasoline}} = (91\ \text{L})(34.8\ \text{MJ/L}) = 3170\ \text{MJ}.$$

Thus, the gasoline-powered Silverado carries 4.4 times as much energy as its electric powered sibling. However, the efficiency of a gasoline-powered car is approximately 25%, while an electric-powered car can be close to 90% efficient. Thus, the usable energy of the electric powered car is

$$E_{\text{electric, usable}} = 0.9(720\ \text{MJ}) = 648\ \text{MJ},$$

and the usable energy of the gasoline-powered car is

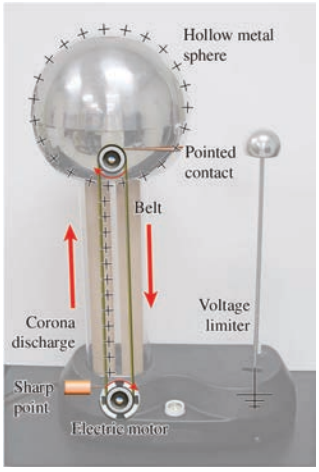
$$E_{\text{gasoline, usable}} = 0.25(3170\ \text{MJ}) = 792\ \text{MJ}.$$

In both case the truck's efficiency and consequently the usable energy depend very strongly on driving conditions. The final numbers for the usable energy should be rounded to 1 significant digit in both cases. But the basic point is clear: You can see that electric-powered cars and trucks now can achieve similar driving distances between re-fueling stops as gas-powered cars and trucks are able to, which is different than it was even only five years ago.

Van de Graaff Generator

One means of creating large electric potentials is a **Van de Graaff generator,** a device invented by the American physicist Robert J. Van de Graaff (1901–1967). Large Van de Graaff generators can produce electric potentials of millions of volts. More modest Van de Graaff generators, such as the one shown in Figure 23.11, can produce several hundred thousand volts and are often used in physics classrooms.

(a)



(b)

FIGURE 23.11 (a) A Van de Graaff generator used in physics classrooms.
(b) The Van de Graaff generator can produce very high electric potentials by carrying charge from a corona discharge on a rubber belt up to a hollow metal sphere, where the charge is extracted from the belt by a sharp piece of metal attached to the inner surface of the sphere.

a-b: W. Bauer and G. D. Westfall

A Van de Graaff generator uses a *corona discharge* to apply a positive charge to a nonconducting moving belt. Putting a high positive voltage on a conductor with a sharp point creates the corona discharge. The electric field on the sharp point is much stronger than on the flat surface of the conductor (see Chapter 22). The air around the sharp point is ionized. The ionized air molecules have a net positive charge, which causes the ions to be repelled away from the sharp point and deposited on the rubber belt. The moving belt, driven by an electric motor, carries the charge up into a hollow metal sphere, where the charge is taken from the belt by a pointed contact connected to the metal sphere. The charge that builds up on the metal sphere distributes itself uniformly around the outside of the sphere. On the Van de Graaff generator shown in Figure 23.11, a voltage limiter is used to keep the generator from producing sparks larger than desired.

EXAMPLE 23.3 Tandem Van de Graaff Accelerator

A Van de Graaff accelerator is a particle accelerator that uses high electric potentials for studying nuclear physics processes of astrophysical relevance. A tandem Van de Graaff accelerator with a terminal potential difference of 10.0 MV (10.0 million volts), is diagrammed in Figure 23.12. This terminal potential difference is created in the center of the accelerator by a larger, more sophisticated version of the classroom Van de Graaff generator. Negative ions are created in the ion source by attaching an electron to the atoms to be accelerated. The negative ions then accelerate toward the positively charged terminal. Inside the terminal, the ions pass through a thin foil that strips off electrons, producing positively charged ions that then are accelerated away from the terminal and out of the tandem accelerator.

FIGURE 23.12 A tandem Van de Graaff accelerator.

PROBLEM 1

What is the highest kinetic energy that carbon nuclei can attain in this tandem accelerator?

SOLUTION 1

A tandem Van de Graaff accelerator has two stages of acceleration. In the first stage, each carbon ion has a net charge of $q_1 = -e$. After the stripper foil, the maximum charge any carbon ion can have is $q_2 = +6e$. The potential difference over which the ions are accelerated is $\Delta V = 10$ MV. The kinetic energy gained by each carbon ion is

$$\Delta K = |\Delta U| = |q_1 \Delta V| + |q_2 \Delta V| = K,$$

or

$$K = e\Delta V + 6e\Delta V = 7e\Delta V,$$

assuming that the initial speed of the ions is close to zero.

Putting in the numerical values, we get

$$K = 7\left(1.602 \cdot 10^{-19}\ \text{C}\right)\left(10 \cdot 10^{6}\ \text{V}\right) = 1.12 \cdot 10^{-11}\ \text{J}.$$

Nuclear physicists often use electron-volts instead of joules to express the kinetic energy of accelerated nuclei:

$$K = 7e\Delta V = 7e\left(10 \cdot 10^{6}\ \text{V}\right) = 7 \cdot 10^{7}\ \text{eV} = 70\ \text{MeV}.$$

PROBLEM 2

What is the highest speed that carbon nuclei can attain in this tandem accelerator?

SOLUTION 2

To determine the speed, we use the relationship between kinetic energy and speed:

$$K = \frac{1}{2}mv^2,$$

where $m = 1.99 \cdot 10^{-26}$ kg is the mass of the carbon nucleus. Solving this equation for the speed, we get

$$v = \sqrt{\frac{2K}{m}} = \sqrt{\frac{2\left(1.12 \cdot 10^{-11}\ \text{J}\right)}{1.99 \cdot 10^{-26}\ \text{kg}}} = 3.36 \cdot 10^{7}\text{m/s},$$

which is 11% of the speed of light.

Concept Check 23.2

A cathode ray tube uses a potential difference of 5.0 kV to accelerate electrons and produce an electron beam that makes images on a phosphor screen. What is the speed of these electrons as a percentage of the speed of light?

a) 0.025%

b) 0.22%

c) 1.3%

d) 4.5%

e) 14%

SOLVED PROBLEM 23.1 Beam of Oxygen Ions

PROBLEM

Fully stripped (all electrons removed) oxygen $\left({}^{16}\mathrm{O}\right)$ ions are accelerated from rest in a particle accelerator using a total potential difference of $10.0\ \mathrm{MV} = 1.00 \cdot 10^{7}\ \mathrm{V}$. The ${}^{16}\mathrm{O}$ nucleus has 8 protons and 8 neutrons. The accelerator produces a beam of $3.13 \cdot 10^{12}$ ions per second. This ion beam is completely stopped in a beam dump. What is the total power the beam dump has to absorb?

SOLUTION

THINK

Power is energy per unit time. We can calculate the energy of each ion and then the total energy in the beam per unit time to obtain the power dissipated in the beam dump.

SKETCH

Figure 23.13 illustrates a beam of fully stripped oxygen ions being stopped in a beam dump.

FIGURE 23.13 A beam of fully stripped oxygen ions stops in a beam dump.

RESEARCH

The electric potential energy gained by each ion during the acceleration process is

$$U_{\text{ion}} = q\Delta V = ZeV,$$

where $Z = 8$ is the atomic number of oxygen, $e = 1.602 \cdot 10^{-19}\ \mathrm{C}$ is the charge of a proton, and $V = 1.00 \cdot 10^{7}\ \mathrm{V}$ is the electric potential across which the ions are accelerated.

SIMPLIFY

The power of the beam, which is dissipated in the beam dump, is then

$$P = NU_{\text{ion}} = NZeV,$$

where $N = 3.13 \cdot 10^{12}$ ions/s is the number of ions per second stopped in the beam dump.

CALCULATE

Putting in the numerical values, we get

$$\begin{aligned} P = NZeV &= \left(3.13 \cdot 10^{12}\ \text{s}^{-1}\right)(8)\left(1.602 \cdot 10^{-9}\ \text{C}\right)\left(1.00 \cdot 10^{7}\ \text{V}\right) \\ &= 40.1141\ \text{W}. \end{aligned}$$

ROUND

We report our result to three significant figures:

$$P = 40.1\ \text{W}.$$

DOUBLE-CHECK

We can relate the change in kinetic energy for each ion to the change in electric potential energy of each ion:

$$\Delta K = \Delta U = \frac{1}{2}mv^2 = U_{\text{ion}} = ZeV.$$

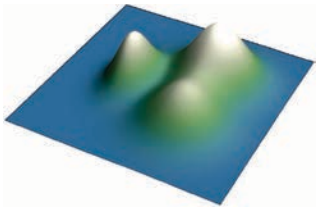
The mass of an oxygen nucleus is $2.33 \cdot 10^{-26}$ kg. The velocity of each ion is then

$$v = \sqrt{\frac{2ZeV}{m}} = \sqrt{\frac{2(8)\left(1.602 \cdot 10^{-19}\ \text{C}\right)\left(1.00 \cdot 10^{7}\ \text{V}\right)}{2.66 \cdot 10^{-26}\ \text{kg}}} = 3.10 \cdot 10$$

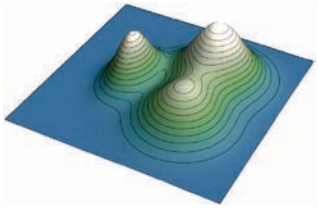
which is about 10% of the speed of light, which seems reasonable for the velocity of the ions. Thus, our result seems reasonable.

23.3 Equipotential Surfaces and Lines

Imagine you had to map out a ski resort with three peaks, like the one shown in Figure 23.14a. In Figure 23.14b, lines of equal elevation have been superimposed on the peaks. You could walk along each of these lines, without ever going uphill or downhill, and would be guaranteed to reach the point from which you started. These lines are lines of constant gravitational potential, because the gravitational potential is a function of the elevation only, and the elevation remains constant on each of the lines. Figure 23.14c shows a top view of the contour lines of equal elevation, which mark the equipotential lines for the gravitational potential. If you have understood this figure, the following discussion of electric potential lines and surfaces should be easy to follow.



(a)



(b)

(c)

FIGURE 23.14 (a) Ski resort with three peaks; (b) the same peaks with lines of equal elevation superimposed; (c) the contour lines of equal elevation in a two-dimensional plot.

When an electric field is present, the electric potential has a value everywhere in space. Points that have the same electric potential form an **equipotential surface.** Charged particles can move along an equipotential surface without having any work done on them by the electric field. According to principles of electrostatics, the surface of a conductor must be an equipotential surface; otherwise, the free electrons on the conductor surface would accelerate. The discussion in Chapter 22 established that the electric field is zero everywhere inside the body of a conductor. This means that the entire volume of the conductor must be at the same potential; that is, the entire conductor is an equipotential.

Equipotential surfaces exist in three dimensions (Figure 23.15); however, symmetries in the electric potential allow us to represent equipotential surfaces in two dimensions, as **equipotential lines** in the plane in which the charges reside. Before determining the shape and location of these equipotential surfaces, let's first look at some qualitative features of some of the simplest cases (for which the electric fields were determined in Chapter 22).

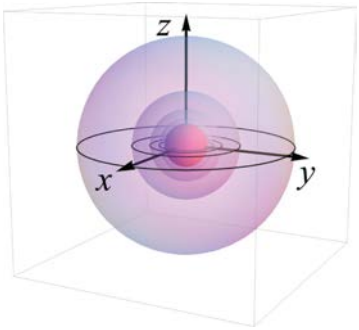


FIGURE 23.15
Concentric equipotential surfaces with values of 5 V, 4 V, 3 V, 2 V, and 1 V around a spherical conductor with a potential of 5 V centered at the origin of an *xyz*-coordinate system. The circles represent the intersections of the equipotential spheres with the *xy*-plane and are equipotential lines.

In drawing equipotential lines, we note that charges can move perpendicular to any electric field line without having any work done on them by the electric field, because according to equation 23.4, the scalar product of the electric field and the displacement is then zero. If the work done by the electric field is zero, the potential remains the same, by equation 23.8. Thus, *equipotential lines and planes are always perpendicular to the direction of the electric field.* (In Figure 23.14b, the elevation map of the ski resort, the equivalent of electric field lines would be the lines of steepest descent, which are, of course, always perpendicular to the lines of equal elevation.)

Before examining the particular equipotential surfaces resulting from different electric field configurations, let's note the two most important general observations of this section, which hold for all of the following cases:

1. The surface of any conductor forms an equipotential surface.
2. Equipotential surfaces are always perpendicular to the electric field lines at any point in space.

Constant Electric Field

A constant electric field has straight, equally spaced, and parallel field lines. Thus, such a field produces equipotential surfaces in the form of parallel planes, because of the condition that the equipotential surfaces or equipotential lines have to be perpendicular to the field lines. These planes are represented in two dimensions as equally spaced equipotential lines (Figure 23.16).

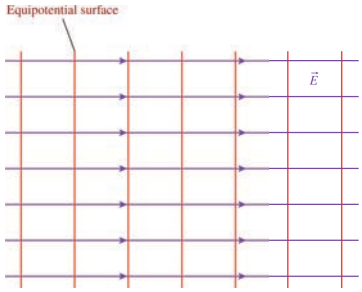

FIGURE 23.16
Equipotential surfaces (red lines) from a constant electric field. The purple lines with the arrowheads represent the electric field.

Single Point Charge

Figure 23.17 shows the electric field and corresponding equipotential lines due to a single point charge. The electric field lines extend radially from a positive point charge, as shown in Figure 23.17a. In this case, the field lines point away from the positive charge and terminate at infinity. For a negative charge, as shown in Figure 23.17b, the field lines originate at infinity and terminate at the negative charge. The equipotential lines are spheres centered on the point charge. (In the two-dimensional views shown in the figure, the circles represent the lines where the plane of the page cuts through equipotential spheres.) The values of the potential difference between neighboring equipotential lines are equal, producing equipotential lines that are close together near the charge and more widely spaced away from the charge. Note again that the equipotential lines are always perpendicular to the electric field lines. Equipotential surfaces do not have arrows like the field lines, because the potential is a scalar.

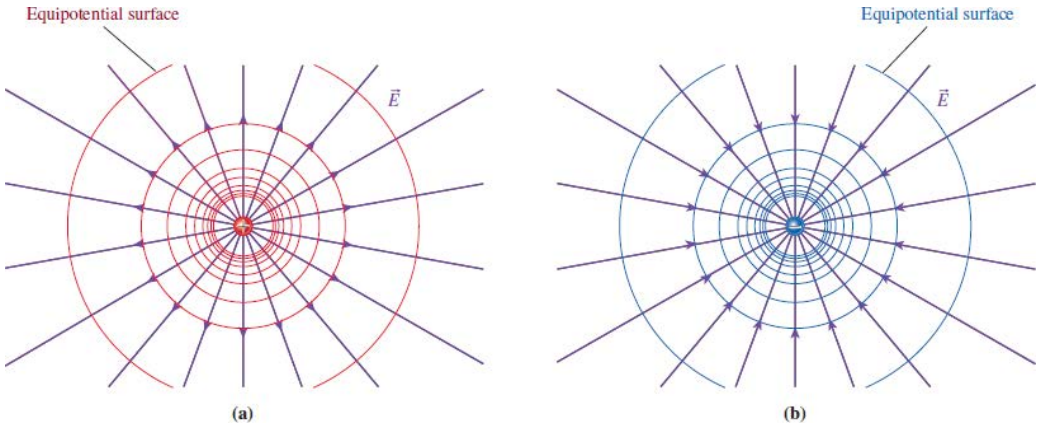

FIGURE 23.17 Equipotential surfaces and electric field lines from (a) a single positive point charge and (b) a single negative point charge.

Two Oppositely Charged Point Charges

Figure 23.18 shows the electric field lines from two oppositely charged point charges, along with equipotential surfaces depicted as equipotential lines. An electrostatic force would attract these two point charges toward each other, but this discussion assumes that the charges are fixed in space and cannot move. The electric field lines originate at the positive charge and terminate on the negative charge. Again, the equipotential lines are always perpendicular to the electric field lines. The red lines in this figure represent positive equipotential surfaces, and the blue lines represent negative equipotential surfaces. Positive charges produce positive potential, and negative charges produce negative potential (relative to the value of the potential at infinity). Close to each charge, the resultant electric field lines and the resultant equipotential lines resemble those for a single point charge. Away from the vicinity of each charge, the electric field and the electric potential are the sums of the fields and potentials due to the two charges. The electric fields add as vectors, while the electric potentials add as scalars. Thus, the electric field is defined at all points in space in terms of a magnitude and a direction, while the electric potential is defined solely by its value at a given point in space and has no direction associated with it.

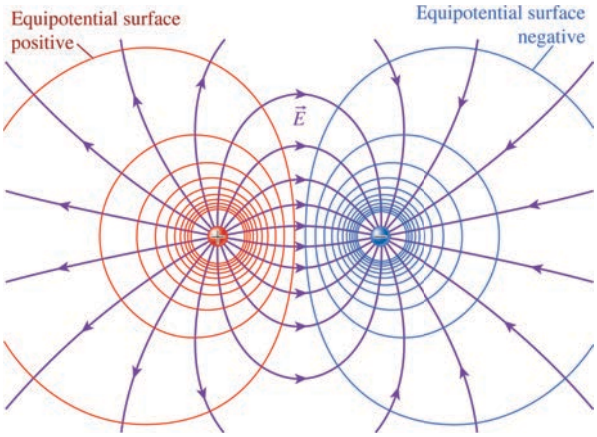

FIGURE 23.18 Equipotential surfaces created by point charges of the same magnitude but opposite sign. The red lines represent positive potential, and the blue lines represent negative potential. The purple lines with the arrowheads represent the electric field.

Self-Test Opportunity 23.1

Suppose the charges in Figure 23.18 were located at $(x, y) = (-10\ \text{cm}, 0)$ and $(x, y) = (+10\ \text{cm}, 0)$. What would the electric potential be along the y-axis $(x = 0)$?

Self-Test Opportunity 23.2

Suppose the charges in Figure 23.19 were located at $(x, y) = (-10\ \text{cm}, 0)$ and $(x, y) = (+10\ \text{cm}, 0)$. Would $(x, y) = (0, 0)$ correspond to a maximum, a minimum, or a saddle point in the electric potential?

Two Identical Point Charges

Figure 23.19 shows electric field lines and equipotential surfaces resulting from two identical positive point charges. These two charges experience a repulsive electrostatic force. Because both charges are positive, the equipotential surfaces represent positive potentials. Again, the electric field and electric potential result from the sums of the fields and potentials, respectively, due to the two charges.

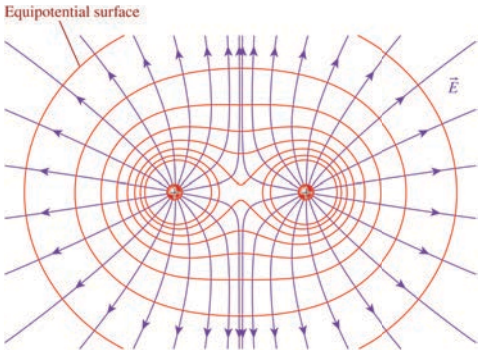

FIGURE 23.19 Equipotential surfaces (red lines) from two identical positive point charges. The purple lines with the arrowheads represent the electric field.

23.4 Electric Potential of Various Charge Distributions

The electric potential is defined as the work required to place a unit charge at a point, and work is a force acting over a distance. Also, the electric field can be defined as the force acting on a unit charge at a point. Therefore, it seems that the potential at a point should be related to the field strength at that point. In fact, electric potential and electric field are directly related; we can determine either one given an expression for the other.

Page 726

To determine the electric potential from the electric field, we start with the definition of the work done on a particle with charge q by a force, $\vec{F}$, over a displacement, $\vec{ds}$:

$$dW = \vec{F} \bullet \vec{ds}.$$

In this case, the force is given by $\vec{F} = q\vec{E}$, so

$$dW = q\vec{E} \bullet \vec{ds}. \qquad \textbf{(23.10)}$$

Integration of equation 23.10 as the particle moves in the electric field from some initial point to some final point gives

$$W = W_{\mathrm{e}} = \int_{\mathrm{i}}^{\mathrm{f}} q\vec{E} \bullet \vec{ds} = q \int_{\mathrm{i}}^{\mathrm{f}} \vec{E} \bullet \vec{ds}.$$

Using equation 23.8 to relate the work done to the change in electric potential, we get

$$\Delta V = V_{\mathrm{f}} - V_{\mathrm{i}} = -\frac{W_{\mathrm{e}}}{q} = -\int_{\mathrm{i}}^{\mathrm{f}} \vec{E} \bullet \vec{ds}.$$

As mentioned earlier, the usual convention is to set the electric potential to zero at infinity. With this convention, we can express the potential at some point $\vec{r}$ in space as

$$V\left(\vec{r}\right) - V(\infty) \equiv -V\left(\vec{r}\right) = -\int_{\infty}^{\vec{r}} \vec{E} \bullet d\vec{s}. \qquad \textbf{(23.11)}$$

Concept Check 23.3

In the figure, the lines represent equipotential lines. A charged object is moved from point *P* to point *Q.* How does the amount of work done on the object compare for these three cases?

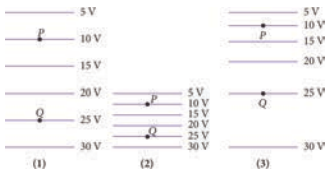
a) All three cases involve the same work.

b) The most work is done in case 1.

c) The most work is done in case 2.

d) The most work is done in case 3.

e) Cases 1 and 3 involve the same amount of work, which is more than is involved in case 2.



Point Charge

Let's use equation 23.11 to determine the electric potential due to a point charge, q. The electric field due to a point charge, q (for now, taken as positive), at a distance r from the charge is given by

$$E = \frac{kq}{r^2}.$$

The direction of the electric field is radial from the point charge. Assume that the integration is carried out along a radial line from infinity to a point at a distance R from the point charge, such that $\vec{E} \bullet \vec{ds} = Edr$. Then we can use equation 23.11 to obtain

$$V(R) = -\int_{\infty}^{R} \vec{E} \bullet \vec{ds} = -\int_{\infty}^{R} \frac{kq}{r^2}\, dr = \left[\frac{kq}{r}\right]_{\infty}^{R} = \frac{kq}{R}.$$

Self-Test Opportunity 23.3

Obtaining equation 23.12 for the electric potential from a point charge involved integrating along a radial line from infinity to a point at a distance R from the point charge. How would the result change if the integration were carried out over a different path?

Thus, the electric potential due to a point charge at a distance r from the charge is given by

$$V = \frac{kq}{r}. \qquad \textbf{(23.12)}$$

Concept Check 23.4

What is the electric potential 45.5 cm away from a point charge of 12.5 pC?

a) 0.247 V

b) 1.45 V

c) 4.22 V

d) 10.2 V

e) 25.7 V

Equation 23.12 also holds when $q < 0$. A positive charge produces a positive potential, and a negative charge produces a negative potential, as shown in Figure 23.20.

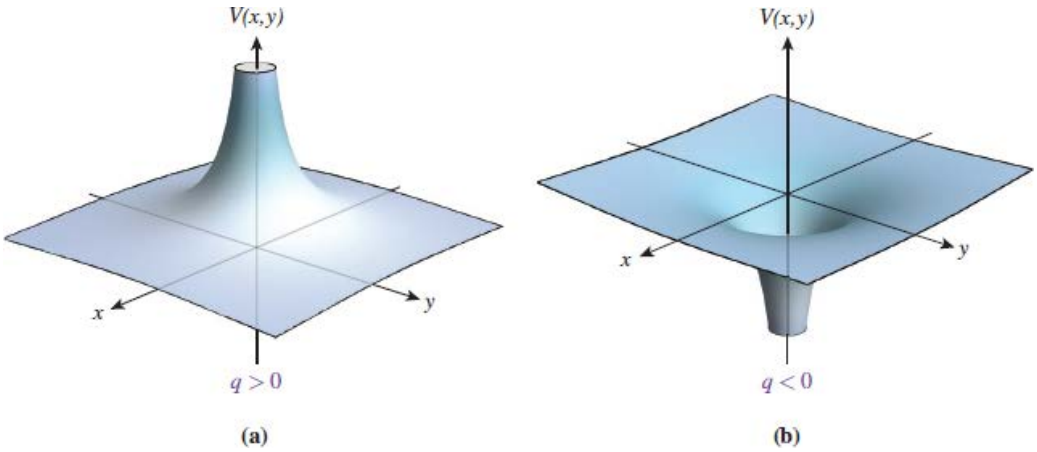


FIGURE 23.20 Electric potential due to (a) a positive point charge and (b) a negative point charge.

In Figure 23.20, the electric potential is calculated for all points in the xy-plane. The vertical axis represents the value of the potential at each point on the plane, $V(x, y)$, found using $r = \sqrt{x^2 + y^2}$. The potential is not calculated close to $r = 0$ because it becomes infinite there. You can see from Figure 23.20 how the circular equipotential lines shown in Figure 23.17 originate.

SOLVED PROBLEM 23.2 Fixed and Moving Positive Charges

PROBLEM

A positive charge of 4.50 μC is fixed in place. A particle of mass 6.00 g and charge +3.00 μC is fired with an initial speed of 66.0 m/s directly toward the fixed charge from a distance of 4.20 cm away. How close does the moving charge get to the fixed charge before it comes to rest and starts moving away from the fixed charge?

SOLUTION

THINK

The moving charge will gain electric potential energy as it nears the fixed charge. The negative of the change in potential energy of the moving charge is equal to the change in kinetic energy of the moving charge because $\Delta K + \Delta U = 0$.

SKETCH

We set the location of the fixed charge at $x = 0$, as shown in Figure 23.21. The moving charge starts at $x = d_i$, moves with initial speed $v = v_0$, and comes to rest at $x = d_f$.

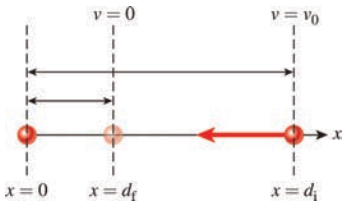

FIGURE 23.21 Two positive charges. One charge is fixed in place at $x = 0$, and the second charge begins moving with velocity $\vec{v}_0$ at $x = d_i$ and has zero velocity at $x = d_f$.

RESEARCH

The moving charge gains electric potential energy as it approaches the fixed charge and loses kinetic energy until it stops. At that point, all the original kinetic energy of the moving charge has been converted to electric

potential energy. Using energy conservation, we can write this relationship as

$$\begin{aligned}\Delta K + \Delta U = 0 \Rightarrow \Delta K = -\Delta U \Rightarrow \\ 0 - \frac{1}{2}mv_0^2 = -q_{\text{moving}}\Delta V \Rightarrow \\ \frac{1}{2}mv_0^2 = q_{\text{moving}}\Delta V.\end{aligned}$$

(i)

The electric potential experienced by the moving charge is due to the fixed charge, so we can write the change in potential as

$$\Delta V = V_\text{f} - V_\text{i} = k\frac{q_\text{fixed}}{d_\text{f}} - k\frac{q_\text{fixed}}{d_\text{i}} = kq_\text{fixed}\left(\frac{1}{d_\text{f}} - \frac{1}{d_\text{i}}\right)$$ **(ii)**

SIMPLIFY

Substituting the expression for the potential difference from equation (ii) into equation (i), we find

$$\begin{aligned}\frac{1}{2}mv_0^2 = q_{\text{moving}}\Delta V = kq_{\text{moving}}q_{\text{fixed}}\left(\frac{1}{d_\text{f}} - \frac{1}{d_\text{i}}\right) \Rightarrow \\ \frac{1}{d_\text{f}} - \frac{1}{d_\text{i}} = \frac{mv_0^2}{2kq_{\text{moving}}q_{\text{fixed}}} \Rightarrow \\ \frac{1}{d_\text{f}} = \frac{1}{d_\text{i}} + \frac{mv_0^2}{2kq_{\text{moving}}q_{\text{fixed}}}.\end{aligned}$$

CALCULATE

Putting in the numerical values, we get

$$\frac{1}{d_\text{f}} = \frac{1}{0.0420\ \text{m}} + \frac{(0.00600\ \text{kg})(66.0\text{m/s})^2}{2\left(8.99\cdot10^9\ \text{N m}^2/\text{C}^2\right)\left(3.00\cdot10^{-6}\text{C}\right)\left(4.50\cdot10^{-}\right.}$$

or

$$d_\text{f} = 0.00760545\ \text{m}.$$

ROUND

We report our result to three significant figures:

$$d_\mathrm{f} = 0.00761\ \mathrm{m} = 0.761\ \mathrm{cm}.$$

DOUBLE-CHECK

The final distance of 0.761 cm is less than the initial distance of 4.20 cm. At the final distance, the electric potential energy of the moving charge is

$$\begin{aligned} U &= q_\mathrm{moving} V = q_\mathrm{moving}\left(k\frac{q_\mathrm{fixed}}{d_\mathrm{f}}\right) = k\frac{q_\mathrm{moving}q_\mathrm{fixed}}{d_\mathrm{f}} \\ &= \left(8.99\cdot 10^9\ \mathrm{N\,m^2/C^2}\right)\frac{\left(3.00\cdot 10^{-6}\mathrm{C}\right)\left(4.50\cdot 10^{-6}\mathrm{C}\right)}{0.00761\mathrm{m}} = 16.0\ \mathrm{J}. \end{aligned}$$

The electric potential energy at the initial distance is

$$\begin{aligned} U &= q_\mathrm{moving} V = q_\mathrm{moving}\left(k\frac{q_\mathrm{fixed}}{d_\mathrm{i}}\right) = k\frac{q_\mathrm{moving}q_\mathrm{fixed}}{d_\mathrm{i}} \\ &= \left(8.99\cdot 10^9\mathrm{N\,m^2/C^2}\right)\frac{\left(3.00\cdot 10^{-6}\mathrm{C}\right)\left(4.50\cdot 10^{-6}\mathrm{C}\right)}{0.0420\ \mathrm{m}} = 2.9\ \mathrm{J}. \end{aligned}$$

The initial kinetic energy is

$$K = \frac{1}{2}mv^2 = \frac{(0.00600\ \mathrm{kg})(66.0\ \mathrm{m/s})^2}{2} = 13.1\ \mathrm{J}.$$

We can see that the equation based on energy conservation, from which the solution process started, is satisfied:

$$\begin{aligned} \frac{1}{2}mv^2 &= \Delta U \\ 13.1\ \mathrm{J} &= 16.0\ \mathrm{J} - 2.9\ \mathrm{J} = 13.1\ \mathrm{J}. \end{aligned}$$

This gives us confidence that our result for the final distance is correct.

System of Point Charges

Assuming again that the electric potential is zero at an infinite distance from the origin, we calculate the electric potential due to a system of n point charges by adding the potentials due to all the charges:

$$V = \sum_{i=1}^{n} V_i = \sum_{i=1}^{n} \frac{kq_i}{r_i}. \qquad \textbf{(23.13)}$$

Equation 23.13 can be proved by inserting the expression for the total electric field from n charges $\left(\overrightarrow{E}_{\mathrm{t}} = \overrightarrow{E}_1 + \overrightarrow{E}_2 + \cdots + \overrightarrow{E}_n\right)$ into equation 23.11 and integrating term by term. The summation in equation 23.13 produces a potential at any point in space that has a value but no direction. Thus, calculating the potential due to a group of point charges is usually much simpler than calculating the electric field, which involves the addition of vectors.

EXAMPLE 23.4 Superposition of Electric Potentials

Let's calculate the electric potential at a given point due to a system of point charges. Figure 23.22 shows three point charges: $q_1 = +1.50\ \mu\text{C}$, $q_2 = +2.50\ \mu\text{C}$, and $q_3 = -3.50\ \mu\text{C}$. Charge q_1 is located at (0,a), q_2 is located at (0,0), and q_3 is located at (b,0), where $a = 8.00\ \text{m}$ and $b = 6.00\ \text{m}$.

The electric potential at point P is the sum of the potentials due to the three charges:

$$V = \sum_{i=1}^{3} \frac{kq_i}{r_i} = k\left(\frac{q_1}{r_1} + \frac{q_2}{r_2} + \frac{q_3}{r_3}\right) = k\left(\frac{q_1}{b} + \frac{q_2}{\sqrt{a^2 + b^2}} + \frac{q_3}{a}\right)$$

$$= \left(8.99 \cdot 10^9\ \text{N m}^2/\text{C}^2\right)\left(\frac{1.50 \cdot 10^{-6}\ \text{C}}{6.00\ \text{m}} + \frac{2.50 \cdot 10^{-6}\ \text{C}}{\sqrt{(8.00\ \text{m})^2 + (6.00\ \text{r}}}\right.$$

$$= 562\ \text{V}.$$

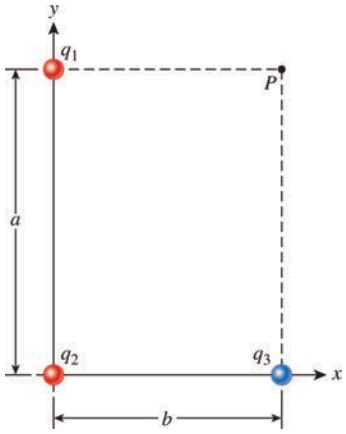

FIGURE 23.22
Electric potential at a point due to three point charges.

Note that the potential due to q_3 is negative at point P, but the sum of the potentials is positive.

This example is similar to Example 22.1, in which we calculated the electric field at point P due to three charges. Note that this calculation of the electric potential due to three charges is much simpler than that calculation.

Concept Check 23.5

Two protons are located in space in the three ways shown in the figure. Rank the three cases from highest to lowest net electric potential, V, produced at point P.

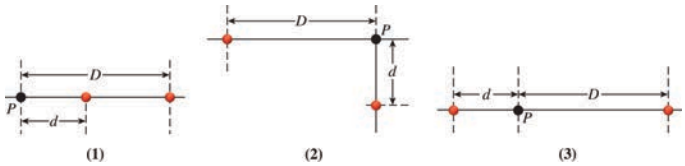
a) $2 > 3 > 1$

b) All three potentials are the same.

c) $3 > 2 > 1$

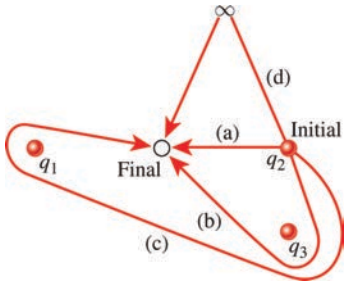
d) The potentials are equal for cases 1 and 3, with the potential for case 2 lower.

e) $1 > 2 > 3$



Concept Check 23.6

Three identical positive point charges are located at fixed points in space. Then charge q_2 is moved from its initial location to a final location as shown in the figure. Four different paths, marked (a) through (d), are shown. Path (a) follows the shortest line; path (b) takes q_2 around q_3; path (c) takes q_2 around q_3 and q_1; path (d) takes q_2 out to infinity and then to the final location. Which path requires the least work?



a) path (a)

b) path (b)

c) path (c)

d) path (d)

e) The work is the same for all the paths.

SOLVED PROBLEM 23.3 Minimum Potential

PROBLEM

A charge of $q_1 = 0.829\,\text{nC}$ is placed at $r_1 = 0$ on the x-axis. Another charge of $q_2 = 0.275\,\text{nC}$ is placed at $r_2 = 11.9\,\text{cm}$ on the x-axis. At which point along the x-axis between the two charges does the electric potential resulting from both of them have a minimum?

SOLUTION

THINK

We can express the electric potential due to the two charges as the sum of the electric potentials from the individual charges. To obtain the minimum potential, we take the derivative of the potential and set it equal to zero. We can then solve for the distance where the derivative is zero.

SKETCH

Figure 23.23 shows the locations of the two charges.

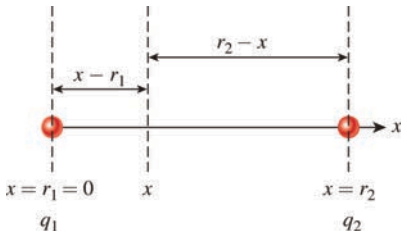


FIGURE 23.23 Two charges placed along the x-axis.

RESEARCH

We can express the electric potential produced along the x-axis by the two charges as

$$V = V_1 + V_2 = k\frac{q_1}{x - r_1} + k\frac{q_2}{r_2 - x} = k\frac{q_1}{x} + k\frac{q_2}{r_2 - x}.$$

Note that the quantities x and $r_2 - x$ are always positive for $0 < x < r_2$. To find the minimum, we take the derivative of the electric potential:

$$\frac{dV}{dx} = -k\frac{q_1}{x^2} - k\frac{q_2}{(r_2 - x)^2}(-1) = k\frac{q_2}{(r_2 - x)^2} - k\frac{q_1}{x^2}.$$

SIMPLIFY

Setting the derivative of the electric potential equal to zero and rearranging, we obtain

$$k\frac{q_2}{(r_2-x)^2}=k\frac{q_1}{x^2}.$$

Dividing out k and rearranging, we get

$$\frac{x^2}{(r_2-x)^2}=\frac{q_1}{q_2}.$$

Now we can take the square root and rearrange:

$$x=\pm(r_2-x)\sqrt{\frac{q_1}{q_2}}.$$

Because $x>0$ and $(r_2-x)>0$, the sign must be positive. Solving for x, we get

$$x=\frac{r_2\sqrt{\frac{q_1}{q_2}}}{1+\sqrt{\frac{q_1}{q_2}}}=\frac{r_2}{\sqrt{\frac{q_2}{q_1}}+1}.$$

CALCULATE

Putting in the numerical values results in

$$x=\frac{0.119\text{ m}}{1+\sqrt{\frac{0.275\text{ nC}}{0.829\text{ nC}}}}=0.0755097\text{ m}.$$

ROUND

We report our result to three significant figures:

$$x=0.0755\text{ m}=7.55\text{ cm}.$$

DOUBLE-CHECK

We can double-check our result by plotting (for example, with a graphing calculator) the electric potential resulting from the two charges and

graphically determining the minimum (Figure 23.24).

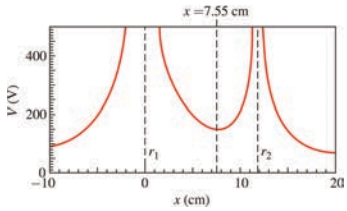

FIGURE 23.24 Graph of the electric potential resulting from two charges.

The minimum of the electric potential is located at $x = 7.55$ cm, which confirms our calculated result.

Continuous Charge Distribution

We can also determine the electric potential due to a continuous distribution of charge. To do this, we divide the charge into differential elements of charge, dq, and find the electric potential resulting from that differential charge as if it were a point charge. This is the way charge distributions were treated in determining electric fields in Chapter 22. The differential charge, dq, can be expressed in terms of a charge per unit length times a differential length, $\lambda\, dx$; in terms of a charge per unit area times a differential area, $\sigma\, dA$; or in terms of a charge per unit volume times a differential volume, $\rho\, dV$. The electric potential resulting from the charge distribution is obtained by integrating over the contributions from the differential charges. Let's consider an example involving the electric potential due to a one-dimensional charge distribution.

EXAMPLE 23.5 Finite Line of Charge

What is the electric potential at a distance d along the perpendicular bisector of a thin wire with length $2a$ and linear charge distribution λ (Figure 23.25)?

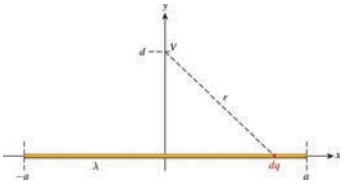

FIGURE 23.25
Calculating the electric potential due to a line of charge.

The differential electric potential, dV, at a distance d along the perpendicular bisector of the wire due to a differential charge, dq, is given by

$$dV = k\frac{dq}{r}.$$

The electric potential due to the whole wire is found by integrating dV along the length of the wire:

$$V = \int_{-a}^{a} dV = \int_{-a}^{a} k\frac{dq}{r}. \qquad \textbf{(i)}$$

With $dq = \lambda dx$ and $r = \sqrt{x^2 + d^2}$, we can rewrite equation (i) as

$$V = \int_{-a}^{a} k\frac{\lambda dx}{\sqrt{x^2 + d^2}} = \kappa\lambda \int_{-a}^{a} \frac{dx}{\sqrt{x^2 + d^2}}.$$

Finding this integral in a table or evaluating it with software gives

$$\int_{-a}^{a} \frac{dx}{\sqrt{x^2 + d^2}} = \left[\ln\left(x + \sqrt{x^2 + d^2}\right)\right]_{-a}^{a} = \ln\left(\frac{\sqrt{a + d^2} + a}{\sqrt{a^2 + d^2} - a}\right).$$

Thus, the electric potential at a distance d along the perpendicular bisector of a finite line of charge is given by

$$V = \kappa\lambda \ln\left(\frac{\sqrt{a^2 + d^2} + a}{\sqrt{a^2 + d^2} - a}\right).$$

Self-Test Opportunity 23.4

Sketch the graph of the electric potential due to a hollow conducting charged sphere as a function of the radial coordinate *r* from zero to three times the sphere's radius, *R*.

SOLVED PROBLEM 23.4 Charged Disk

PROBLEM

A charge of 3.50 nC is uniformly applied to a disk of radius 1.00 cm. What is the electric potential at a distance of 4.50 mm from the disk along its symmetry axis, assuming, as usual, that the potential is zero at an infinite distance?

SOLUTION

THINK

A point charge creates the electric potential $V(r) = kq/r$, but since the charge in this case is distributed over an area, we cannot use this relationship but have to perform an integration. The general procedure for this integration is always the same: We divide the total charge into small increments, dq, compute the electric potential for each, and then integrate over all the charge increments. In this case, our task is to find the potential on a point along the symmetry axis of the disk, and so we should make use of this symmetry in our integration procedure.

Page 732

SKETCH

A sketch of the problem situation is given in Figure 23.26.

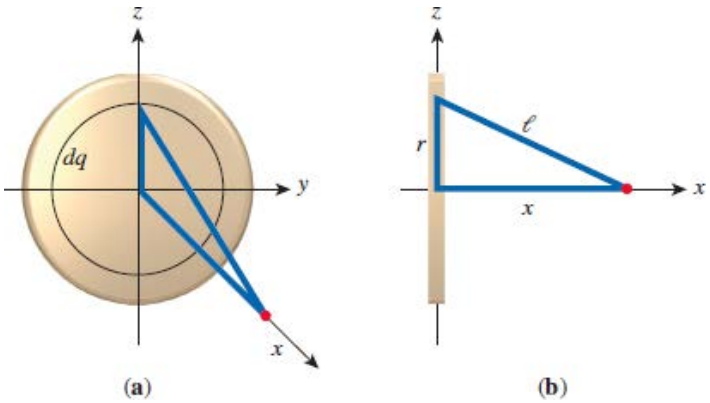

FIGURE 23.26 Electric potential on the symmetry axis of a disk: (a) front view, (b) side view.

RESEARCH

The surface charge density on the disk is $\sigma = q/A$, where A is the area of the disk, $A = \pi R^2$. Further, the charge is distributed symmetrically

around the symmetry axis, the x-axis in Figure 23.26. This motivates the use of a thin ring of width dr for our differential charge unit: $dq = \sigma dA$, with $dA = 2\pi r dr$. You can see in Figure 23.26 that every point on the ring is an equal distance ℓ from the point (marked by the red dot) at which we want to evaluate the potential. The contribution of dq to the electric potential is then $dV = kdq/\ell$, and the total potential is $V = \int dV$. The last thing we need to do is to relate the distance ℓ to the distance x between the point and the center of the disk. From part (b) of Figure 23.26, you can see that this relationship is given by $\ell = \sqrt{r^2 + x^2}$.

SIMPLIFY

Putting the pieces together, we find that the potential on the symmetry axis of the disk as a function of the distance to the center is given by

$$V(x) = \int dV = \int \frac{k}{\ell} dq = \int \frac{k\sigma}{\ell} dA = \int \frac{k\sigma}{\ell} 2\pi r \, dr.$$

After inserting the expressions we found for the charge density, s, and the distance, ℓ we are ready to integrate over r from zero to the radius of the disk, R:

$$V(x) = \frac{2kq}{R^2} \int_0^R \frac{r}{\sqrt{x^2 + r^2}} dr = \frac{2kq}{R^2} \sqrt{x^2 + r^2} \Big|_0^R = \frac{2kq}{R^2} \left(\sqrt{x^2 + R \right.}$$

CALCULATE

Inserting the given numerical values, we find

$$V(4.5\,\text{mm}) = \frac{2\left(8.98755 \cdot 10^9\,\text{N m}^2/\text{C}^2\right)\left(3.5 \cdot 10^{-9}\text{C}\right)}{\left(0.01\,\text{m}\right)^2} \left(\sqrt{\left(4.5 \cdot 10\right.} \right.$$
$$= 4067 \cdot 85\,\text{N m/C}.$$

ROUND

We round our final result to three significant figures: $V(4.5\,\text{mm}) = 4.07\,\text{kV}$. (We have used $1\,\text{N m} = 1\,\text{J}$ and $1\,\text{J}/1\,\text{C} = 1\,\text{V}$ to get the proper unit, the volt, for the potential.)

DOUBLE-CHECK

We have already done the simple check of noting that the units of our answer are correct. As another check, we can look at the limiting case where the radius of the disk shrinks to zero, that is, where it becomes a point charge. The potential at a distance of 4.50 mm from a 3.50-nC point charge is

$$V_{\text{point}}(4.5\ \text{mm}) = \frac{\left(8.988 \cdot 10^{9}\text{N m}^2/\text{C}^2\right)\left(3.5 \cdot 10^{-9}\text{C}\right)}{0.0045\ \text{m}} = 6.99\,\text{kV}.$$

This result is comforting because it is of the same order of magnitude as our calculated answer, just slightly larger, as we would expect. Figure 23.27 compares the graph of the electric potential due to the charged disk (blue curve) with the graph of the potential due to a point charge (red curve). As expected, the distribution of the charge does not matter at large distances, and our calculated potential approaches that for a point charge. For distances smaller than the radius of the disk, however, the difference becomes very pronounced. In particular, note that for $x \to 0$ the potential due to a uniformly charged disk does not diverge but has a maximum of $2kq/R$.

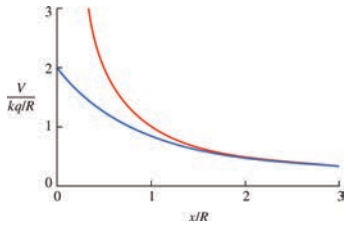

FIGURE 23.27
Comparison of the electric potential due to the uniformly charged disk with radius *R* (blue curve) and that due to a point charge (red curve).

23.5 Finding the Electric Field from the Electric Potential

As we mentioned earlier, we can determine the electric field starting with the electric potential. This calculation uses equations 23.8 and 23.10:

$$-qdV = q\vec{E} \bullet \vec{ds},$$

where $\vec{ds}$ is a vector from an initial point to a final point located a small (infinitesimal) distance away. The component of the electric field, E_s, along the direction of $\vec{ds}$ is given by the partial derivative

$$E_s = -\frac{\partial V}{\partial s}. \qquad \textbf{(23.14)}$$

(Chapter 15 on waves applied partial derivatives, and they were treated much like conventional derivatives, which we'll continue to do here.) Thus, we can find any component of the electric field by taking the partial derivative of the potential along the direction of that component. We can then write the components of the electric field in terms of partial derivatives of the potential:

$$E_x = -\frac{\partial V}{\partial x}; \quad E_y = -\frac{\partial V}{\partial y}; \quad E_z = -\frac{\partial V}{\partial z}. \qquad \textbf{(23.15)}$$

The equivalent vector calculus formulation is $\vec{E} = -\vec{\nabla}V \equiv -(\partial V/\partial x,\ \partial V/\partial y,\ \partial V/\partial z)$, where the operator $\vec{\nabla}$ is called the **gradient.** Thus, the electric field can be determined either graphically, by measuring the negative of the change of the potential per unit distance perpendicular to an equipotential line, or analytically, by using equation 23.15.

Concept Check 23.7

Suppose an electric potential is described by $V(x, y, z) = -\left(5x^2 + y + z\right)$ in volts. Which of the following expressions describes the associated electric field, in units of volts per meter?

a) $\vec{E} = 5\hat{x} + 2\hat{y} + 2\hat{z}$

b) $\vec{E} = 10x\hat{x}$

c) $\vec{E} = 5x\hat{x} + 2\hat{y}$

d) $\vec{E} = 10x\hat{x} + \hat{y} + \hat{z}$

e) $\vec{E} = 0$

Concept Check 23.8

In the figure, the lines represent equipotential lines. How does the magnitude of the electric field, *E,* at point *P* compare for the three cases?

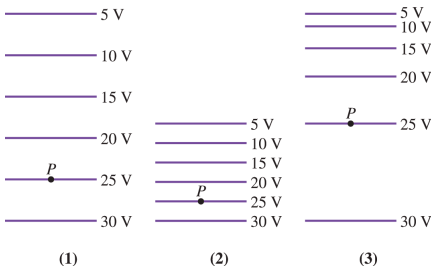
a) $E_1 = E_2 = E_3$

b) $E_1 > E_2 > E_3$

c) $E_1 > E_2 < E_3$

d) $E_3 > E_1 > E_2$

e) $E_3 < E_1 < E_2$



To visually reinforce the concepts of electric fields and potentials, the following example shows how a graphical technique can be used to find the

field given the potential.

EXAMPLE 23.6 Graphical Extraction of the Electric Field

Let's consider a system of three point charges with values $q_1 = -6.00\ \mu\text{C}$, and $q_2 = -3.00\ \mu\text{C}$, and $q_3 = +9.00\ \mu\text{C}$, located at positions $(x_1, y_1) = (1.5\ \text{cm}, 9.0\ \text{cm})$, $(x_2, y_2) = (6.0\ \text{cm}, 8.0\ \text{cm})$, and $(x_3, y_3) = (53\ \text{cm}, 2.0\ \text{cm})$. Figure 23.28 shows the electric potential, $V(x, y)$, resulting from these three charges, with equipotential lines calculated at potential values from $-5000\ \text{V}$ to $5000\ \text{V}$ in 1000-V increments shown in Figure 23.29.

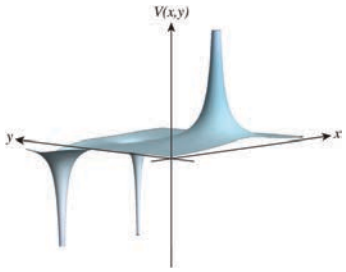


FIGURE 23.28
Electric potential due to three charges.

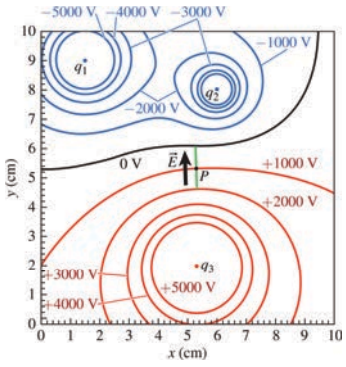

FIGURE 23.29
Equipotential lines for the electric potential due to three point charges.

We can calculate the magnitude of the electric field at point P using equation 23.14 and graphical techniques. To perform this task, we use the green line in Figure 23.29, which is drawn through point P perpendicular

to the equipotential line because the electric field is always perpendicular to the equipotential lines, reaching from the equipotential line of 0 V to the line of 2000 V. As you can see from Figure 23.29, the length of the green line is 1.5 cm. Therefore, the magnitude of the electric field can be approximated as

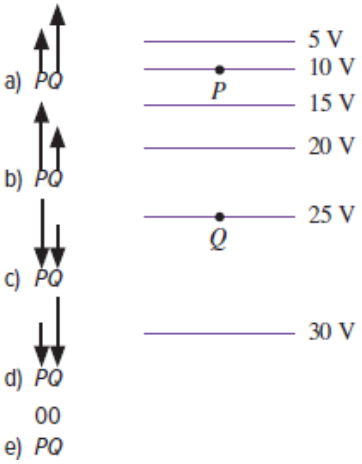
$$|E_s| = \left| -\frac{\Delta V}{\Delta s} \right| = \left| \frac{(+2000\ \text{V}) - (0\ \text{V})}{1.5\ \text{cm}} \right| = 1.3 \cdot 10^5 \text{V/m},$$

where Δs is the length of the line through point P. The negative sign in equation 23.14 indicates that the direction of the electric field between neighboring equipotential lines points from the 2000-V equipotential line to the zero potential line.

In Chapter 22, we derived an expression for the electric field along the perpendicular bisector of a finite line of charge:

Concept Check 23.9

In the figure, the lines represent equipotential lines. A positive charge is placed at point *P,* and then another positive charge is placed at point *Q.* Which set of vectors best represents the relative magnitudes and directions of the electric field forces exerted on the positive charges at *P* and *Q*?



In Example 23.5, we found an expression for the electric potential along the perpendicular bisector of a finite line of charge; here we replace the coordinate d used in that example with the distance in the y-direction:

$$V = k\lambda \ln\left(\frac{\sqrt{y^2+a^2}+a}{\sqrt{y^2+a^2}-a}\right), \qquad \textbf{(23.16)}$$

We can find the y-component of the electric field from the potential using equation 23.15:

$$\begin{aligned} E_y &= -\frac{\partial V}{\partial y} \\ &= -\frac{\partial\left(k\lambda \ln\left(\frac{\sqrt{y^2+a^2}+a}{\sqrt{y^2+a^2}-a}\right)\right)}{\partial y} \\ &= -k\lambda\left(\frac{\partial\left(\ln\left(\sqrt{y^2+a^2}+a\right)\right)}{\partial y} - \frac{\partial\left(\ln\left(\sqrt{y^2+a^2}-a\right)\right)}{\partial y}\right). \end{aligned}$$

Page 735

Taking the partial derivative (remember that we can treat the partial derivative like a regular derivative), we obtain for the first term

$$\frac{\partial}{\partial y}\left(\ln\left(\sqrt{y^2+a^2}+a\right)\right) = \underbrace{\left(\frac{1}{\sqrt{y^2+a^2}+a}\right)}_{\text{derivative of ln}}\underbrace{\left(\frac{1}{2}\frac{1}{\sqrt{y^2+a^2}}\right)}_{\text{derivative of }\sqrt{y^2+a^2}}\underbrace{(2y}_{\text{derivativ}}$$

where the fact that the derivative of the natural log function is $d(\ln x)/dx = 1/x$ and the chain rule of differentiation have been used. (The outer and inner derivatives are indicated under the terms that they generate.) A similar expression can be found for the second term. Using the values of the derivatives, we find the component of the electric field:

$$E_y = -k\lambda\left(\frac{y}{y^2+a^2+a\sqrt{y^2+a^2}} - \frac{y}{y^2+a^2-a\sqrt{y^2+a^2}}\right) = \frac{2k\lambda}{y}.$$

This result is the same as that for the electric field in the y-direction derived in Chapter 22 by integrating over a finite line of charge.

Concept Check 23.10

In the figure, the lines represent equipotential lines. What is the direction of the electric field at point *P*?

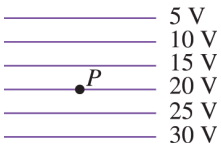
a) up

b) down

c) left

d) right

e) The electric field at *P* is zero.



Concept Check 23.11

Three pairs of parallel plates have the same plate separation and potentials on each plate as indicated in the drawing. The electric field, *E,* is uniform between each pair of plates and perpendicular to them. Rank the magnitude of *E* between the plates, from highest to lowest.

a) $1 > 2 > 3$

b) $3 > 2 > 1$

c) The magnitudes for 3 and 2 are equal and greater than the magnitude for 1

d) The three magnitudes are equal.

e) The magnitude for 2 is greater than that for 1 and 3, which are the same.

23.6 Electric Potential Energy of a System of Point Charges

Section 23.1 discussed the electric potential energy of a point charge in a given external electric field, and Section 23.4 described how to calculate the electric potential due to a system of point charges. This section combines these two pieces of information to find the electric potential energy of a system of point charges. Consider a system of charges that are infinitely far apart. To bring these charges into proximity with each other, work must be done on the charges, which changes the electric potential energy of the system. The electric potential energy of a system of point charges is defined as the work required to bring the charges together from being infinitely far apart.

As an example, let's find the electric potential energy of a system of two point charges (Figure 23.30). Assume that the two charges start at an infinite separation. We then bring point charge q_1 into the system. Because the system without charges has no electric field and no corresponding electric force, this action does not require that any work be done on the charge. Keeping this charge stationary, we bring the second point charge, q_2, from infinity to a distance r from q_1. Using equation 23.6, we can write the electric potential energy of the system as

$$U = q_2 V, \tag{23.17}$$

where

$$V = \frac{kq_1}{r}. \tag{23.18}$$

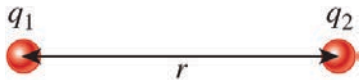


FIGURE 23.30 Two point charges separated by a distance r.

Thus, the electric potential energy of this system of two point charges is

$$U = \frac{kq_1q_2}{r}. \tag{23.19}$$

From the work-energy theorem, the work, W, that must be done on the particles to bring them together and keep them stationary is equal to U. If the two charges have the same sign, $W = U > 0$, positive work must be done to bring them together from infinity and keep them motionless. If the two charges have opposite signs, negative work must be done to bring them together from infinity and hold them motionless. To determine U for more than two point charges, we assemble them from infinity one charge at a time, in any order.

EXAMPLE 23.7 Four Point Charges

Let's calculate the electric potential energy of a system of four point charges, shown in Figure 23.31. The four point charges have the values $q_1 = +1.0\,\mu\text{C}$, $q_2 = +2.0\,\mu\text{C}$, $q_3 = -3.0\,\mu\text{C}$, and $q_4 = +4.0\,\mu\text{C}$. The charges are placed with $a = 6.0\,\text{m}$ and $b = 4.0\,\text{m}$.

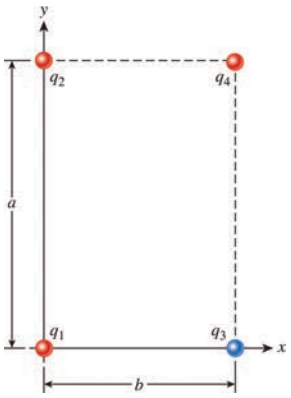

FIGURE 23.31 Calculating the potential energy of a system of four point charges.

PROBLEM

What is the electric potential energy of this system of four point charges?

SOLUTION

We begin the calculation with the four charges infinitely far apart and assume that the electric potential energy is zero in that configuration. We bring in q_1 and position that charge at (0,0). This action does not change the electric potential energy of the system. Now we bring in q_2 and place that charge at (0,a). The electric potential energy of the system is now

$$U = \frac{kq_1q_2}{a}.$$

Bringing q_3 in from an infinite distance and placing it at (b,0) changes the potential energy of the system through the interaction of q_3 with q_1 and the interaction of q_3 with q_2. The new potential energy is

$$U = \frac{kq_1q_2}{a} + \frac{kq_1q_3}{b} + \frac{kq_2q_3}{\sqrt{a^2 + b^2}}.$$

Finally, bringing in q_4 and placing it at (b,a) changes the potential energy of the system through interactions with q_1, q_2, and q_3, bringing the total electric potential energy of the system to

$$U = \frac{kq_1q_2}{a} + \frac{kq_1q_3}{b} + \frac{kq_2q_3}{\sqrt{a^2+b^2}} + \frac{kq_1q_4}{\sqrt{a^2+b^2}} + \frac{kq_2q_4}{b} + \frac{kq_3q_4}{a}.$$

Note that the order in which the charges are brought from infinity will not change this result. (You can try a different order to verify this statement.) Putting in the numerical values, we obtain

$$U = \left(3.0 \cdot 10^{-3}\ \text{J}\right) + \left(-6.7 \cdot 10^{-3}\ \text{J}\right) + \left(-7.5 \cdot 10^{-3}\ \text{J}\right) + \left(5.0 \cdot 10^{-}\right.$$

From the calculation in Example 23.7, we extrapolate the result to obtain a formula for the electric potential energy of a collection of point charges:

$$U = k \sum_{ij(\text{pairings})} \frac{q_i q_j}{r_{ij}}, \tag{23.20}$$

where i and j label each pair of charges, the summation is over each pair ij (for all $i \neq j$), and r_{ij} is the distance between the charges in each pair. An alternative way to write this double sum is

$$U = \frac{1}{2} k \sum_{j=1}^{n} \sum_{i=1, i \neq j}^{n} \frac{q_i q_j}{\left| \vec{r}_i - \vec{r}_j \right|},$$

which is more explicit than the equivalent formulation of equation 23.20.

EXAMPLE 23.8 Electric Potential Energy of a Uniformly Charged Sphere

As an example of the electric potential energy of a more complex system of charges, let's calculate the electric potential energy of a uniform sphere of charge. The sphere has a radius of 20.0 cm and contains a total charge of 3.00 μC.

PROBLEM

What is the electric potential energy of the charged sphere?

SOLUTION

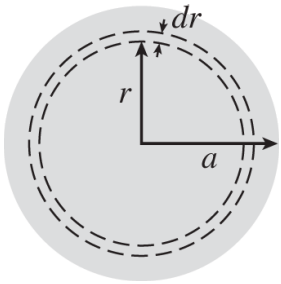
Because the charge distribution is uniform, we can express the charge density of the distribution as

$$\rho = \frac{q_{\text{total}}}{V} = \frac{q_{\text{total}}}{\frac{4}{3}\pi a^3} = \frac{3q_{\text{total}}}{4\pi a^3}.$$

We know that the electric potential energy of two charges q_1 and q_2 separated by a distance r is

$$U = \frac{kq_1q_2}{r}.$$

We will construct the spherical charge distribution by bringing in successive thin spherical layers of charge from infinity. At each step, we will bring in a charge dq and distribute it in a thin layer from r to $r + dr$ around a charge of q_r as illustrated in the figure.



Because the charge distribution is uniform, we can express the charge contained in a sphere of radius r as

$$q_r = \rho\frac{4}{3}\pi r^3.$$

The differential charge added is given by

$$dq = \rho\left(4\pi r^2\right)dr.$$

At each step, the electric potential energy is increased by

$$dU = \frac{kq_r dq}{r}.$$

We calculate the total electric potential energy by integrating dU from $r = 0$ to $r = a$

$$U = \int_0^a \frac{k\left(\rho\frac{4}{3}\pi r^3\right)\left(\rho\left(4\pi r^2\right)\right)}{r}dr = k\frac{16}{3}\rho^2\pi^2\int_0^a r^4 = k\frac{16}{15}\rho^2\pi^2 a^5.$$

Putting in our expression for the charge density gives us

$$U = k\frac{16}{15}\left(\frac{3q_{\text{total}}}{4\pi a^3}\right)^2\pi^2 a^5$$

$$U = \frac{3}{5}\frac{k{q_{\text{total}}}^2}{a} = \frac{3}{5}\frac{\left(8.99{\cdot}10^9\ \text{N m}^2/\text{C}^2\right)\left(3.00{\cdot}10^{-6}\ \text{C}\right)^2}{0.200\ \text{m}} = 0.243\ \text{J}.$$

DISCUSSION

The electric potential energy of a uniform sphere of charge scales with the total charge squared and the inverse of the radius of the spherical distribution.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- The change in the electric potential energy, ΔU, of a point charge moving in an electric field is equal to the negative of the work done on the point charge by the electric field W_{e}: $\Delta U = U_{\mathrm{f}} - U_{\mathrm{i}} = -W_{\mathrm{e}}$.
- The change in electric potential energy, ΔU, is equal to the charge, q, times the change in electric potential, ΔV : $\Delta U = q\Delta V$.
- Equipotential surfaces and equipotential lines represent locations in space that have the same electric potential. Equipotential surfaces are always perpendicular to the electric field lines.
- A surface of a conductor is an equipotential surface.
- The change in electric potential can be determined from the electric field by integrating over the field: $\Delta V = -\int_{\mathrm{i}}^{\mathrm{f}} \overrightarrow{E} \bullet \overrightarrow{ds}$. Setting the potential equal to zero at infinity gives $V = \int_{\mathrm{i}}^{\infty} \overrightarrow{E} \bullet \overrightarrow{ds}$.
- The electric potential due to a point charge, q, at a distance r from the charge is given by $V = \dfrac{\mathrm{kq}}{r}$.
- The electric potential due to a system of n point charges can be expressed as an algebraic sum of the individual potentials: $V = \sum_{i=1}^{n} V_i$.
- The electric field can be determined from gradients of the electric potential in each component direction: $E_x = -\dfrac{\partial V}{\partial x}, \quad E_y = -\dfrac{\partial V}{\partial y}, \quad E_z = -\dfrac{\partial V}{\partial z}$.
- The electric potential energy of a system of two point charges is given by $U = \dfrac{\mathrm{kq}_1 q_2}{r}$.

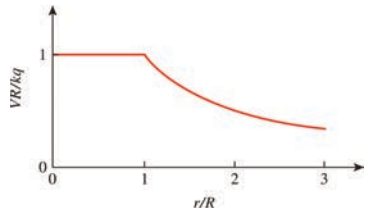
ANSWERS TO SELF-TEST OPPORTUNITIES

23.1 The electric potential along the y-axis is zero.

23.2 $(x, y) = (0, 0)$ corresponds to a saddle point.

23.3 Nothing would change. The electrostatic force is conservative, and for a conservative force, the work is path-independent.

23.4



PROBLEM-SOLVING GUIDELINES

1. A common source of error in calculations is confusing the electric field, $\vec{E}$, the electric potential energy, U, and the electric potential, V. Remember that an electric field is a vector quantity produced by a charge distribution; electric potential energy is a property of the charge distribution; and electric potential is a property of the field. Be sure you know what it is that you're calculating.

2. Be sure to identify the point with respect to which you are calculating the potential energy or potential. Like calculations involving electric fields, calculations involving potentials can use a linear charge distribution (λ), a planar charge distribution (σ), or a volume charge distribution (ρ).

3. Since potential is a scalar, the total potential due to a system of point charges is calculated by simply adding the individual potentials due to all the charges. For a continuous charge distribution, you need to calculate the potential by integrating over the differential charge. Assume that the potential produced by the differential charge is the same as the potential from a point charge!

MULTIPLE-CHOICE QUESTIONS

23.1 A positive charge is released and moves along an electric field line. This charge moves to a position of

a) lower potential and lower potential energy.

b) lower potential and higher potential energy.

c) higher potential and lower potential energy.

d) higher potential and higher potential energy.

23.2 A proton is placed midway between points A and B. The potential at point A is -20 V, and the potential at point B $+20$ V. The potential at the midpoint is 0 V. The proton will

a) remain at rest.

b) move toward point B with constant velocity.

c) accelerate toward point A.

d) accelerate toward point B.

e) move toward point A with constant velocity.

23.3 What would be the consequence of setting the potential at $+100$ V at infinity, rather than taking it to be zero there?

a) Nothing; the field and the potential would have the same values at every finite point.

b) The electric potential would become infinite at every finite point, and the electric field could not be defined.

c) The electric potential everywhere would be 100 V higher, and the electric field would be the same.

d) It would depend on the situation. For example, the potential due to a positive point charge would drop off more slowly with distance, so the magnitude of the electric field would be less.

23.4 In which situation is the electric potential the highest?

a) at a point 1 m from a point charge of 1 C

b) at a point 1 m from the center of a uniformly charged spherical shell with a radius of 0.5 m and a total charge of 1 C

c) at a point 1 m from the center of a uniformly charged rod with a length of 1 m and a total charge of 1 C

d) at a point 2 m from a point charge of 2 C

e) at a point 0.5 m from a point charge of 0.5 C

23.5 The amount of work done to move a positive point charge q on an equipotential surface of 1000 V relative to that done to move the charge on an equipotential surface of 10 V is

a) the same.

b) less.

c) more.

d) dependent on the distance the charge moves.

23.6 A solid conducting sphere of radius R is centered about the origin of an xyz-coordinate system. A total charge Q is distributed uniformly on the surface of the sphere. Assuming, as usual, that the electric potential is zero at an infinite distance, what is the electric potential at the center of the conducting sphere?

a) zero

b) $Q/\varepsilon_0 R$

c) $Q/2\pi\varepsilon_0 R$

d) $Q/4\pi\varepsilon_0 R$

23.7 Which of the following angles between an electric dipole moment and an applied electric field will result in the most stable state?

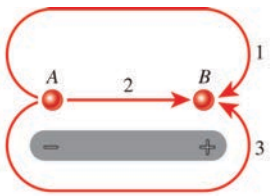
a) 0 rad

b) $\pi/2$ rad

c) π rad

d) The electric dipole moment is not stable under any condition in an applied electric field.

23.8 A positive point charge is to be moved from point A to point B in the vicinity of an electric dipole. Which of the three paths shown in the figure will result in the most work being done by the dipole's electric field on the point charge?



a) path 1

b) path 2

c) path 3

d) The work is the same on all three paths.

23.9 Each of the following pairs of charges are separated by a distance *d*. Which pair has the highest potential energy?

a) $+5$ C and $+3$ C

b) $+5$ C and -3 C

c) -5 C and $+3$ C

d) All pairs have the same potential energy.

23.10 A negatively charged particle revolves in a clockwise direction around a positively charged sphere. The work done on the negatively charged particle by the electric field of the sphere is

a) positive.

b) negative.

c) zero.

23.11 A hollow conducting sphere of radius *R* is centered about the origin of an *xyz*-coordinate system. A total charge *Q* is distributed uniformly over the surface of the sphere. Assuming, as usual, that the electric potential is zero at an infinite distance, what is the electric potential at the center of the sphere?

a) zero

b) $2kQ/R$

c) kQ/R

d) $kQ/2R$

e) $kQ/4R$

23.12 A solid conducting sphere of radius *R* has a charge *Q* evenly distributed over its surface, producing an electric potential V_0 at the surface. How much charge must be added to the sphere to increase the potential at the surface to $2V_0$?

a) $Q/2$

b) Q

c) $2Q$

d) Q^2

e) $2Q^2$

23.13 Which one of the following statements is not true?

a) Equipotential lines are parallel to the electric field lines.

b) Equipotential lines for a point charge are circular.

c) Equipotential surfaces exist for any charge distribution.

d) When a charge moves on an equipotential surface, the work done on the charge is zero.

23.14 If a proton and an alpha particle (composed of two protons and two neutrons) are each accelerated from rest through the same potential difference, how do their resulting speeds compare?

a) The proton has twice the speed of the alpha particle.

b) The proton has the same speed as the alpha particle.

c) The proton has half the speed of the alpha particle.

d) The speed of the proton is $\sqrt{2}$ times the speed of the alpha particle.

e) The speed of the alpha particle is $\sqrt{2}$ times the speed of the proton.

CONCEPTUAL QUESTIONS

23.15 High-voltage power lines are used to transport electricity cross country. These wires are favored resting places for birds. Why don't the birds die when they touch the wires?

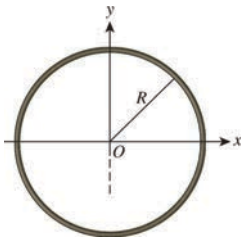
23.16 The Ludington pumped hydro storage facility is an artificial lake located 35 m above Lake Michigan and can hold approximately 100 million cubic meters of water. How does this compare to the storage capacity of the electric truck of Example 23.2?

23.17 Can two equipotential lines cross? Why or why not?

23.18 Why is it important, when soldering connectors onto a piece of electronic circuitry, to leave no pointy protrusions from the solder joints?

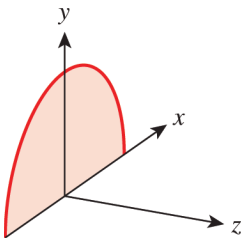
23.19 Using Gauss's Law and the relation between electric potential and electric field, show that the potential outside a uniformly charged sphere is identical to the potential of a point charge placed at the center of the sphere and equal to the total charge of the sphere. What is the potential at the surface of the sphere? How does the potential change if the charge distribution is not uniform but has spherical (radial) symmetry?

23.20 A metal ring has a total charge q and a radius R, as shown in the figure. Without performing any calculations, predict the value of the electric potential and the electric field at the center of the circle.



23.21 Find an integral expression for the electric potential at a point on the z-axis a distance H from a half-disk of radius R (see the figure). The half-disk has uniformly distributed charge over its surface, with charge distribution σ.

23.22 An electron moves away from a proton. Describe how the potential it encounters changes. Describe how its potential energy is changing.



23.23 The electric potential energy of a continuous charge distribution can be found in a way similar to that used for systems of point charges in Section 23.6, by breaking the distribution up into suitable pieces. Find the electric potential energy of an *arbitrary* spherically symmetrical charge distribution, $\rho(r)$. Do ***not*** assume that $\rho(r)$ represents a point charge, that it is constant, that it is piecewise-constant, or that it does or does not end at any finite radius, r. Your expression must cover all possibilities. Your expression may include an integral or integrals that cannot be evaluated without knowing the specific form of $\rho(r)$. (*Hint:* A spherical pearl is built up of thin layers of nacre added one by one.)

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 23.1

23.24 In molecules of gaseous sodium chloride, the chloride ion has one more electron than proton, and the sodium ion has one more proton than electron. These ions are separated by about 0.236 nm. How much work would be required to increase the distance between these ions to 1.00 cm?

•23.25 A metal ball with a mass of $3.00 \cdot 10^{-6}$ kg and a charge of $+5.00$ mC has a kinetic energy of $6.00 \cdot 10^{8}$ J. It is traveling directly at an infinite plane of charge with a charge distribution of $+4.00\ \mathrm{C/m^2}$. If it is currently 1.00 m away from the plane of charge, how close will it come to the plane before stopping?

Section 23.2

23.26 An electron is accelerated from rest through a potential difference of 370. V. What is its final speed?

23.27 How much work would be done by an electric field in moving a proton from a point at a potential of $+180.$ V to a point at a potential of -60.0 V?

23.28 What potential difference is needed to give an alpha particle (composed of 2 protons and 2 neutrons) 200. keV of kinetic energy?

23.29 A proton, initially at rest, is accelerated through a potential difference of 500. V. What is its final velocity?

23.30 A 10.0-V battery is connected to two parallel metal plates placed in a vacuum. An electron is accelerated from rest from the negative plate toward the positive plate.

a) What kinetic energy does the electron have just as it reaches the positive plate?

b) What is the speed of the electron just as it reaches the positive plate?

•**23.31** A proton gun fires a proton from midway between two plates, A and B, which are separated by a distance of 10.0 cm; the proton initially moves at a speed of 150.0 km/s toward plate B. Plate A is kept at zero potential, and plate B at a potential of 400.0 V.

a) Will the proton reach plate B?

b) If not, where will it turn around?

c) With what speed will it hit plate A?

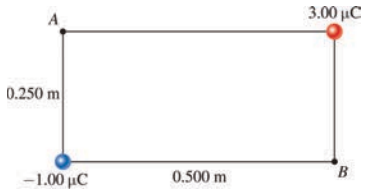
•**23.32** Fully stripped (all electrons removed) sulfur $\left({}^{32}\mathrm{S}\right)$ ions are accelerated from rest in an accelerator that uses a total voltage of $1.00 \cdot 10^{9}$ V. ${}^{32}\mathrm{S}$ has 16 protons and 16 neutrons. The accelerator produces a beam consisting of $6.61 \cdot 10^{12}$ ions per second. This beam of ions is completely stopped in a beam dump. What is the total power the beam dump has to absorb?

Section 23.4

23.33 Two point charges are located at two corners of a rectangle, as shown in the figure.

a) What is the electric potential at point A?

b) What is the potential difference between points A and B?

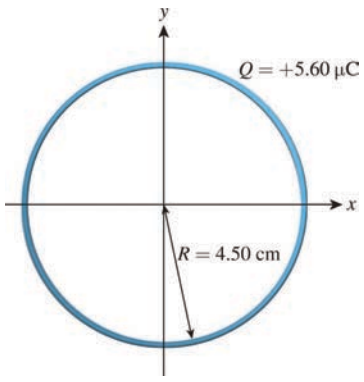


23.34 Four identical point charges $(+1.61\ \text{nC})$ are placed at the corners of a rectangle, which measures 3.00 m by 5.00 m. If the electric potential is taken to be zero at infinity, what is the potential at the geometric center of this rectangle?

23.35 If a Van de Graaff generator has an electric potential of $1.00 \cdot 10^5$ V and a diameter of 20.0 cm, find how many more protons than electrons are on its surface.

23.36 One issue encountered during the exploration of Mars has been the accumulation of static charge on land-roving vehicles, resulting in a potential of 100. V or more. Calculate how much charge must be placed on the surface of a sphere of radius 1.00 m for the electric potential just above the surface to be 100. V. Assume that the charge is uniformly distributed.

23.37 A charge $Q = +5.60\ \mu\text{C}$ is uniformly distributed on a thin cylindrical plastic shell. The radius, R, of the shell is 4.50 cm. Calculate the electric potential at the origin of the xy-coordinate system shown in the figure. Assume that the electric potential is zero at points infinitely far away from the origin.



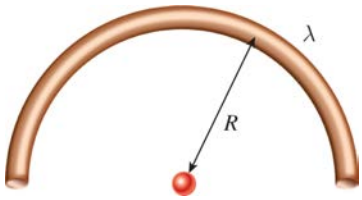
23.38 A hollow spherical conductor with a 5.00- cm radius has a surface charge of 8.00 nC.

a) What is the potential 8.00 cm from the center of the sphere?

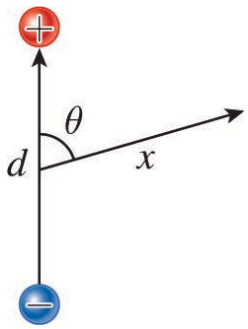
b) What is the potential 3.00 cm from the center of the sphere?

c) What is the potential at the center of the sphere?

23.39 Find the potential at the center of curvature of the (thin) wire shown in the figure. It has a (uniformly distributed) charge per unit length of $\lambda = 3.00 \cdot 10^{-8}$ C/m and a radius of curvature of $R = 8.00$ cm.



•**23.40** Consider a dipole with charge q and separation d. What is the potential a distance x from the center of this dipole at an angle θ with respect to the dipole axis, as shown in the figure?



•**23.41** A spherical water drop 50.0 μm in diameter has a uniformly distributed charge of +20.0 pC. Find (a) the potential at its surface and (b) the potential at its center.

•**23.42** Consider an electron in the ground state of the hydrogen atom, separated from the proton by a distance of 0.0529 nm.

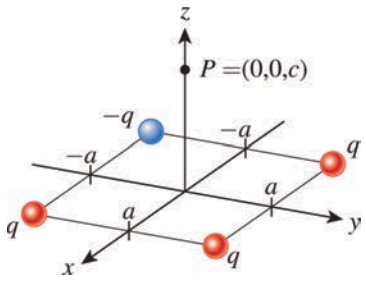
a) Viewing the electron as a satellite orbiting the proton in the electric potential, calculate the speed of the electron in its orbit.

b) Calculate an effective escape speed for the electron.

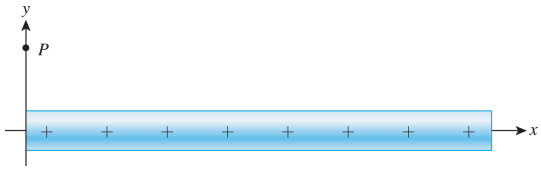
c) Calculate the energy of an electron having this speed, and from it determine the energy that must be given to the electron to ionize the hydrogen atom.

•**23.43** Four point charges are arranged in a square with side length $2a$, where $a = 2.70$ cm. The charges have the same magnitude, 1.50 nC; three of them are positive and one is negative as shown in the figure. What is the value

of the electric potential generated by these four point charges at point $P = (0, 0, c)$, where $c = 4.10$ cm?



•**23.44** The plastic rod of length L shown in the figure has the nonuniform linear charge distribution $\lambda = cx$, where c is a positive constant. Find an expression for the electric potential at point P on the y-axis, a distance y from one end of the rod.

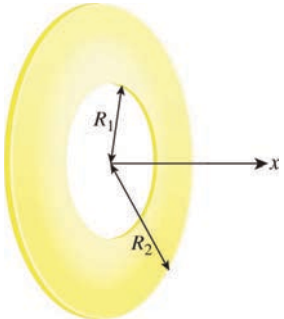


•• **23.45** An electric field varies in space according to this equation: $\vec{E} = E_0 x e^{-x}\,\hat{x}$.

a) For what value of x does the electric field have its largest value, $x_{\max}$?

b) What is the potential difference between the points at $x = 0$ and $x = x_{\max}$?

•• **23.46** Derive an expression for electric potential along the axis (the x-axis) of a disk with a hole in the center, as shown in the figure, where R_1 and R_2 are the inner and outer radii of the disk. What would the potential be if $R_1 = 0$?



Section 23.5

23.47 An electric field is established in a nonuniform rod. A voltmeter is used to measure the potential difference between the left end of the rod and a point a distance x from the left end. The process is repeated, and it is found that the data are described by the relationship $\Delta V = 270.x^2$, where ΔV has the units $\mathrm{V/m^2}$. What is the x-component of the electric field at a point 13.0 cm from the left end?

23.48 Two parallel plates are held at potentials of $+200.0$ V and -100.0 V. The plates are separated by 1.00 cm.

a) Find the electric field between the plates.

b) An electron is initially placed halfway between the plates. Find its kinetic energy when it hits the positive plate.

23.49 A 2.50- mg dust particle with a charge of 1.00 μC falls at a point $x = 2.00$ m in a region where the electric potential varies according to $V(x) = \left(2.00\ \mathrm{V/m^2}\right)x^2 - \left(3.00\ \mathrm{V/m^3}\right)x^3$. With what acceleration will the particle start moving after it touches down?

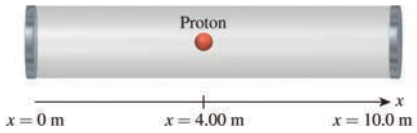
23.50 The electric potential in a volume of space is given by $V(x, y, z) = x^2 + xy^2 + yz$. Determine the electric field in this region at the coordinate (3,4,5).

•**23.51** The electric potential inside a 10.0- m-long linear particle accelerator is given by $V = \left(3000 - 5x^2/\mathrm{m^2}\right)$ V, where x is the distance from the left plate along the accelerator tube, as shown in the figure.

a) Determine an expression for the electric field along the accelerator tube.

b) A proton is released (from rest) at $x = 4.00$ m. Calculate the acceleration of the proton just after it is released.

c) What is the impact speed of the proton when (and if) it collides with the plate?



•**23.52** An infinite plane of charge has a uniform charge distribution of $+4.00\ \mathrm{nC/m^2}$ and is located in the yz-plane at $x = 0$. A $+11.0$-nC fixed point charge is located at $x = +2.00$ m.

a) Find the electric potential $V(x)$ on the x-axis from $0 < x < +2.00$ m.

b) At what position(s) on the x-axis between $x = 0$ and $x = +2.00$ m is the electric potential a minimum?

c) Where on the x-axis between $x = 0$ m and $x = +2.00$ m could a positive point charge be placed and not move?

•23.53 Use $V = \dfrac{kq}{r}$, $E_x = -\dfrac{\partial V}{\partial x}$, $E_y = -\dfrac{\partial V}{\partial y}$, and $E_z = -\dfrac{\partial V}{\partial z}$ to derive the expression for the electric field of a point charge, q.

•23.54 Show that an electron in a one-dimensional electrical potential, $V(x) = Ax^2$, where the constant A is a positive real number, will execute simple harmonic motion about the origin. What is the period of that motion?

•• 23.55 The electric field, $\vec{E}\left(\vec{r}\right)$, and the electric potential, $V\left(\vec{r}\right)$, are calculated from the charge distribution, $\rho\left(\vec{r}\right)$, by integrating Coulomb's Law and then the electric field. In the other direction, the field and the charge distribution are determined from the potential by suitably differentiating. Suppose the electric potential in a large region of space is given by $V(r) = V_0 \exp\left(-r^2/a^2\right)$, where V_0 and a are constants and $r = \sqrt{x^2 + y^2 + z^2}$ is the distance from the origin.

a) Find the electric field $\vec{E}\left(\vec{r}\right)$ in this region.

b) Determine the charge density, $\rho\left(\vec{r}\right)$, in this region, which gives rise to the potential and field.

c) Find the total charge in this region.

d) Roughly sketch the charge distribution that could give rise to such an electric field.

•• 23.56 The electron beam emitted by an electron gun is controlled (steered) with two sets of parallel conducting plates: a horizontal set to control the vertical motion of the beam, and a vertical set to control the horizontal motion of the beam. The beam is emitted with an initial velocity of $2.00 \cdot 10^7$ m/s. The width of the plates is $d = 5.00$ cm, the separation between the plates is $D = 4.00$ cm, and the distance between the edge of the plates and a target screen is $L = 40.0$ cm. In the absence of any applied voltage, the electron beam hits the origin of the xy-coordinate system on the observation screen. What voltages need to be applied to the two sets of plates for the electron beam to hit a target placed on the observation screen at coordinates $(x, y) = (0\text{ cm}, 8.00\text{ cm})$?

Section 23.6

23.57 Nuclear fusion reactions require that positively charged nuclei be brought into close proximity, against the electrostatic repulsion. As a simple example, suppose a proton is fired at a second, stationary proton from a large distance away. What kinetic energy must be given to the moving proton to get it to come within $1.00 \cdot 10^{-15}$ m of the target? Assume that there is a head-on collision and that the target is fixed in place.

23.58 Fission of a uranium nucleus (containing 92 protons) produces a barium nucleus (56 protons) and a krypton nucleus (36 protons). The fragments fly apart as a result of electrostatic repulsion; they ultimately emerge with a total of 200. MeV of kinetic energy. Use this information to estimate the size of the uranium nucleus; that is, treat the barium and krypton nuclei as point charges and calculate the separation between them at the start of the process.

23.59 A deuterium ion and a tritium ion each have charge $+e$. What work has to be done on the deuterium ion in order to bring it within $1.00 \cdot 10^{-14}$ m of the tritium ion? This is the distance within which the two ions can fuse, as a result of strong nuclear interactions that overcome electrostatic repulsion, to produce a helium-5 nucleus. Express the work in electron-volts.

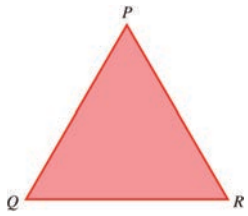
•**23.60** Three charges, q_1, q_2, and q_3, are located at the corners of an equilateral triangle with side length of 1.20 m. Find the work done in each of the following cases:

a) to bring the first particle, $q_1 = 1.00$ pC, to P from infinity

b) to bring the second particle, $q_2 = 2.00$ pC, to Q from infinity

c) to bring the last particle, $q_3 = 3.00$ pC, to R from infinity

d) Find the total potential energy stored in the final configuration of q_1, q_2, and q_3.



•**23.61** Two metal balls of mass $m_1 = 5.00\ g$ (diameter $= 5.00$ mm) and $m_2 = 8.00\ g$ (diameter $= 8.00$ mm) have positive charges of $q_1 = 5.00$ nC and $q_2 = 8.00$ nC, respectively. A force holds them in place so that their centers are separated by 8.00 mm. What will their velocities be after the force has been removed and they are separated by a large distance?

Additional Exercises

23.62 Two protons at rest and separated by 1.00 mm are released simultaneously. What is the speed of either at the instant when the two are 10.0 mm apart?

23.63 A 12- V battery is connected between a hollow metal sphere with a radius of 1 m and a ground, as shown in the figure. What are the electric field and the electric potential inside the hollow metal sphere?

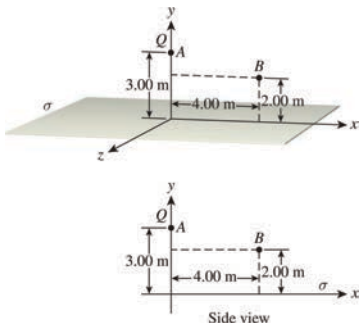
23.64 A solid metal ball with a radius of 3.00 m has a charge of 4.00 mC. If the electric potential is zero far away from the ball, what is the electric potential at each of the following positions?

a) at $r = 0$ m, the center of the ball

b) at $r = 3.00$ m, on the surface of the ball

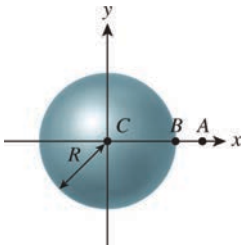
c) at $r = 5.00$ m

23.65 An insulating sheet in the *xz*-plane is uniformly charged with a charge distribution $\sigma = 3.50 \cdot 10^{-6}\ \mathrm{C/m^2}$. What is the change in potential when a charge of $Q = 1.25\ \mu\mathrm{C}$ is moved from position *A* to position *B* in the figure?



23.66 Suppose that an electron inside a cathode ray tube starts from rest and is accelerated by the tube's voltage of 21.9 kV. What is the speed (in km/s) with which the electron $\left(\text{mass} = 9.11 \cdot 10^{-31}\ \text{kg}\right)$ hits the screen of the tube?

23.67 A conducting solid sphere (radius of $R = 18.0$ cm, charge of $q = 6.10 \cdot 10^{-6}$ C is shown in the figure. Calculate the electric potential at a point 24.0 cm from the center (point *A*), a point on the surface (point *B*), and at the center of the sphere (point *C*). Assume that the electric potential is zero at points infinitely far away from the origin of the coordinate system.



23.68 A classroom Van de Graaff generator accumulates a charge of $1.00 \cdot 10^{-6}$ C on its spherical conductor, which has a radius of 10.0 cm and stands on an insulating column. Neglecting the effects of the generator base or any other objects or fields, find the potential at the surface of the sphere. Assume that the potential is zero at infinity.

23.69 A Van de Graaff generator has a spherical conductor with a radius of 25.0 cm. It can produce a maximum electric field of $2.00 \cdot 10^{6}$ V/m. What are the maximum voltage and charge that it can hold?

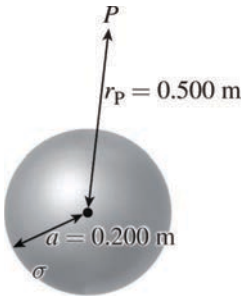
23.70 A proton with a speed of $1.23 \cdot 10^{4}$ m/s is moving from infinity directly toward a second proton. Assuming that the second proton is fixed in place, find the position where the moving proton stops momentarily before turning around.

23.71 Two metal spheres of radii $r_1 = 10.0$ cm and $r_2 = 20.0$ cm, respectively, have been positively charged so that each has a total charge of 100. μC.

a) What is the ratio of their surface charge distributions?

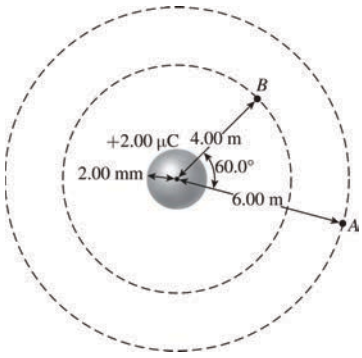
b) If the two spheres are connected by a copper wire, how much charge flows through the wire before the system reaches equilibrium?

23.72 The solid metal sphere of radius $a = 0.200$ m shown in the figure has a surface charge distribution of σ. The potential difference between the surface of the sphere and a point P at a distance $r_{\mathrm{p}} = 0.500$ m from the center of the sphere is $\Delta V = V_{\mathrm{surface}} - \mathrm{V_p} = +4\pi\mathrm{V} = +12.566$ V. Determine the value of σ.



23.73 A particle with a charge of $+5.00\ \mu\text{C}$ is released from rest at a point on the x-axis, where $x = 0.100\ \text{m}$. It begins to move as a result of the presence of a $+9.00$ -μC charge that remains fixed at the origin. What is the kinetic energy of the particle at the instant it passes the point $x = 0.200\ \text{m}$?

23.74 The sphere in the figure has a radius of 2.00 mm and carries a $+2.00$ -μC charge uniformly distributed throughout its volume. What is the potential difference, $V_\text{B} - V_\text{A}$, if the angle between the two radii to points A and B is 60.0°? Is the potential difference dependent on the angle? Would the answer be the same if the charge distribution had an angular dependence, $\rho = \rho(\theta)$?



•**23.75** Two metallic spheres have radii of 10.0 cm and 5.00 cm, respectively. The magnitude of the electric field on the surface of each sphere is 3600. V/m. The two spheres are then connected by a long, thin metal wire. Determine the magnitude of the electric field on the surface of each sphere when they are connected.

•**23.76** A ring with charge Q and radius R is in the yz-plane and centered on the origin. What is the electric potential a distance x above the center of the ring? Derive the electric field from this relationship.

•**23.77** A charge of 0.681 nC is placed at $x = 0$. Another charge of 0.167 nC is placed at $x_1 = 10.9\ \text{cm}$ on the x-axis.

a) What is the combined electric potential of these two charges at $x = 20.1\ \text{cm}$, also on the x-axis?

b) At which point(s) on the x-axis does this potential have a minimum?

•**23.78** A point charge of $+2.00\ \mu\text{C}$ is located at (2.50 m,3.20 m). A second point charge of $-3.10\ \mu\text{C}$ is located at $(-2.10\ \text{m}, 1.00\ \text{m})$.

a) What is the electric potential at the origin?

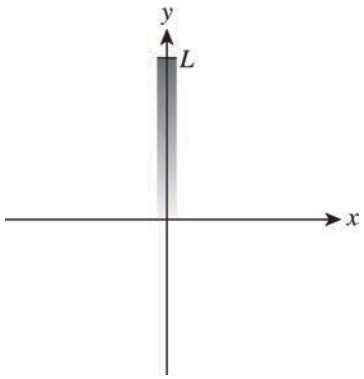
b) Along a line passing through both point charges, at what point(s) is (are) the electric potential(s) equal to zero?

•**23.79** A total charge of $Q = 4.20 \cdot 10^{-6}\ \text{C}$ is placed on a conducting sphere (sphere 1) of radius $R = 0.400\ \text{m}$.

a) What is the electric potential, V_1, at the surface of sphere 1 assuming that the potential infinitely far away from it is zero? (*Hint:* What is the change in potential if a charge is brought from infinitely far away, where $V(\infty) = 0$, to the surface of the sphere?)

b) A second conducting sphere (sphere 2) of radius $r = 0.100$ m with an initial net charge of zero ($q = 0$) is connected to sphere 1 using a long thin metal wire. How much charge flows from sphere 1 to sphere 2 to bring them into equilibrium? What are the electric fields at the surfaces of the two spheres at equilibrium?

•**23.80** A thin line of charge is aligned along the positive y-axis from $0 \leq y \leq L$, with $L = 4.0$ cm. The charge is not uniformly distributed but has a charge per unit length of $\lambda = Ay$, with $A = 8.00 \cdot 10^{-7}$ C/m^2. Assuming that the electric potential is zero at infinite distance, find the electric potential at a point on the x-axis as a function of x. Give the value of the electric potential at $x = 3.00$ cm.



•**23.81** Two fixed point charges are on the x-axis. A charge of -3.00 mC is located at $x = +2.00$ m and a charge of $+5.00$ mC is located at $x = -4.00$ m.

a) Find the electric potential, $V(x)$, for an arbitrary point on the x-axis.

b) At what position(s) on the x-axis is $V(x) = 0$?

c) Find $E(x)$ for an arbitrary point on the x-axis.

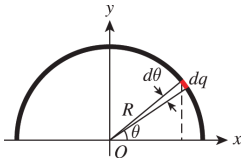
•**23.82** One of the greatest physics experiments in history measured the charge-to-mass ratio of an electron, q/m. If a uniform potential difference is created between two plates, atomized particles—each with an integral amount of charge—can be suspended in space. The assumption is that the particles of unknown mass, M, contain a net number, n, of electrons of mass m and charge q. For a plate separation of d, what is the potential difference necessary to suspend a particle of mass M containing n net electrons? What is the acceleration of the particle if the voltage is cut in half? What is the acceleration of the particle if the voltage is doubled?

•**23.83** A uniform linear charge distribution of total positive charge Q has the shape of a half-circle of radius R, as shown in the figure.

a) Without performing any calculations, predict the electric potential produced by this linear charge distribution at point *O*.

b) Confirm, through direct calculations, your prediction of part (a).

c) Make a similar prediction for the electric field.



•• **23.84** A point charge Q is placed a distance R from the center of a conducting sphere of radius a, with $R > a$ (the point charge is outside the sphere). The sphere is grounded, that is, connected to a distant, unlimited source and/or sink of charge at zero potential. (Neither the distant ground nor the connection directly affects the electric field in the vicinity of the charge and sphere.) As a result, the sphere acquires a charge opposite in sign to Q, and the point charge experiences an attractive force toward the sphere.

a) Remarkably, the electric field *outside the sphere* is the same as would be produced by the point charge Q plus an imaginary *mirror-image* point charge q, with magnitude and location that make the set of points corresponding to the surface of the sphere an equipotential of potential zero. That is, the imaginary point charge produces the same field contribution outside the sphere as the actual surface charge on the sphere. Calculate the value and location of q. (*Hint:* By symmetry, q must lie somewhere on the axis that passes through the center of the sphere and the location of Q.)

b) Calculate the force exerted on point charge Q and directed toward the sphere, in terms of the original quantities Q, R, and a.

c) Determine the actual nonuniform surface charge distribution on the conducting sphere.

MULTI-VERSION EXERCISES

23.85 A uniform spherical charge distribution with radius 0.145 m contains 50. 0 μC of charge. The charge is split into two spherical charge distributions, each with the same charge density as the original sphere of charge. These two charge distributions are placed far apart. What is the change in electric potential energy?

23.86 Two uniform spherical charge distributions, originally located far apart, each have the same radius and the same charge. These two charge distributions are combined into one spherical charge distribution with a radius of 0.105 m and a total charge of 15. 0 μC with the same charge density as the two smaller spherical charge distributions. What is the change in electric potential energy?

23.87 A uniform spherical charge distribution contains 20. 0 μC of charge. The charge is split into two spherical charge distributions, each with the same charge density as the original sphere of charge. These two charge distributions are placed far apart. The change in electric potential energy is -5.00 J. What is the radius of the initial spherical charge distribution?

23.88 A solid conducting sphere of radius $R = 1.895$ m is charged, and the magnitude of the electric field at the surface of the sphere is $3.165 \cdot 10^5$ V/m. What is the electric potential 29.81 cm from the surface of the sphere?

23.89 A solid conducting sphere of radius R is charged, and the magnitude of the electric field at the surface of the sphere is $3.269 \cdot 10^5$ V/m. The electric potential 32.37 cm from the surface of the sphere is $2.843 \cdot 10^5$ V. What is the radius, R, of the sphere?

23.90 A solid conducting sphere of radius $R = 1.351$ m is charged, and the magnitude of the electric potential 34.95 cm from the surface of the sphere is $3.618 \cdot 10^5$ V. What is the magnitude of the electric field at the surface of the sphere?

Multi-Version Exercises 772

Touch screens, such as the one shown in Figure 24.1, have become very common, found on everything from computer screens to cell phones to voting machines. They work in several ways, one of which involves using a property of conductors called *capacitance,* which we'll study in this chapter. Capacitance appears whenever two conductors—any two conductors—are separated by a small distance. The contact of a finger with a touch screen causes a change in capacitance that can be detected.

FIGURE 24.1 Interacting with the touch screen of an iPad.

W. Bauer and G. D. Westfall

Capacitors have the very useful capability of storing electric charge and then releasing it very quickly. Thus, they are useful in camera flash attachments, cardiac defibrillators, and even

experimental fusion reactors—anything that needs a large electric charge delivered quickly. Most circuits of any kind contain at least one capacitor. However, capacitance has a downside. It can also appear where it's not wanted, for example, between neighboring conductors in a tiny electronics circuit, where it can create "cross talk"—unwanted interference between circuit components.

Because capacitors are one of the basic elements of electric circuits, this chapter examines how they function in simple circuits. The next two chapters will cover additional basic circuit elements and their uses.

WHAT WE WILL LEARN

- Capacitance is the ability to store electric charge.
- Capacitors usually consist of two separated conductors or conducting plates.
- A capacitor can store charge on one plate, and there is typically an equal and opposite charge on the other plate.
- The capacitance of a capacitor is the charge stored on the plates divided by the resulting electric potential difference.
- A capacitor can store electric potential energy.
- A common type of capacitor is the parallel plate capacitor, consisting of two flat parallel conducting plates.
- The capacitance of a given capacitor depends on its geometry.
- In a circuit, capacitors wired in parallel or in series can be replaced by an equivalent capacitance.
- The capacitance of a given capacitor is increased when a dielectric material is placed between the plates.
- A dielectric material reduces the electric field between the plates of a capacitor as a result of the alignment of molecular dipole moments in the dielectric material.

24.1 Capacitance

Figure 24.2 shows that capacitors come in a variety of sizes and shapes. In general, a **capacitor** consists of two separated conductors, which are usually called *plates* even if they are not simple planes. If we take apart one of these capacitors, we might find two sheets of metal foil separated by an insulating layer of Mylar, as shown in Figure 24.3. The sandwiched layers of metal foil and Mylar can be rolled up with another insulating layer into a compact form that does not resemble two parallel conductors, as shown in Figure 24.4. This technique produces capacitors with some of the physical formats shown in Figure 24.2. The insulating layer between the two metal foils plays a crucial role in the characteristics of the capacitor.

FIGURE 24.2 Some representative types of capacitors.

W. Bauer and G. D. Westfall

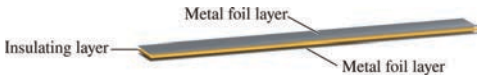

FIGURE 24.3 Two sheets of metal foil separated by an insulating layer.

FIGURE 24.4 The metal foil and Mylar sandwich shown in Figure 24.3 can be rolled up with an insulating layer to produce a capacitor with a compact geometry.

To study the properties of capacitors, we'll assume a convenient geometry and then generalize the results. Figure 24.5 shows a **parallel plate capacitor,** which consists of two parallel conducting plates, each with area A, separated by a distance, d, and assumed to be in a vacuum. The capacitor is charged by placing a charge of $+q$ on one plate and a charge of $-q$ on the other plate. (It is not necessary to put exactly opposite charges onto the two plates of the capacitor to charge it; any difference in charge will do. But, for practical purposes, the overall device should remain neutral, and this requires charges of equal magnitude and opposite sign on the two plates.) Because the plates are conductors, they are equipotential surfaces; thus, the electrons on the plates will distribute themselves uniformly over the surfaces.

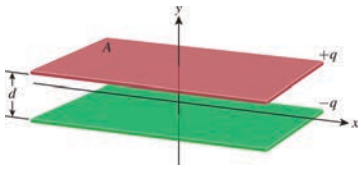

FIGURE 24.5
Parallel plate capacitor consisting of two conducting plates, each having area *A,* separated by a distance *d*.

Let's apply the results obtained in Chapter 23 to determine the electric potential and electric field for the parallel plate capacitor. (In principle, we could do this by calculating the electric potential and electric field for continuous charge distributions. However, for this physical configuration we would need to use a computer to provide the solution.) Let's place the origin of the coordinate system in the middle between the two plates, with the x-axis aligned with the two plates. Figure 24.6 shows a three-dimensional plot of the electric potential, $V(x,y)$, in the xy-plane, similar to the plots in Chapter 23.

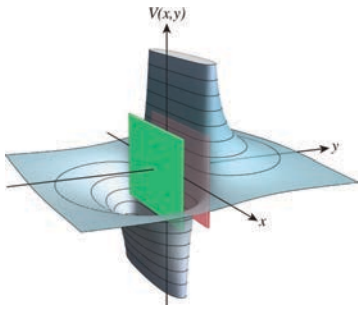

FIGURE 24.6
Electric potential in the xy-plane for the two oppositely charged parallel plates (superimposed) of Figure 24.5.

The potential in Figure 24.6 has a very steep (and approximately linear) drop between the two plates and a more gradual drop outside the plates. This means that the electric field can be expected to be strongest between the plates and weaker outside. Figure 24.7a presents a contour plot of the electric potential shown in Figure 24.6 for the two parallel plates. Negative potential values are shaded in green, and positive values in pink. The equipotential lines, which are the lines where the three-dimensional equipotential surfaces intersect the *xy*-plane, displayed in Figure 24.6 are also shown in this plot, as are representations of the two plates. Note that the equipotential lines between the two plates are all parallel to each other and equally spaced.

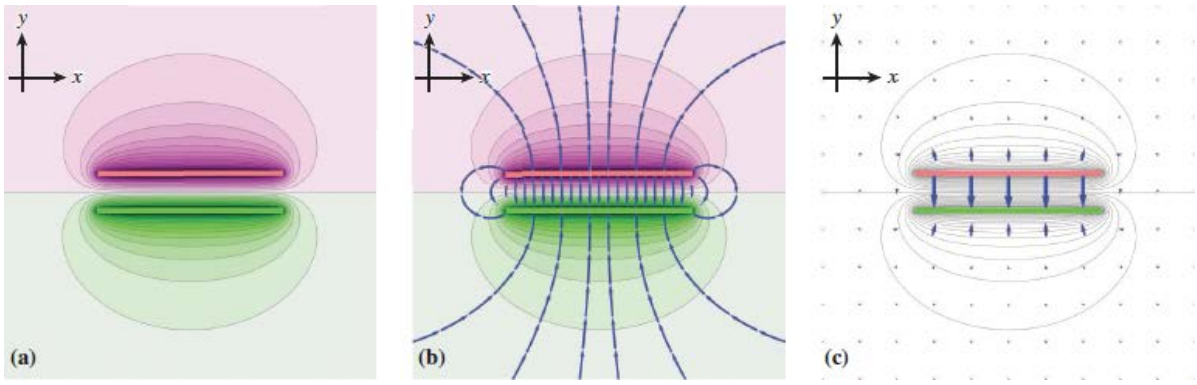

FIGURE 24.7 (a) Two-dimensional contour plot of the same potential as in Figure 24.6. (b) Contour plot with electric field lines superimposed. (c) Electric field strength at regularly spaced points in the *xy*-plane represented by the sizes of the arrows.

In Figure 24.7b, the electric field lines have been added to the contour plot. The electric field is determined using $\vec{E}\left(\vec{r}\right) = -\vec{\nabla}V\left(\vec{r}\right)$, introduced in Chapter 23. Far away from the two plates, the electric field looks very similar to that generated by a dipole composed of two point charges. It is easy to see that the electric field lines are perpendicular to the potential contour lines (which represent the equipotential surfaces!) everywhere in space.

But the electric field lines in Figure 24.7b do not convey adequate information about the magnitude of the electric field. Another representation of the electric field, in Figure 24.7c, displays the electric field vectors at regularly spaced grid points in the *xy*-plane. (The contour shading of the potential has been removed to reduce visual clutter.) In this plot, the field strength at each point of the grid is proportional to the size of the arrow at that point. You can clearly see that the electric field between the two plates is perpendicular to the plates and much larger in magnitude than the field outside the plates. The field in the space outside the plates is called the *fringe field*. If the plates are moved closer together, the electric field between the plates remains the same, while the fringe field is reduced.

The potential difference, ΔV, between the two parallel plates of the capacitor is proportional to the amount of charge on the plates. The proportionality constant is the **capacitance, *C,*** of the device, defined as

$$C = \left| \frac{q}{\Delta V} \right|. \qquad \textbf{(24.1)}$$

The capacitance of a device depends on the area of the plates and the distance between them but not on the charge or the potential difference. (This will be shown for this and other geometries in the following sections.) By definition, the capacitance is a positive number. It tells how much charge is required to produce a given potential difference between the plates. The larger the capacitance, the more charge is required to produce a given potential difference. (Note that it is a common practice to use *V,* not ΔV, to represent potential difference. Be sure you understand when *V* is being used for potential and when it is being used for potential difference.)

Equation 24.1, the definition of capacitance, can be rewritten in this commonly used form:

$$q = C\Delta V.$$

Equation 24.1 indicates that the units of capacitance are the units of charge divided by the units of potential, or coulombs per volt. A new unit was assigned to capacitance, named after British physicist Michael Faraday (1791–1867). This unit is called the **farad (F)**:

$$1\ \text{F} = \frac{1\ \text{C}}{1\ \text{V}}. \tag{24.2}$$

One farad represents a very large capacitance. Typically, capacitors have a capacitance in the range from $1\ \mu\text{F} = 1 \cdot 10^{-6}\text{F}$ to $1\ \text{pF} = 1 \cdot 10^{-12}\text{F}$.

With the definition of the farad, we can write the electric permittivity of free space, ϵ_0 (introduced in Chapter 21), as $8.85 \cdot 10^{-12}\ \text{F/m}$.

24.2 Circuits

The next few chapters will introduce more and more complex and interesting circuits. So let's look at what a circuit is, in general.

An **electric circuit** consists of simple wires or other conducting paths that connect circuit elements. These circuit elements can be capacitors, which we'll examine in depth in this chapter. Other important circuit elements are resistors (introduced in Chapter 25), the voltmeter and the ammeter (introduced in Chapter 26), transistors (which can be used as on-off switches or as amplifiers; also covered in Chapter 26), and inductors (discussed in Chapter 29).

Circuits usually need some kind of power, which can be provided either by a battery or by an AC (alternating current) power source. The concept of a battery, a device that maintains a potential difference across its terminals through chemical reactions, was introduced in Chapter 23; for the purpose of a circuit, it can be viewed simply as an external source of electrostatic potential difference, something that delivers a fixed potential difference (which is commonly called *voltage*). An AC power source can produce the same result with a specially designed circuit that maintains a fixed potential difference. Chapter 29 on induction and Chapter 30 on electromagnetic oscillations and current will discuss AC power sources in more detail. Figure 24.8 shows the symbols for circuit elements, which are used throughout this and the following chapters.

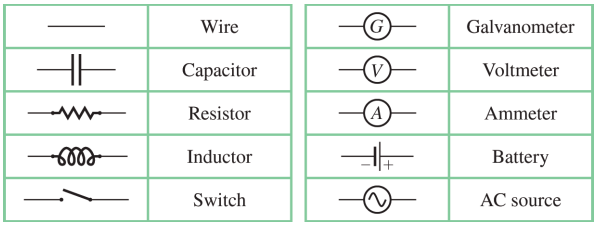

FIGURE 24.8 Commonly used symbols for circuit elements.

Charging and Discharging a Capacitor

A capacitor is charged by connecting it to a battery or to a constant-voltage power supply to create a circuit. Charge flows to the capacitor from the battery or power supply until the potential difference across the capacitor is the same as the supplied voltage. If the capacitor is disconnected, it retains its charge and potential difference. A real capacitor is subject to charge leaking away over time. However, in this chapter, we'll assume that an isolated capacitor retains its charge and potential difference indefinitely.

Figure 24.9 illustrates this charging process with a circuit diagram. In this diagram, the lines represent conducting wires. The battery (power supply) is represented by the symbol $\dashv\vdash$, which is labeled with plus and minus signs indicating the potential assignments of the terminals and with the potential difference, V. The capacitor is represented by the symbol $\perp\!\!\!\perp$, which is labeled C. This circuit also contains a switch. When the switch is between positions *a* and *b,* the battery is not connected and the circuit is open. When the switch is at position *a,* the circuit is closed; the battery is connected across the capacitor, and the capacitor charges. When the switch is at position *b,* the circuit is closed in a different manner. The battery is removed from the circuit, the two plates of the capacitor are connected to each other, and charge can flow from one plate to the other through the wire, which now forms a physical connection between the plates. When the charge has dissipated on the two plates, the potential difference between the plates drops to zero, and the capacitor is said to be discharged. (Charging and discharging of a capacitor are covered in quantitative detail in Chapter 26.)

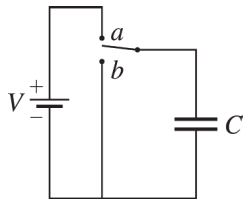

FIGURE 24.9 Simple circuit used for charging and discharging a capacitor.

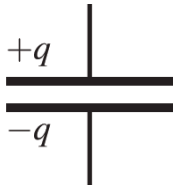
Concept Check 24.1

The figure shows a charged capacitor. What is the net charge on the capacitor?



a) $(+q) + (-q) = 0$

b) $|+q| + |-q| = 0$

c) $|+q| + |-q| = 2q$

d) $(+q) + (-q) = 2q$

e) q

24.3 Parallel Plate Capacitor and Other Types of Capacitors

Section 24.1 discussed the general features of the electric potential and the electric field of two parallel plates of opposite charge. This section examines how to determine the electric field strength between the plates and the potential difference between the two plates. Let's consider an ideal parallel plate capacitor in the form of a pair of parallel conducting plates in a vacuum with charge $+q$ on one plate and charge $-q$ on the other plate (Figure 24.10). (This ideal parallel plate capacitor has very large plates, that are very close together, much closer than shown in Figure 24.10. This configuration allows us to neglect the fringe field, the small electric field outside the space between the plates, shown in Figure 24.7c.) When the plates are charged, the upper plate has charge $+q$ and the lower plate has charge $-q$ The electric field between the two plates points from the positively charged plate downward toward the negatively charged plate. The field near the ends of the plates, the fringe field (compare Figure 24.7), can be neglected; that is, we can assume that the electric field is constant, with magnitude *E,* everywhere between the plates and zero elsewhere. The electric field is always perpendicular to the surface of the two parallel plates.

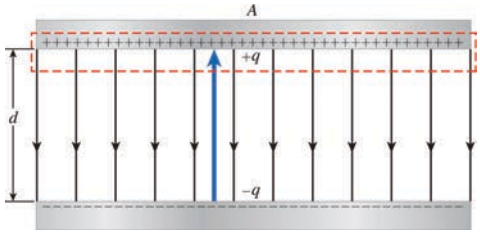


FIGURE 24.10 Side view of a parallel plate capacitor consisting of two plates with the same surface area, *A*, and separated by a small distance, *d*. The red dashed line is a Gaussian surface. The black arrows pointing downward represent the electric field. The blue arrow indicates an integration path.

The electric field can be found using Gauss's Law:

$$\oiint \vec{E} \bullet d\vec{A} = \frac{q}{\epsilon_0}. \qquad \textbf{(24.3)}$$

How do we evaluate the integral over the Gaussian surface (whose cross section is outlined by a red dashed line in Figure 24.10)? We add the contributions from the top, the bottom, and the sides. The sides of the Gaussian surface are very small, so we can ignore the contributions from the fringe field. The top surface passes through the conductor, where the electric field is zero (remember shielding; see Chapter 22). This leaves only the bottom part of the Gaussian surface. The electric field vectors point straight down and are perpendicular to the conductor surfaces. The vector normal to the surface, $d\vec{A}$, points in the same direction and is thus parallel to $\vec{E}$. Therefore, the scalar product is $\vec{E} \bullet d\vec{A} = EdA \cos 0^\circ = E\, dA$. For the integral over the Gaussian surface, we then have

$$\oiint \vec{E} \bullet d\vec{A} = \iint_{\text{bottom}} EdA = E \iint_{\text{bottom}} dA = EA,$$

where A is the area of the plate. In other words, for the parallel plate capacitor, Gauss's Law yields

$$EA = \frac{q}{\epsilon_0}, \tag{24.4}$$

where A is the surface area of the positively charged plate and q is the magnitude of the charge on the positively charged plate. The charge on each plate resides entirely on the inside surface because of the presence of opposite charge on the other plate.

The electric potential difference across the two plates in terms of the electric field is

$$\Delta V = -\int_1^{\text{f}} \vec{E} \bullet d\vec{s}. \tag{24.5}$$

The path of integration is chosen to be from the negatively charged plate to the positively charged plate, along the blue arrow in Figure 24.10. Since the electric field is antiparallel to this integration path (see Figure 24.10), the scalar product is $\vec{E} \bullet d\vec{s} = E\,ds \cos 180^\circ = -Eds$. Thus, the integral in equation 24.5 reduces to

$$\Delta V = Ed = \frac{qd}{\epsilon_0 A},$$

where we used equation 24.4 to relate the electric field to the charge. Combining this expression for the potential difference and the definition of capacitance (equation 24.1) gives an expression for the capacitance of a parallel plate capacitor:

$$C = \left| \frac{q}{\Delta V} \right| = \frac{\epsilon_0 A}{d}. \qquad \textbf{(24.6)}$$

Note that the capacitance of a parallel plate capacitor depends only on the area of the plates and the distance between the plates. In other words, only the geometry of a capacitor affects its capacitance. The amount of charge on the capacitor or the potential difference between its plates does not affect its capacitance.

Concept Check 24.2

Suppose you charge a parallel plate capacitor using a battery and then remove the battery, isolating the capacitor and leaving it charged. You then move the plates of the capacitor farther apart. The potential difference between the plates will

a) increase.

b) decrease.

c) stay the same.

d) not be determinable.

Self-Test Opportunity 24.1

You charge a parallel plate capacitor using a battery. You then remove the battery and isolate the capacitor. If you decrease the distance between the plates of the capacitor, what will happen to the electric field between the plates?

EXAMPLE 24.1 Area of a Parallel Plate Capacitor

A parallel plate capacitor has plates that are separated by 1.00 mm (Figure 24.11).

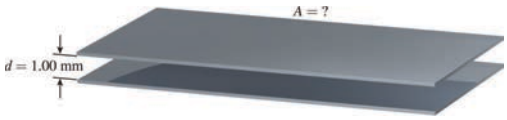

FIGURE 24.11 A parallel plate capacitor with plates separated by 1.00 mm.

PROBLEM

What is the area required to give this capacitor a capacitance of 1.00 F?

SOLUTION

The capacitance is given by

$$C = \frac{\epsilon_0 A}{d}. \qquad \textbf{(i)}$$

Solving equation (i) for the area and putting in $d = 1.00 \cdot 10^{-3}\text{m}$ and $C = 1.00\ \text{F}$, we get

$$A = \frac{dC}{\epsilon_0} = \frac{\left(1.00 \cdot 10^{-3}\ \text{m}\right)\left(1.00\ \text{F}\right)}{\left(8.85 \cdot 10^{-12}\ \text{F/m}\right)} = 1.13 \cdot 10^{8}\ \text{m}^2.$$

If these plates were square, each one would be 10.6 km by 10.6 km (6.59 mi by 6.59 mi)! This result emphasizes that a farad is an extremely large amount of capacitance.

Concept Check 24.3

Suppose you have a parallel plate capacitor with area A and plate separation d, but space constraints on a circuit board force you to reduce the area of the capacitor by a factor of 2. What do you have to do to compensate and retain the same value of the capacitance?

a) reduce d by a factor of 2

b) increase d by a factor of 2

c) reduce d by a factor of 4

d) increase d by a factor of 4

Cylindrical Capacitor

Consider a capacitor constructed of two collinear conducting cylinders with vacuum between them (Figure 24.12). The inner cylinder has radius r_1, and the outer cylinder has radius r_2. The inner cylinder has charge $-q$, and the outer cylinder has charge $+q$. The electric field between the two cylinders is then directed radially inward and perpendicular to the surfaces of both cylinders. As for a parallel plate capacitor, we assume that the cylinders are long and that there is essentially no fringe field near their ends.

We can apply Gauss's Law to find the electric field between the two cylinders, using a Gaussian surface in the form of a cylinder with radius *r* and length *L* that is collinear with the two cylinders of the capacitor, as shown in Figure 24.12. The enclosed charge is then $-q$, because only the negatively charged surface of the capacitor is inside the Gaussian surface. The normal vector to the Gaussian surface, $d\vec{A}$, points radially outward and is thus antiparallel to the electric field. This means that $\vec{E} \bullet d\vec{A} = EdA \cos 180^\circ = -E\, dA$. Applying Gauss's Law and using the fact that the surface of the cylinder has area $A = 2\pi rL$ results in

$$\oiint \vec{E} \bullet d\vec{A} = -E \oiint dA = -E2\pi rL = \frac{-q}{\epsilon_0}. \quad \textbf{(24.7)}$$

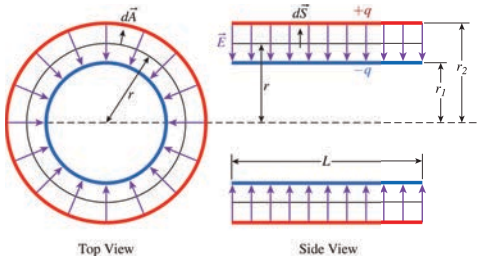

FIGURE 24.12 Cylindrical capacitor consisting of two long collinear conducting cylinders. The black circle represents a Gaussian surface. The purple arrows represent the electric field.

Equation 24.7 can be rearranged to give an expression for the magnitude of the electric field:

$$E = \frac{q}{\epsilon_0 2\pi r L}, \quad \text{for } r_1 < r_2.$$

The potential difference between the two cylindrical capacitor plates is obtained by integrating over the electric field, $\Delta V = -\int_1^{\mathrm{f}} \vec{E} \bullet d\vec{s}$. For the integration path in the radial direction from the negatively charged cylinder at r_1 to the positively charged cylinder at r_2, the electric field is antiparallel to the path. Thus, $\vec{E} \bullet d\vec{s}$ in equation 24.5 becomes $-E\,dr$. Therefore,

$$\Delta V = -\int_1^{\mathrm{f}} \vec{E} \bullet d\vec{s} = \int_{r_1}^{r_2} E dr = \int_{r_1}^{r_2} \frac{q}{\epsilon_0 2\pi r} dr = \frac{q}{\epsilon_0 2\pi L} \ln$$

This expression for the potential difference and equation 24.1 yield an expression for the capacitance:

$$C = \left| \frac{q}{\Delta V} \right| = \frac{q}{\frac{q}{\epsilon_0 2\pi L} \ln(r_2/r_1)} = \frac{2\pi\epsilon_0 L}{\ln(r_2/r_1)}. \quad \textbf{(24.8)}$$

Just as for a parallel plate capacitor, the capacitance of a cylindrical capacitor depends only on its geometry.

Spherical Capacitor

Now let's consider a spherical capacitor formed by two concentric conducting spheres with radii r_1 and r_2 and vacuum between them (Figure 24.13). The inner sphere has charge $+q$. and the outer sphere has charge $-q$. The electric field is perpendicular to the surfaces of both spheres and points radially from the inner, positively charged sphere to the outer, negatively charged sphere, as shown by the purple arrows in Figure 24.13. (Previously, for the parallel plate and cylindrical capacitors, the integration was from the negative to the positive charge. Here we'll see what happens when the direction is reversed.) To determine the magnitude of the electric field, we employ Gauss's Law, using a Gaussian surface consisting of a sphere concentric with the two spherical conductors and having a radius r such that $r_1 < r < r_2$. The electric field is also perpendicular to the Gaussian surface everywhere, so we have

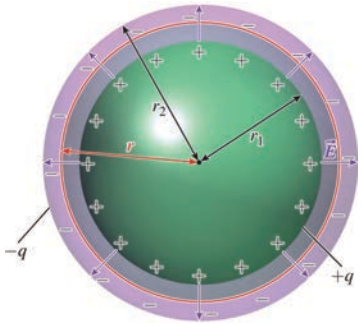

FIGURE 24.13
Spherical capacitor consisting of two concentric conducting spheres. The Gaussian surface is represented by the red circle of radius *r*.

$$\oiint \vec{E} \bullet d\vec{A} = EA = E\left(4\pi r^2\right) = \frac{q}{\epsilon_0}. \qquad \textbf{(24.9)}$$

Solving equation 24.9 for E gives

$$E = \frac{q}{4\pi\epsilon_0 r^2}, \quad \text{for } r_1 < r < r_2.$$

For the potential difference, we proceed in a fashion similar to that used for the cylindrical capacitor and obtain

$$\Delta V = -\int_1^{\mathrm{f}} \vec{E} \bullet \vec{ds} = -\int_{r_1}^{r_2} E dr = \int_{r_1}^{r_2} \frac{q}{4\pi\epsilon_0 r^2} dr = -\frac{q}{4\pi\epsilon}$$

In this case, $\Delta V < 0$. Why? Because we integrated from the positive charge to the negative charge! The positive charge is at a higher potential than the negative one, resulting in a negative potential difference. Equation 24.1 gives the capacitance of a spherical capacitor as the absolute value of the charge divided by the absolute value of the potential difference:

$$C = \left|\frac{q}{\Delta V}\right| = \frac{q}{\frac{q}{4\pi\epsilon_0}\left(\frac{1}{r_1} - \frac{1}{r_2}\right)} = \frac{4\pi\epsilon_0}{\left(\frac{1}{r_1} - \frac{1}{r_2}\right)}.$$

This can be rewritten in a more convenient form:

$$C = 4\pi\epsilon_0 \frac{r_1 r_2}{r_2 - r_1}. \qquad \textbf{(24.10)}$$

Note that again the capacitance depends only on the geometry of the device.

Concept Check 24.4

If the inner and outer radii of a spherical capacitor are increased by a factor of 2, what happens to the capacitance?

a) It is reduced by a factor of 4.

b) It is reduced by a factor of 2.

c) It stays the same.

d) It is increased by a factor of 2.

e) It is increased by a factor of 4.

We can obtain the capacitance of a single conducting sphere from equation 24.10 by assuming that the outer spherical conductor is infinitely far away. With $r_2 = \infty$ and $r_1 = R$, the capacitance of an isolated spherical conductor is given by

$$C = 4\pi\epsilon_0 R. \qquad \textbf{(24.11)}$$

24.4 Capacitors in Circuits

As stated earlier, a circuit is a set of electrical devices connected by conducting wires. Capacitors can be wired in circuits in different ways, but the two most fundamental ones are parallel connection and series connection.

Capacitors in Parallel

Figure 24.14 shows a circuit with three capacitors in **parallel connection.** Each of the three capacitors has one plate wired directly to the positive terminal of a battery with potential difference V and one plate wired directly to the negative terminal of that battery. The same circuit appears in the upper part of Figure 24.15, and the lower part of this figure shows the value of the potential at each part of the circuit in a three-dimensional plot. This illustrates that all capacitor plates connected to the positive terminal of the battery are at the same potential. The other plates of the capacitors are all at the potential of the negative terminal of the battery (set to zero). (The negative and positive terminals of the battery are joined with a light blue sheet to show that these two terminals are part of the same device and to provide a better visual representation of the potential difference between the two terminals. The plates of each capacitor are joined by a light gray band.)

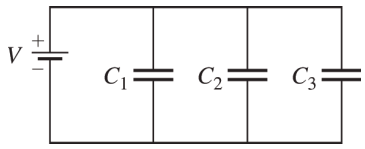

FIGURE 24.14
Simple circuit with a battery and three capacitors in parallel.

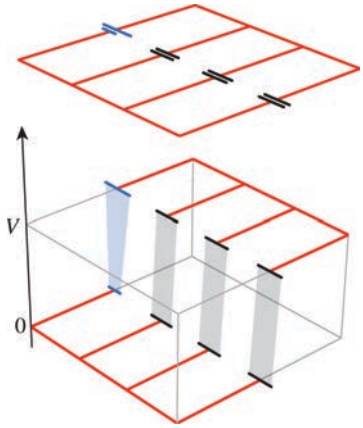

FIGURE 24.15 The potential in different parts of the circuit of Figure 24.14.

The key insight provided by Figure 24.15 is that the potential difference across each of the three capacitors is the same, ΔV. Thus, for the three capacitors in this circuit, we have

$$q_1 = C_1 \Delta V$$
$$q_2 = C_2 \Delta V$$
$$q_3 = C_3 \Delta V.$$

In general, the charge on each capacitor can have a different value. The three capacitors can be viewed as one equivalent capacitor that holds a total charge q, given by

$$q = q_1 + q_2 + q_3 = C_1 \Delta V + C_2 \Delta V + C_3 \Delta V = (C_1 + C_2 +$$

Thus, the equivalent capacitance for this capacitor is

$$C_{\text{eq}} = C_1 + C_2 + C_3.$$

This result can be extended to any number, n, of capacitors connected in parallel:

$$C_{\text{eq}} = \sum_{i=1}^{n} C_{\text{i}}. \qquad \textbf{(24.12)}$$

In other words, the equivalent capacitance of a system of capacitors in parallel is just the sum of the capacitances. Thus, several capacitors in parallel in a circuit can be replaced with an equivalent capacitance given by equation 24.12, as shown in Figure 24.16.

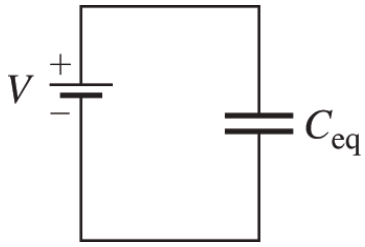

FIGURE 24.16 The three capacitors in Figure 24.14 can be replaced with an equivalent capacitance.

Capacitors in Series

Figure 24.17 shows a circuit with three capacitors in **series connection.** In this configuration, the battery produces an equal charge of $+q$ on the right plate of each capacitor and an equal charge of $-q$ on the left plate of each capacitor. This fact can be made clear by starting when the capacitors are uncharged. The battery is then connected to the series arrangement of the three capacitors. The positive plate of C_3 is connected to the positive terminal of the battery and begins to collect positive charge supplied by the battery. This positive charge induces a negative charge of equal magnitude onto the other plate C_3.

The negatively charged plate of C_3 is connected to the right plate of C_2, which then becomes positively charged because no net charge can accumulate on the isolated section consisting of the left plate of C_3 and the right plate of C_2. The positively charged plate of C_2 induces a negative charge of equal magnitude onto the other plate of C_2. In turn, the negatively charged plate of C_2 leaves a positive charge on the plate of C_1 connected to it, which induces a negative charge onto the left plate of C_1. The negatively charged plate of C_1 is connected to the negative terminal of the battery. Thus, charge flows from the battery, charging the positive plate of C_3 to a charge of value $+q$. and inducing a corresponding charge of $-q$ on the negatively charged plate of C_1. Therefore, each capacitor does indeed end up with the same charge.

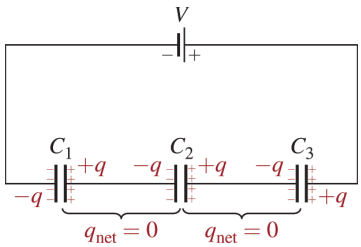

FIGURE 24.17
Simple circuit with three capacitors in series.

When the three capacitors in the circuit in Figure 24.17 are charged, the sum of the potential drops across all three must equal the potential difference supplied by the battery. This is illustrated in Figure 24.18, a three-dimensional representation of the potential in the circuit with the three capacitors in series, similar to that in Figure 24.15. (Note that the potential drops at the three capacitors in series are not equal; this is true in general for a series connection.)

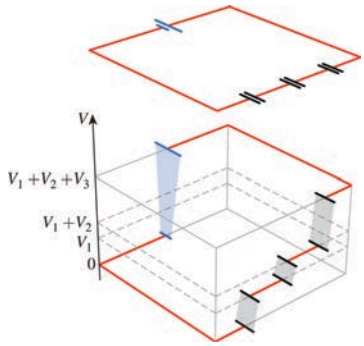

FIGURE 24.18 The potential in a circuit with three capacitors in series.

As you can see from Figure 24.18, the potential drops across the three capacitors must add up to the total potential difference, ΔV, supplied by the battery. Because each capacitor has the same charge, we have

$$\Delta V = \Delta V_1 + \Delta V_2 + \Delta V_3 = \frac{q}{C_1} + \frac{q}{C_2} + \frac{q}{C_3} = q\left(\frac{1}{C_1} + \frac{1}{C_2}\right.$$

The equivalent capacitance can be written as

$$\Delta V = \frac{q}{C_{\text{eq}}},$$

where

$$\frac{1}{C_{\text{eq}}} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}. \qquad \textbf{(24.13)}$$

Thus, the three capacitors in series in the circuit shown in Figure 24.17 can be replaced with an equivalent capacitance given by equation 24.13, yielding the same circuit diagram as that in Figure 24.16.

Concept Check 24.5

For a circuit with three capacitors in series, the equivalent capacitance must always be

a) equal to the largest of the three individual capacitances.

b) equal to the smallest of the three individual capacitances.

c) larger than the largest of the three individual capacitances.

d) smaller than the smallest of the three individual capacitances.

Concept Check 24.6

The potential drop for a circuit with three capacitors of different individual capacitances in series connection is

a) the same across each capacitor and has the same value as the potential difference supplied by the battery.

b) the same across each capacitor and has $\frac{1}{3}$ of the value of the potential difference supplied by the battery.

c) largest across the capacitor with the smallest capacitance.

d) largest across the capacitor with the largest capacitance.

For a system of n capacitors, equation 24.13 generalizes to

$$\frac{1}{C_{\text{eq}}} = \sum_{i=1}^{n} \frac{1}{C_i}. \qquad \textbf{(24.14)}$$

Thus, the capacitance of a system of capacitors in series is always less than the smallest capacitance in the system.

Finding equivalent capacitances for capacitors in series and in parallel allows problems involving complicated circuits to be solved, as the following example illustrates.

Self-Test Opportunity 24.2

What is the equivalent capacitance for four 10.0-μF capacitors connected in series? What is the equivalent capacitance for four 10.0-μF capacitors connected in parallel?

Concept Check 24.7

Three capacitors, each with capacitance *C*, are connected as shown in the figure. What is the equivalent capacitance for this arrangement of capacitors?

a) $C/3$

b) $3C$

c) $C/9$

d) $9C$

e) none of the above

EXAMPLE 24.2 System of Capacitors

PROBLEM

Consider the circuit shown in Figure 24.19a, a complicated-looking arrangement of five capacitors with a battery. What is the combined capacitance of this set of five capacitors? If each capacitor has a capacitance of 5.0 nF, what is the equivalent capacitance of the arrangement? If the potential difference of the battery is 12 V, what is the charge on each capacitor?

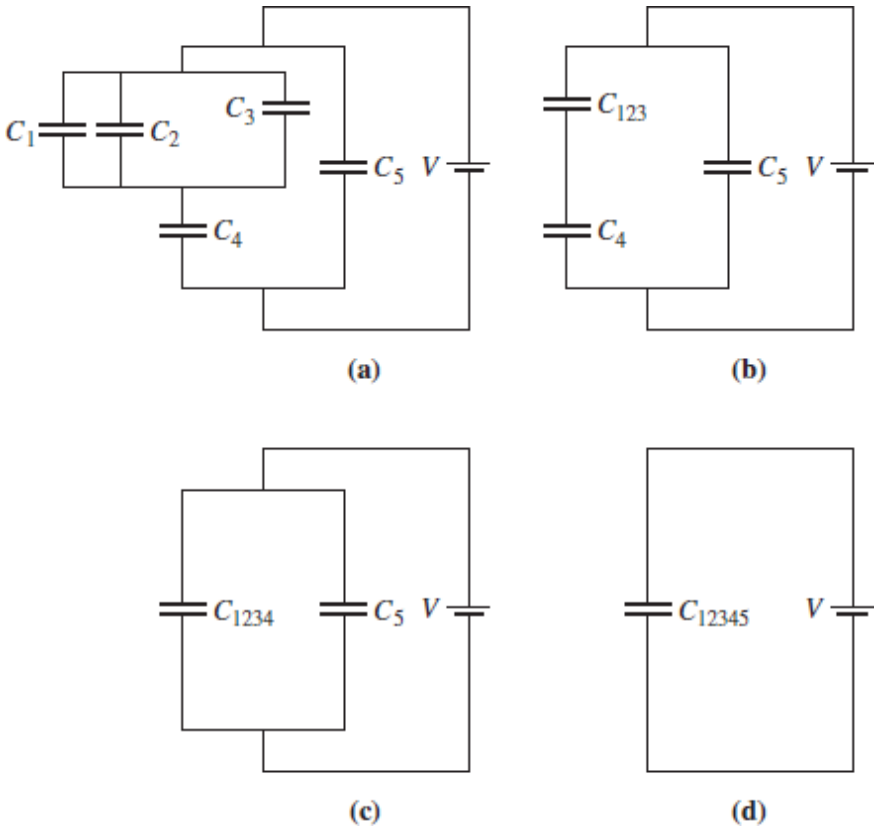

FIGURE 24.19 System of capacitors: (a) original circuit configuration; (b) reducing parallel capacitors to their equivalent; (c) reducing series capacitors to their equivalent; (d) equivalent capacitance for the entire set of capacitors.

SOLUTION

This problem may look complicated at first, but it can be simplified into sequential steps, using the rules for equivalent capacitances of capacitors in series and in parallel. We begin with the innermost circuit structures and work outward.

STEP 1

Looking at capacitors 1 and 2 in Figure 24.19a, we see right away that they are in parallel. Because capacitor 3 is some distance away, it is less obvious that it is also in parallel with 1 and 2. However, the upper plates of all three of these capacitors are connected by wires and are thus at the same potential. The same goes for their lower plates, so all three are indeed in parallel. According to equation 24.12, the equivalent capacity for these three capacitors is

$$C_{123} = \sum_{i=1}^{3} C_i = C_1 + C_2 + C_3.$$

This replacement is shown in Figure 24.19b.

STEP 2

In Figure 24.19b, C_{123} and C_4 are in series. Thus, their equivalent capacitance is, according to equation 24.14,

$$\frac{1}{C_{1234}} = \frac{1}{C_{123}} + \frac{1}{C_4} \Rightarrow C_{1234} = \frac{C_{123}C_4}{C_{123} + C_4}.$$

This replacement is shown in Figure 24.19c.

STEP 3

Finally, C_{1234} and C_5 are in parallel in Figure 24.19c. Therefore, we can repeat the calculation for two capacitors in parallel and find the equivalent capacitance of all five capacitors:

$$C_{12345} = C_{1234} + C_5 = \frac{C_{123}C_4}{C_{123} + C_4} + C_5 = \frac{(C_1 + C_2 +$$
$$C_1 + C_2 + C$$

This result gives us the simple circuit shown in Figure 24.19d.

STEP 4: INSERT THE NUMBERS FOR THE CAPACITORS

We can now find the equivalent capacitance if all the capacitors have identical 5.0-nF capacitances:

$$\left(\frac{(5.0+5.0+5.0)5.0}{5.0+5.0+5.0+5.0}+5.0\right)\text{nF}=8.8\text{ nF}.$$

As you can see, more than half of the total capacitance of this arrangement is provided by capacitor 5 alone. This result shows that you need to be extremely careful about how you arrange capacitors in circuits.

STEP 5: CALCULATE THE CHARGES ON THE CAPACITORS

C_{1234} and C_5 are in parallel. Thus, they have the same potential difference across them, 12 V. The charge on C_5 is then

$$q_5=C_5\Delta V=(5.0\text{ nF})(12\text{ V})=60.\text{ nC}.$$

C_{1234} is composed of C_{123} and C_4 in series. Thus, C_{123} and C_4 must have the same charge q_4, so

$$\Delta V=\Delta V_{123}+\Delta V_4=\frac{q_4}{C_{123}}+\frac{q_4}{C_4}=q_4\left(\frac{1}{C_{123}}+\frac{1}{C_4}\right)$$

The charge on C_4 is then

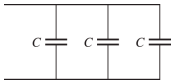
$$q_4=\Delta V\frac{C_{123}C_4}{C_{123}+C_4}=\Delta V\frac{(C_1+C_2+C_3)C_4}{C_1+C_2+C_3+C_4}=(12\text{ V}$$

C_{123} is equivalent to three capacitors in parallel, and it also has the same charge as C_4, or 45 nC. The three capacitors C_1, C_2, and C_3 have the same capacitance, the same potential difference across them as they are in parallel, and the sum of the charge on these three capacitors must equal 45 nC. Therefore, we can calculate the charge on C_1, C_2, and C_3:

$$q_1 = q_2 = q_3 = \frac{45 \text{ nC}}{3} = 15 \text{ nC}.$$

Concept Check 24.8

Three capacitors, each with capacitance *C*, are connected as shown in the figure. What is the equivalent capacitance for this arrangement of capacitors?



a) $C/3$

b) $3C$

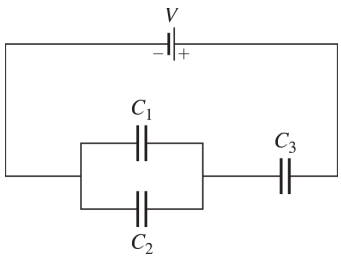
c) $C/9$

d) $9C$

e) none of the above

Concept Check 24.9

Three capacitors are connected to a battery as shown in the figure. If $C_1 = C_2 = C_3 = 10.0\ \mu\text{F}$ and $V = 10.0\ \text{V}$, what is the charge on capacitor C_3?



a) 66.7μC

b) 100.μC

c) 150.μC

d) 300.μC

e) 457.μC

24.5 Energy Stored in Capacitors

Capacitors are extremely useful for storing electric potential energy. They are much more useful than batteries if the potential energy has to be converted into other energy forms very quickly. One application of capacitors for the storage and rapid release of electric potential energy is described in Example 24.4, about the high-powered laser at the National Ignition Facility. Let's examine how much energy can be stored in a capacitor.

A battery must do work to charge a capacitor. This work can be conceptualized in terms of changing the electric potential energy of the capacitor. In order to accomplish the charging process, charge has to be moved against the potential between the two capacitor plates. As noted earlier in this chapter, the larger the charge of the capacitor is, the larger the potential difference between the plates. This means that the more charge already on the capacitor, the harder it becomes to add a differential amount of charge to the capacitor. The differential work, *dW,* done by a battery with potential difference ΔV to put a differential charge, *dq,* on a capacitor with capacitance *C* is

$$dW = \Delta V' \, dq' = \frac{q'}{C} dq',$$

where $\Delta V'$ and q' are the instantaneous (increasing) potential difference and charge, respectively, on the capacitor during the charging process. The total work, W_{t}, required to bring the capacitor to its full charge, *q,* is given by

$$W_{\text{t}} = \int dW = \int_0^q \frac{q'}{C} dq' = \frac{1}{2} \frac{q^2}{C}.$$

This work is stored as electric potential energy:

$$U = \frac{1}{2}\frac{q^2}{C} = \frac{1}{2}C(\Delta V)^2 = \frac{1}{2}q\Delta V. \qquad \textbf{(24.15)}$$

All three of the formulations for the stored electric potential energy in equation 24.15 are equally valid. Each can be transformed to one of the others by using $q = C\Delta V$ and eliminating one of the three quantities in favor of the other two.

The **electric energy density,** *u,* is defined as the electric potential energy per unit volume:

$$u = \frac{U}{\text{volume}}.$$

(*Note: V* is not used to represent the volume here, because in this context it is reserved for the potential.)

For the special case of a parallel plate capacitor that has no fringe field, it is easy to calculate the volume enclosed between two plates of area *A* separated by a perpendicular distance *d*. It is the area of each plate times the distance between the plates, or *Ad*. Using equation 24.15 for the electric potential energy, we obtain

$$u = \frac{U}{Ad} = \frac{\frac{1}{2}C(\Delta V)^2}{Ad} = \frac{C(\Delta V)^2}{2Ad}.$$

Using equation 24.6 for the capacitance of a parallel plate capacitor with vacuum between the plates, we get

$$u = \frac{(\epsilon_0 A/d)(\Delta V)^2}{2Ad} = \frac{1}{2}\epsilon_0\left(\frac{\Delta V}{d}\right)^2.$$

Recognizing that $\Delta V/d$ is the magnitude of the electric field, *E,* we obtain an expression for the electric energy density for a parallel plate capacitor:

$$u = \frac{1}{2}\epsilon_0 E_2. \qquad \textbf{(24.16)}$$

This result, although derived for a parallel plate capacitor, is in fact much more general. The electric potential energy stored in any electric field per unit volume occupied by that field can be described using equation 24.16.

Concept Check 24.10

How much energy is stored in the $180\text{-}\mu\text{F}$ capacitor of a camera flash unit charged to 300.0 V?

a) 1.22 J

b) 8.10 J

c) 45.0 J

d) 155 J

e) 300 J

EXAMPLE 24.3 Thundercloud

Suppose a thundercloud with a width of 2.0 km and a length of 3.0 km hovers at an altitude of 0.50 km over a flat area. The cloud carries a charge of 160 C, and the ground has no charge.

PROBLEM 1

What is the potential difference between the cloud and the ground?

SOLUTION 1

We can approximate the cloud-ground system as a parallel plate capacitor. Its capacitance is, according to Equation 24.6,

$$C = \frac{\epsilon_0 A}{d} = \frac{\left(8.85 \cdot 10^{-12}\ \text{F/m}\right)(2.0\ \text{km})(3.0\ \text{km})}{0.50\ \text{km}} = 0.1$$

Because we know the charge carried by the cloud, 160 C, it is tempting to insert this value into the relationship among charge, capacitance, and potential difference (equation 24.1) to find the desired answer. However, a parallel plate capacitor with a charge of $+q$ on one plate and $-q$ on the other has a charge difference of $2q$ between the plates. For the cloud-ground system, $2q = 160$ C, or $q = 80.$ C. Alternatively, we can think of the cloud as a charged insulator and use the result from Section 22.9, that the field due to a plane sheet of charge is $E = \sigma/2\epsilon_0$, to justify the factor of $\frac{1}{2}$. Now we can use equation 24.1 and obtain

$$\Delta V = \frac{q}{C} = \frac{80.\ \text{C}}{0.11\ \mu\text{F}} = 7.3 \cdot 10^8\ \text{V}.$$

The potential difference is more than 700 million volts!

PROBLEM 2

Lightning strikes require electric field strengths of approximately 2.5 mv/m. Are the conditions described in the problem statement sufficient for a lightning strike?

SOLUTION 2

We use the potential difference between cloud and ground and the given distance between them to calculate the magnitude of the electric field:

$$E = \frac{\Delta V}{d} = \frac{7.3 \cdot 10^8 \text{ V}}{0.50 \text{ m}} = 1.5 \text{ MV/m}.$$

From this result, we can conclude that no lightning will develop in these conditions. However, if the cloud drifted over a radio tower, the electric field strength would likely increase and lead to a lightning discharge.

PROBLEM 3

What is the total electric potential energy contained in the field between this thundercloud and the ground?

SOLUTION 3

From equation 24.15, the total electric potential energy stored in the cloud-ground system is

$$U = \frac{1}{2} q \Delta V = 0.5(80. \text{ C})\left(7.3 \cdot 10^8 \text{ V}\right) = 2.9 \cdot 10^{10} \text{ J}.$$

For comparison, this energy is sufficient to run a typical 1500-W hair dryer for more than 5000 hours.

SOLVED PROBLEM 24.1 Energy Stored in Capacitors

PROBLEM

Suppose many capacitors, each with $C = 90.0\ \mu\text{F}$, are connected in parallel across a battery with a potential difference of $\Delta V = 160.0\ \text{V}$. How many capacitors are needed to store 95.6 J of energy?

SOLUTION

THINK

The equivalent capacitance of many capacitors connected in parallel is given by the sum of the capacitances of all the capacitors. We can calculate the energy stored from the equivalent capacitance of the capacitors in parallel and the potential difference of the battery.

SKETCH

Figure 24.20 shows a circuit with n capacitors connected in parallel across a battery.

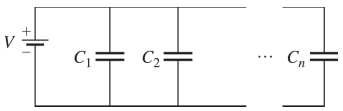


FIGURE 24.20 A circuit with n capacitors connected in parallel across a battery.

RESEARCH

The equivalent capacitance, C_{eq}, of n capacitors, each with capacitance C, connected in parallel is

$$C_{\text{eq}} = C_1 + C_2 + \cdots C_n = nC.$$

The energy stored in the capacitors is then given by

$$U = \frac{1}{2}C_{\text{eq}}(\Delta V)^2 = \frac{1}{2}nC(\Delta V)^2. \qquad \textbf{(i)}$$

SIMPLIFY

Solving equation (i) for the required number of capacitors gives us

$$n = \frac{2U}{C(\Delta V)^2}.$$

CALCULATE

Putting in the numerical values, we get

$$n = \frac{2(95.6\ \text{J})}{\left(90.0 \cdot 10^{-6}\ \text{C}\right)(160.0\ \ \text{V})^2} = 82.986.$$

ROUND

We report our result as an integer number of capacitors:

$$n = 83 \text{ capacitors}.$$

DOUBLE-CHECK

The capacitance of 83 capacitors with $C = 90.0\ \mu\text{F}$ is

$$C_{\text{eq}} = 83(90.0\ \mu\text{F}) = 0.00747\ \text{F}.$$

Charging this capacitor with a 160 V battery produces a stored energy of

$$U = \frac{1}{2}C_{\text{eq}}(\Delta V)^2 = \frac{1}{2}(0.00747\text{F})(160.0\text{ V})^2 = 95.6\text{ J}.$$

Thus, our answer for the number of capacitors is consistent.

EXAMPLE 24.4 The National Ignition Facility

The National Ignition Facility (NIF) is a high-powered laser designed to produce fusion reactions similar to those that occur in the Sun. The laser uses a short, high-energy pulse of light to heat and compress a small pellet containing isotopes of hydrogen. The laser is powered by 192 power-conditioning modules (Figure 24.21), each containing twenty 300.-μF capacitors connected in parallel and charged to 24.0 kV The capacitors are charged over a period of 90.0 s. The laser is then fired by discharging all the energy stored in the capacitors in 400.-μs.

FIGURE 24.21
Forty-eight power-conditioning modules in one of four bays at the National Ignition Facility at Lawrence Livermore National Laboratory.

Lawrence Livermore National Lab

PROBLEM 1

How much energy is stored in the capacitors of NIF?

SOLUTION 1

The capacitors are connected in parallel. Thus, the equivalent capacitance of each power-conditioning module is

$$C_{\text{eq}} = 20(300.\ \mu\text{F}) = 6.00\ \text{mF}.$$

The energy stored in each power-conditioning module is

$$U = \frac{1}{2}C_{\text{eq}}(\Delta V)^2 = \frac{1}{2}\left(6.00 \cdot 10^{-3}\ \text{F}\right)\left(24.0 \cdot 10^{3}\ \text{V}\right)^2 = 1$$

Thus, the total energy stored in all the capacitors of NIF is

$$U_{\text{total}} = 192(17.3\ \text{MJ}) = 332\ \text{MJ}.$$

PROBLEM 2

What is the average power released by the power-conditioning modules during the laser pulse?

SOLUTION 2

The power is the energy per unit time, which is given by

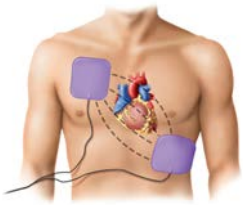
$$p = \frac{\Delta U}{\Delta t} = \frac{332\ \text{MJ}}{400.\ \mu\text{s}} = \frac{332.10^{6}\ \text{J}}{400. \cdot 10^{-6}\ \text{s}} = 8.30 \cdot 10^{11}\ \text{W} =$$

In comparison, the average electrical power generated in the United States in 2020 was 0.48 TW. Of course, the 0.830 TW of power delivered to the NIF laser is maintained for only a small fraction of a second. The NIF lasers use this electrical energy and produce slightly over 2 MJ of energy in the form of ultraviolet light, which is released on the fusion target in approximately 4 ns. This results in a laser power of more than 500 TW.

Defibrillator

An important application of capacitors is the portable automatic external defibrillator (AED), a device designed to shock the heart of a person who is in ventricular fibrillation. A typical AED is shown in Figure 24.22a.

(a)



(b)

FIGURE 24.22
(a) An automatic external defibrillator (AED) in its holder on a wall. (b) Schematic diagram showing where to place the hands-free electrodes.

Being in ventricular fibrillation means that the heart is not beating in a regular pattern. Instead, the signals that control the beating of the heart are erratic, preventing the heart from performing its function of maintaining regular blood circulation

throughout the body. This condition must be treated within a few minutes to avoid permanent damage or death. Having many AED devices located in accessible public places allows quick treatment of this condition.

An AED provides a pulse of electrical current intended to stimulate the heart to beat regularly. Typically, an AED is designed to analyze a person's heartbeat automatically, determine if the person is in ventricular fibrillation, and administer the electrical pulse if required. The operator of the AED must attach the electrodes of the AED to the chest of the person experiencing the problem and push the start button. The AED will do nothing if the person is not in ventricular defibrillation. If the AED determines that the person is in ventricular fibrillation, the AED will instruct the operator to press the button to initiate the electrical pulse. Note that an AED is not designed to restart a heart that is not beating. Rather it is designed to restore a regular heartbeat when the heart is beating erratically.

Typically, an AED delivers 150 J of electric energy to the patient, administered through a pair of electrodes that are attached to the chest area (see Figure 24.22b). This energy is stored by charging a capacitor through a special circuit from a low-voltage battery. This capacitor typically has a capacitance of 100. μF and is charged in 10. s. The power used during charging is

$$p = \frac{E}{t} = \frac{150\ \text{J}}{10.\ \text{s}} = 15\ \text{W},$$

which is within the capability of a simple battery. The energy of the capacitor is then discharged in 10. ms. The instantaneous power during the discharge is

$$p = \frac{E}{t} = \frac{150\ \text{J}}{10.\ \text{ms}} = 15\ \text{kW},$$

which is beyond the capability of a small, portable battery but well within the capabilities of a well-designed capacitor.

The energy stored in the capacitor is $U = \frac{1}{2}C(\Delta V)^2$. When the capacitor is charged, its potential difference is

$$\Delta V = \sqrt{\frac{2U}{C}} = \sqrt{\frac{2(150\ \text{J})}{100.\cdot 10^{-6}\ \text{F}}} = 1.7\ \text{kV}.$$

When the AED delivers an electrical current, the capacitor is charged from a battery contained in the AED. The capacitor is then discharged through the person to stimulate the heart to beat in a regular manner. Most AEDs can deliver the electrical current many times without recharging the battery.

24.6 Capacitors with Dielectrics

The capacitors we have been discussing have air or vacuum between the plates. However, capacitors for just about any commercial application have an insulating material, called a **dielectric,** between the two plates. This dielectric serves several purposes: First, it maintains the separation between the plates. Second, the dielectric insulates the two plates from each other electrically. Third, the dielectric allows the capacitor to maintain a higher potential difference than it could with only air between the plates. Lastly, a dielectric increases the capacitance of the capacitor. We'll see that this ability to increase the capacitance is due to the molecular structure of the dielectric.

Self-Test Opportunity 24.3

One way to increase the capacitance of a parallel plate capacitor, other than by adding a dielectric between the plates, is to decrease the distance between the plates. What is the minimum distance between the plates of a parallel plate capacitor if the space is filled with air and if the maximum potential difference between the plates is to be 100.0 V? (*Hint:* Table 24.1 may be useful.)

Table 24.1 Dielectric Constants and Dielectric Strengths for Some Representative Materials

Material	Dielectric Constant, κ	Dielectric Strength (kV/mm)
Vacuum	1	
Air (1 atm)	1.00059	2.5
Liquid nitrogen	1.454	
Teflon	2.1	60
Polyethylene	2.25	50
Benzene	2.28	
Polystyrene	2.6	24
Lexan	2.96	16
Mica	3–6	150–220
Paper	3	16
Mylar	3.1	280
Plexiglas	3.4	30
Polyvinyl chloride (PVC)	3.4	29
Glass	5	14
Neoprene	16	12
Germanium	16	
Glycerin	42.5	

Dielectric Constants and Dielectric Strengths for Some Representative Materials		
Material	**Dielectric Constant, κ**	**Dielectric Strength (kV/mm)**
Water	80.4	65
Strontium titanate	310	8

Note that these values are approximate and are for room temperature.

Filling the space between the plates of a capacitor completely with a dielectric increases its capacitance by a numerical factor called the **dielectric constant,** κ. We'll assume that the dielectric fills the entire volume between the capacitor plates, unless explicitly stated otherwise. Solved Problem 24.2 considers an example where the filling is only partial.

The capacitance, *C,* of a capacitor containing a dielectric with dielectric constant ***k*** between its plates is given by

$$C = \kappa C_{\text{air}}, \qquad \textbf{(24.17)}$$

where C_{air} is the capacitance of the capacitor without the dielectric.

Placing a dielectric between the plates of a capacitor has the effect of lowering the electric field between the plates (see Section 24.7) and allowing more charge to be stored in the capacitor. For example, the electric field between the plates of a parallel plate capacitor, given by equation 24.4, is modified for a parallel plate capacitor with a dielectric to

$$E = \frac{E_{\text{air}}}{\kappa} = \frac{q}{\kappa \epsilon_0 A} = \frac{q}{\epsilon A}. \qquad \textbf{(24.18)}$$

The constant ϵ_0 is the electric permittivity of free space, previously encountered in Coulomb's Law. The right-hand side of equation 24.18 was obtained by replacing the factor $\kappa\epsilon_0$ with ϵ, the **electric permittivity** of the dielectric. In other words, the electric permittivity of a dielectric is the product of the electric permittivity of free space (the vacuum) and the dielectric constant of the dielectric:

$$\epsilon = \kappa \epsilon_0. \qquad \textbf{(24.19)}$$

Concept Check 24.11

Suppose you charge a parallel plate capacitor with a dielectric between the plates using a battery and then remove the battery, isolating the capacitor and leaving it charged. You then remove the dielectric from between the plates. The potential difference between the plates will

a) increase.

b) decrease.

c) stay the same.

d) not be determinable.

Note that this replacement of ϵ_0 by ϵ is all that is needed to generalize expressions for the capacitance, such as equations 24.6, 24.8, and 24.10, from the values applicable for a capacitor with vacuum between its plates to those appropriate when the capacitor is completely filled with a dielectric. We can now see how the capacitance is increased by adding a dielectric between the plates. The potential difference across a parallel plate capacitor is

$$\Delta V = Ed = \frac{qd}{\kappa\epsilon_0 A}.$$

Therefore, we can write the capacitance as

$$C = \frac{q}{\Delta V} = \frac{\kappa\epsilon_0 A}{d} = \kappa C_{\text{air}}.$$

The **dielectric strength** of a material is a measure of its ability to withstand potential difference. If the electric field strength in the dielectric exceeds the dielectric strength, the dielectric breaks down and begins to conduct charge between the plates via a spark, which usually destroys the capacitor. Thus, a useful capacitor must contain a dielectric that not only provides a given capacitance but also enables the device to hold the required potential difference without breaking down. Capacitors are normally specified by the value of their capacitance and by the maximum potential difference that they are designed to handle.

The dielectric constant of vacuum is defined to be 1, and the dielectric constant of air is close to 1.0. The dielectric constants and dielectric strengths of air and of other common materials used as dielectrics are listed in Table 24.1.

EXAMPLE 24.5 Parallel Plate Capacitor with a Dielectric

PROBLEM 1

Consider a parallel plate capacitor without a dielectric and with capacitance $C = 2.00\ \mu\text{F}$ connected to a battery with potential difference $\Delta V = 12.0\ \text{V}$ (Figure 24.23a). What is the charge stored in the capacitor?

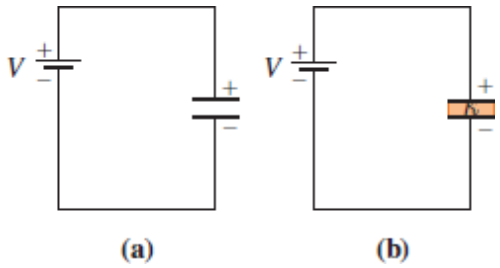


FIGURE 24.23 Parallel plate capacitor connected to a battery: (a) with no dielectric; (b) with a dielectric inserted between the plates.

SOLUTION 1

Using the definition of capacitance (equation 24.1), we have

$$q = C\Delta V = \left(2.00 \cdot 10^{-6}\ \text{F}\right)(12.0\ \text{V}) = 2.40 \cdot 10^{-5}\ \text{C}.$$

PROBLEM 2

In Figure 24.23b, a dielectric with $\kappa = 2.50$ has been inserted between the plates of the capacitor, completely filling the space between them. Now what is the charge on the capacitor?

SOLUTION 2

The capacitance of the capacitor is increased by the dielectric:

$$C = \kappa C_{\text{air}}.$$

The charge is

$$q = \kappa C_{\text{air}} \Delta V = (2.50)\left(2.00 \cdot 10^{-6}\ \text{F}\right)(12.0\ \text{V}) = 6.00 \cdot 1($$

The charge on the capacitor increases when the capacitance increases because the battery maintains a constant potential difference across the capacitor. The battery provides the additional charge until the capacitor is fully charged.

PROBLEM 3

Now suppose the capacitor is disconnected from the battery (Figure 24.24a). The capacitor, which is now isolated, maintains its charge of $q = 6.00 \cdot 10^{-5}$ C and its potential difference of $\Delta V = 12.0$ V. What happens to the charge and potential difference if the dielectric is removed, keeping the capacitor isolated (Figure 24.24b)?

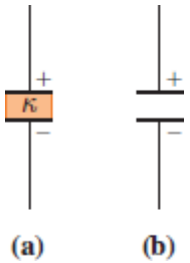

FIGURE 24.24 Isolated capacitor: (a) with dielectric and (b) with dielectric removed.

SOLUTION 3

The charge on the isolated capacitor cannot change when the dielectric is removed because there is nowhere for the charge to flow. Thus, the potential difference on the capacitor is

$$\Delta V = \frac{q}{C} = \frac{6.00 \cdot 10^{-5}\text{C}}{2.00 \cdot 10^{-6}\text{F}} = 30.0\text{V}.$$

The potential difference increases because removing the dielectric increases the electric field and the resulting potential difference between the plates.

PROBLEM 4

Does removing the dielectric change the energy stored in the capacitor?

SOLUTION 4

The energy stored in a capacitor is given by equation 24.15. Before the dielectric was removed, the energy in the capacitor was

$$U = \frac{1}{2}C_{\text{air}}(\Delta V)^2 = \frac{1}{2}\kappa C_{\text{air}}(\Delta V)^2 = \frac{1}{2}(2.50)\left(2.00 \cdot 10^{-}\right.$$

After the dielectric is removed, the energy is

$$U = \frac{1}{2}C_{\text{air}}(\Delta V)^2 = \frac{1}{2}\left(2.00 \cdot 10^{-6}\ \text{F}\right)(30.0\ \text{V})^2 = 9.001($$

The increase in energy from $3.60 \cdot 10^{-4}$ J to $9.00 \cdot 10^{-4}$ J when the dielectric is removed is due to the work done on the dielectric in pulling it out of the electric field between the plates.

Concept Check 24.12

What would happen if the dielectric in the capacitor of Example 24.5 were pulled halfway out and then released?

a) The dielectric would be pulled back into the capacitor.

b) The dielectric would heat up rapidly.

c) The dielectric would be pushed out of the capacitor.

d) The capacitor plates would heat up rapidly.

e) The dielectric would remain in the halfway position, and no heating would be observed.

SOLVED PROBLEM 24.2 Capacitor Partially Filled with a Dielectric

PROBLEM

A parallel plate capacitor is constructed of two square conducting plates with side length $L = 10.0$ cm (Figure 24.25a). The distance between the plates is $d = 0.250$ cm. A dielectric with dielectric constant $\kappa = 15.0$ and thickness 0.250 cm is inserted between the plates. The dielectric is $L = 10.0$ cm wide and $L/2 = 5.00$ cm long, as shown in Figure 24.25a. What is the capacitance of this capacitor?

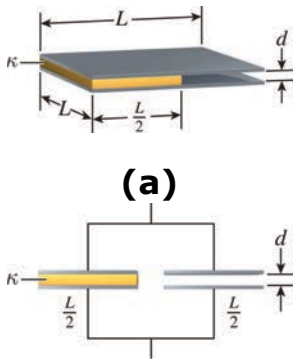

FIGURE 24.25 (a) A parallel plate capacitor with square plates of side length L separated by distance d with a dielectric that is L wide and $L/2$ long and has a dielectric constant κ inserted between the plates. (b) The partially filled capacitor represented as two capacitors in parallel.

SOLUTION

THINK

We have a parallel plate capacitor that is partially filled with a dielectric. We can treat this capacitor as two capacitors in parallel. One capacitor is a parallel plate capacitor with plate area $A = L(L/2)$ and air between the plates; the second capacitor is a parallel plate capacitor with plate area $A = L(L/2)$ and a dielectric between the plates.

SKETCH

Figure 24.25b shows a representation of the partially filled capacitor as two capacitors in parallel: one filled with a dielectric and the other filled with air.

RESEARCH

The capacitance, C_1, of a parallel plate capacitor is given by equation 24.6:

$$C_1 = \frac{\epsilon_0 A}{d},$$

where A is the area of the plates and d is the separation between them. If a dielectric is placed between the plates, the capacitance becomes

$$C_2 = \kappa \frac{\epsilon_0 A}{d},$$

where κ is the dielectric constant. For two capacitors, C_1 and C_2, in parallel, the effective capacitance, C_{12}, is given by

$$C_{12} = C_1 + C_2.$$

SIMPLIFY

Substituting the expressions for the two individual capacitances into the sum, we get

$$C_{12} = \frac{\epsilon_0 A}{d} + \kappa \frac{\epsilon_0 A}{d} = (\kappa + 1)\frac{\epsilon_0 A}{d}. \qquad \textbf{(i)}$$

The area of the plates for each capacitor is

$$A = (L)(L/2) = L^2/2.$$

Inserting the expression for the area into equation (i) gives the capacitance of the partially filled capacitor:

$$C_{12} = (\kappa + 1)\frac{\epsilon_0 \left(L^2/2\right)}{d} = \frac{(\kappa + 1)\epsilon_0 L^2}{2d}.$$

CALCULATE

Putting in the numerical values, we get

$$C_{12} = \frac{(15.0 + 1)\left(8.85 \cdot 10^{-12}\ \text{F/m}\right)(0.100\ \text{m})^2}{2(0.00250\ \text{m})} = 0.832$$

ROUND

We report our result to three significant figures:

$$C_{12} = 2.83 \cdot 10^{-10}\ \text{F} = 283\ \text{pF}.$$

DOUBLE-CHECK

To double-check our answer, we calculate the capacitance of the capacitor without any dielectric:

$$C = \frac{\epsilon_0 A}{d} = \frac{\left(8.85 \cdot 10^{-12}\ \text{F/m}\right)(0.100\ \text{m})^2}{0.0025\ \text{m}} = 3.54 \cdot 10^{-}$$

We then calculate the capacitance of the capacitor if completely filled with dielectric:

$$C = \epsilon\frac{\epsilon_0 A}{d} = (15.0)(35.4\ \text{pF}) = 5.31 \cdot 10^{-10}\ \text{F} = 531\ \text{pF}$$

Our result for the partially filled capacitor is half of the sum of these two results, so it seems reasonable.

EXAMPLE 24.6 Capacitance of a Coaxial Cable

Coaxial cables are used to transport signals, for example, TV signals, between devices with minimum interference from the surroundings. A 20.0 m-long coaxial cable is composed of a conductor and a coaxial conducting shield around the conductor. The space between the conductor and the shield is filled with polystyrene. The radius of the conductor is 0.250 mm, and the radius of the shield is 2.00 mm (Figure 24.26).

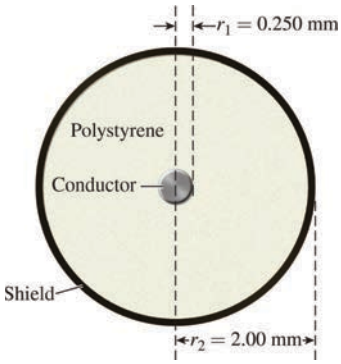

FIGURE 24.26
Cross section of a coaxial cable.

PROBLEM

What is the capacitance of the coaxial cable?

SOLUTION

We can think of the conductor of the coaxial cable as a cylinder because all the charge on the conductor resides on its surface. From Table 24.1, the dielectric constant for polystyrene is 2.6. We can treat the coaxial cable as a cylindrical capacitor with $r_1 = 0.250$ mm and $r_2 = 2.00$ mm filled with a dielectric with $\kappa = 2.6$. Then, we can use equation 24.8 to find the capacitance of the coaxial cable:

$$C = \kappa \frac{2\pi\epsilon_0 L}{\ln(r_1/r_2)} = \frac{2.6(2\pi)\left(8.85 \cdot 10^{-12}\ \text{F/m}\right)(20.0\ \text{m})}{\ln\left[\left(2.00 \cdot 10^{-3}\ \text{m}\right)/\left(2.50 \cdot 10^{-4}\ \text{m}\right)\right]}$$

One interesting application of capacitance and the dielectric constant is in measuring liquid nitrogen levels in cryostats (containers insulated to maintain cold temperatures). It is often difficult to conduct a visual exam to determine how much liquid nitrogen is left in a cryostat. However, if one determines the capacitance, *C*, of the empty cryostat, then, when completely filled with liquid nitrogen, the cryostat should have a capacitance of $\kappa C = 1.454C$, because liquid nitrogen has a dielectric constant of 1.454. The capacitance varies smoothly as a function of the fullness between the maximum value $\kappa C = 1.454C$ for the completely full cryostat and the value *C* for the empty cryostat, giving an easy way to determine how full the cryostat is.

SOLVED PROBLEM 24.3 Charge on a Cylindrical Capacitor

PROBLEM

Consider a cylindrical capacitor with inner radius $r_1 = 10.0$ cm, outer radius $r_2 = 12.0$ cm, and length $L = 50.0$ cm (Figure 24.27a). A dielectric with dielectric constant $\kappa = 12.5$ fills the volume between the two cylinders (Figure 24.27b). The capacitor is connected to a 100.0-V battery and charged completely. What is the charge on the capacitor?

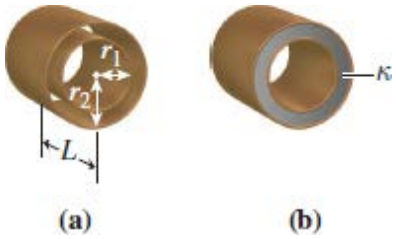

FIGURE 24.27 (a) A cylindrical capacitor with inner radius r_1, outer radius r_2, and length L. (b) A dielectric with dielectric constant κ is inserted between the cylinders.

SOLUTION

THINK

We have a cylindrical capacitor filled with a dielectric. When the capacitor is connected to the battery, charge will accumulate on the capacitor until the capacitor is fully charged. We can calculate the amount of charge on the capacitor.

SKETCH

A circuit diagram with the cylindrical capacitor connected to a battery is shown in Figure 24.28.

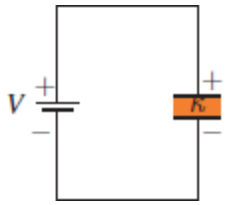

FIGURE 24.28 A cylindrical capacitor connected to a battery.

RESEARCH

The capacitance, C, of a cylindrical capacitor is given by equation 24.8:

$$C = \frac{2\pi\epsilon_0 L}{\ln(r_2/r_1)},$$

where r_1 is the inner radius of the capacitor, r_2 is the outer radius of the capacitor, and L is the length of the capacitor. With a dielectric between the plates, the capacitance becomes

$$C = \kappa\frac{2\pi\epsilon_0 L}{\ln(r_2/r_1)}, \qquad \textbf{(i)}$$

where κ is the dielectric constant. For a capacitor with capacitance C charged to a potential difference ΔV, the charge q is given by equation 24.1:

$$q = C\Delta V. \qquad \textbf{(ii)}$$

SIMPLIFY

Combining equations (i) and (ii) gives

$$q = C\Delta V = \left(\kappa \frac{2\pi\epsilon_0 L}{\ln(r_2/r_1)}\right)\Delta V = \frac{2\kappa\pi\epsilon_0 L\Delta V}{\ln(r_2/r_1)}.$$

CALCULATE

Putting in the numerical values, we get

$$q = \frac{2\kappa\pi\epsilon_0 L\Delta V}{\ln(r_2/r_1)} = \frac{2(12.5)\pi\left(8.85\cdot 10^{-12}\ \mathrm{F/m}\right)(0.500\ \mathrm{m}}{\ln\left[(0.120\ \mathrm{m})/(0.100\ \mathrm{m})\right]}$$

ROUND

We report our result to three significant figures:

$$q = 19.1\cdot 10^{-8}\mathrm{C} = 191\ \mathrm{nC}.$$

DOUBLE-CHECK

Our answer is a very small fraction of a coulomb of charge, so it seems reasonable.

Concept Check 24.13

State whether each of the following statements about an *isolated* parallel plate capacitor is true or false.

a) When the distance between the plates of the capacitor is doubled, the energy stored in the capacitor doubles.

b) Increasing the distance between the plates increases the electric field between the plates.

c) When the distance between the plates is halved, the charge on the plates stays the same

d) Inserting a dielectric between the plates increases the charge on the plates.

e) Inserting a dielectric between the plates decreases the energy stored in the capacitor.

24.7 Microscopic Perspective on Dielectrics

Let's consider what happens at the atomic and molecular level when a dielectric is placed in an electric field. There are two types of dielectric materials: polar dielectrics and nonpolar dielectrics.

A **polar dielectric** is a material composed of molecules that have a permanent electric dipole moment due to their structure. A common example of such a molecule is water. Normally, the directions of electric dipoles are randomly distributed (Figure 24.29a). However, when an electric field is applied to these polar molecules, they tend to align with the field (Figure 24.29b).

Page 764

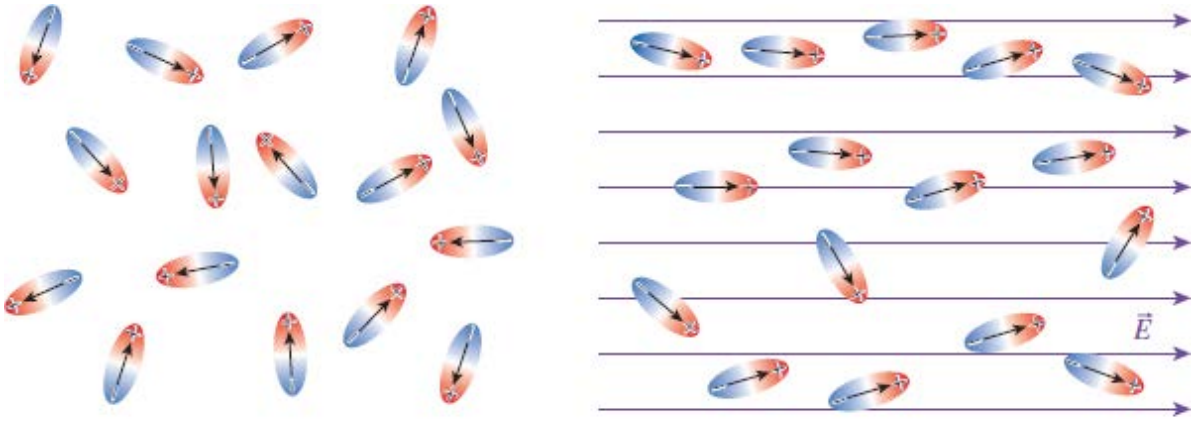

FIGURE 24.29 Polar molecules: (a) randomly distributed and (b) oriented by an external electric field.

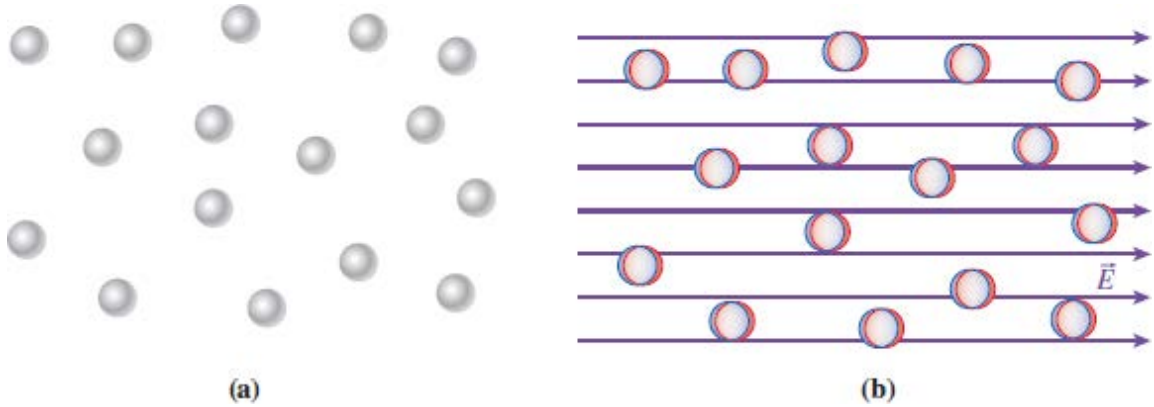

FIGURE 24.30 Nonpolar molecules: (a) with no electric dipole moment and (b) with an electric dipole moment induced by an external electric field.

A **nonpolar dielectric** is a material composed of atoms or molecules that have no inherent electric dipole moment (Figure 24.30a). These atoms or molecules can be induced to have a dipole moment under the influence of an external electric field (Figure 24.30b). The opposite directions of the electric forces acting on the negative and positive charges in the atom or molecule displace these two charge distributions and produce an induced electric dipole moment.

In both polar and nonpolar dielectrics, the fields resulting from the aligned electric dipole moments tend to partially cancel the original external electric field (Figure 24.31). For an electric field, $\vec{E}$, applied across a capacitor with a dielectric between the plates, the resulting electric field, $\vec{E}_{\mathrm{r}}$, inside the capacitor is just the original field plus the electric field induced in the dielectric material, $\vec{E}_{\mathrm{d}}$:

$$\vec{E}_{\mathrm{r}} = \vec{E} + \vec{E}_{\mathrm{d}},$$

or

$$E_{\mathrm{r}} = E - E_{\mathrm{d}}.$$

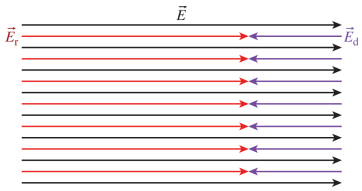

FIGURE 24.31
Partial cancellation of the applied electric field across a parallel plate capacitor by the electric dipoles of a dielectric.

Note that the resulting electric field points in the same direction as the original field but is smaller in magnitude. The dielectric constant is given by $\kappa = E/E_r$.

Electrolytic Capacitors

Instead of consisting of two conducting plates with the gap filled with a dielectric, a capacitor can have one of the plates replaced by an ion-conducting liquid, or electrolyte, that is, a liquid that contains ions that can move freely through it. Most commonly, these *electrolytic capacitors* are constructed of two pieces of aluminum foil, of which one is coated with an insulating oxide layer. The two foil pieces are separated by a paper spacer, which is saturated with the electrolyte. The oxide layer typically has a dielectric constant of ~ 10 and a dielectric strength of $20 - 30\text{kV/mm}$. This layer can therefore be very thin, and this type of electrolytic capacitor has a relatively high charge capacity.

The main drawback of an electrolytic capacitor is that it is polarized and one electrode must always be maintained at a positive potential relative to the other. A reverse potential difference as low as 1-2 V will destroy the oxide layer and lead to short-circuiting and destruction of the capacitor.

Supercapacitors

As we've seen in this chapter, 1 F is a huge amount of capacitance. Even the National Ignition Facility (NIF), which needs the highest possible energy storage, uses only 300-μF capacitors. However, it is possible to create *supercapacitors* (also called *ultracapacitors*) with vastly greater capacitance. This is accomplished by using a material with a very large surface area between the capacitor plates. Activated charcoal is one possibility, as it has a very large surface area because of its foamlike structure at a nanoscale level. Two layers of activated charcoal are given charges of opposite polarity and are separated by an insulating material (represented by the red line in Figure 24.32b). This allows each side of the supercapacitor to store oppositely charged free ions from the electrolyte. The separation between the electrolyte ions and the charges on the activated charcoal is typically on the order of nanometers (nm), that is, millions of times smaller than in conventional capacitors. The activated charcoal provides a surface area many orders of magnitude larger than in conventional capacitors. Since, as noted in Section 24.3, the capacitance is proportional to the surface area and inversely proportional to the plate separation, this technology has resulted in commercially available capacitors with capacitances on the order of kilofarads (kF), that is, millions of times larger than those used in the NIF.

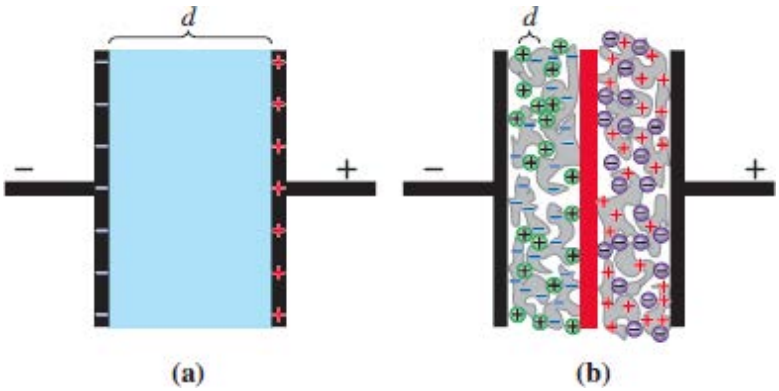

FIGURE 24.32
Comparison of (a) a conventional parallel plate capacitor and (b) a supercapacitor filled with activated charcoal.

Why is the NIF not using supercapacitors? The answer is that these supercapacitors can only function with potential differences of up to 2-3 V. The highest-capacity commercially available supercapacitors have capacitance values of up to 5 kF. Using $U = \frac{1}{2}C(\Delta V)^2$ and $\Delta V = 2$ V shows that a supercapacitor can hold 10 kJ. The 300-μF capacitors used at NIF, when charged to 24 kV, can hold 86.4 kJ. In addition, they can also be discharged much more rapidly, which is crucial for fulfilling the high power requirement of the NIF's laser.

However, supercapacitors can reach energy storage capabilities that rival those of conventional batteries. In addition, supercapacitors can be charged and discharged millions of times, compared to perhaps thousands of times for rechargeable batteries. This, along with their very short charging time, makes them potentially suitable for many applications. For example, there is intense research into using these supercapacitors for electric vehicles. A bus based on this energy storage technology, named *capabus,* is currently in use in Shanghai, China (see Figure 24.33).

FIGURE 24.33 Supercapacitor-powered bus recharging at a bus stop in Shanghai, China.

W. Bauer and G. D. Westfall

A promising line of research on improving the potential difference that supercapacitors can employ is investigating the use of carbon nanotubes and graphene instead of activated charcoal. The first laboratory prototypes are very promising, and commercial products based on this approach could be in use within a few years. Research has also succeeded in improving the energy storage capabilities of supercapacitors while lowering the prices. A 5-kF supercapacitor that cost about $5,000 in 2000 can now be purchased for 1% of that price.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- The capacitance of a capacitor—its ability to store charge—is defined in terms of the charge, q, that can be stored on the capacitor and the potential difference, V, across the plates: $q = C\Delta V$.
- The farad is the unit of capacitance: $1\text{F} = \frac{1\text{C}}{1\text{V}}$.
- The capacitance of a parallel plate capacitor with plates of area A with a vacuum (or air) between the plates separated by distance d is given by $C = \frac{\epsilon_0 A}{d}$.
- The capacitance of a cylindrical capacitor of length L consisting of two collinear cylinders with a vacuum (or air) between the cylinders with inner radius r_1 and outer radius r_2 is given by $C = \frac{2\pi\epsilon_0 L}{\ln(r_2/r_1)}$.
- The capacitance of a spherical capacitor consisting of two concentric spheres with vacuum (or air) between the spheres with inner radius r_1 and outer radius r_2 is given by $C = 4\pi\epsilon_0 \frac{r_1 r_2}{r_2 - r_1}$.
- The electric energy density, u, between the plates of a parallel plate capacitor with vacuum (or air) between the plates is given by $u = \frac{1}{2}\epsilon_0 E^2$.
- A system of n capacitors connected in parallel in a circuit can be replaced by an equivalent capacitance given by the sum of the capacitances of the capacitors: $C_{\text{eq}} = \sum_{i=1}^{n} C_i$.
- A system of n capacitors connected in series in a circuit can be replaced by an equivalent capacitance given by the

reciprocal of the sum of the reciprocal capacitances of the capacitors: $\frac{1}{C_{\text{eq}}} = \sum_{i=1}^{n} \frac{1}{C_i}$.

- When the space between the plates of a capacitor is filled with a dielectric whose dielectric constant is *k* the capacitance increases relative to the capacitance in air: $C = \kappa C_{\text{air}}$.
- The electric potential energy stored in a capacitor is $U = \frac{1}{2} q^2/C = \frac{1}{2} C(\Delta V)^2 = \frac{1}{2} q \Delta V$.

ANSWERS TO SELF-TEST OPPORTUNITIES

24.1 The electric field remains constant.

24.2 Series : $\dfrac{1}{C_{\text{eq}}} = \dfrac{4}{C} \Rightarrow C_{\text{eq}} = \dfrac{1}{4}C = 2.50\ \mu\text{F}.$

Parallel : $C_{\text{eq}} = 4C = 40.0\ \mu\text{F}.$

24.3 $100\ \text{V} = d(2500\text{V/mm}) \Rightarrow d = 0.04\ \text{mm}.$

PROBLEM-SOLVING GUIDELINES: STATIC EQUILIBRIUM

1. Remember that saying a capacitor has charge q means that one plate has charge $+q$ and the other plate has charge $-q$. Be sure you understand how a charge applied to a capacitor is distributed between the two conducting plates; review Example 24.3 if you're uncertain about this.

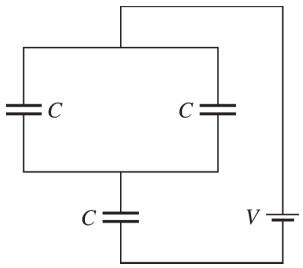
2. It is always a good idea to draw a circuit diagram when solving a problem involving a circuit, if one is not supplied. Identifying series and parallel connections can take some practice, but is usually an important first step in reducing a complicated-looking circuit to an equivalent circuit that is straightforward to deal with. Remember that capacitors connected in series all have the same charge, and capacitors connected in parallel all have the same potential difference.

3. You can remember most of the important results for a capacitor with a dielectric if you remember that a dielectric increases the capacitance. (This is what makes a dielectric useful.) If your calculations show a reduced capacitance with a dielectric, recheck your work.

4. You can calculate the energy stored in a capacitor if you know two out of these three quantities: the charge on a plate, the capacitance of the capacitor, and the potential difference between the plates. Make sure you take advantage of equation 24.15 in the appropriate form.

MULTIPLE-CHOICE QUESTIONS

24.1 In the circuit shown in the figure, the capacitance for each capacitor is C. The equivalent capacitance for these three capacitors is



a) $\frac{1}{3}C$.

b) $\frac{2}{3}C$.

c) $\frac{2}{3}C$.

d) $\frac{3}{5}C$.

e) C.

f) $\frac{5}{3}C$.

24.2 A parallel plate capacitor of capacitance C has plates of area A with distance d between them. When the capacitor is connected to a battery supplying potential difference V, it has a charge of magnitude Q on its plates. While the capacitor is connected to the battery, the distance between the plates is decreased by a factor of 3. The magnitude of the charge on the plates and the capacitance will then be

a) $\frac{1}{3}Q$ and $\frac{1}{3}C$.

b) $\frac{1}{3}Q$ and $3C$.

c) $3Q$ and $3C$.

d) $3Q$ and $\frac{1}{3}C$.

24.3 The distance between the plates of a parallel plate capacitor is reduced by half and the area of the plates is doubled. What happens to the capacitance?

a) It remains unchanged.

b) It doubles.

c) It quadruples.

d) It is reduced by half.

24.4 Which of the following capacitors has the largest charge?

a) a parallel plate capacitor with an area of 10 cm^2 and a plate separation of 2 mm connected to a 10-V battery

b) a parallel plate capacitor with an area of 5 cm^2 and a plate separation of 1 milimeter connected to a 10 V battery

c) a parallel plate capacitor with an area of 10 cm^2 and a plate separation of 4 mm connected to a 5 V battery

d) a parallel plate capacitor with an area of 20 cm^2 and a plate separation of 2 mm connected to a 20-V battery

e) All of the capacitors have the same charge.

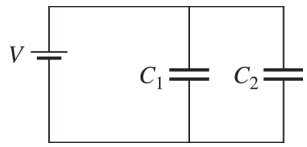
24.5 Two identical parallel plate capacitors are connected in a circuit as shown in the figure. Initially the space between the plates of each capacitor is filled with air. Which of the following changes will double the total amount of charge stored on both capacitors with the same applied potential difference?

a) Fill the space between the plates of C_1 with glass (dielectric constant of 4) and leave C_2 as is.

b) b) Fill the space between the plates of C_1 with Teflon (dielectric constant of 2) and leave C_2 as is.

c) c) Fill the space between the plates of both C_1 and C_2 with Teflon (dielectric constant of 2).

d) d) Fill the space between the plates of both C_1 and C_2 with glass (dielectric constant of 4).



24.6 The space between the plates of an isolated parallel plate capacitor is filled with a slab of dielectric material. The magnitude of the charge *Q* on each plate is kept constant. If the dielectric material is removed the energy stored in the capacitor

a) increases.

b) stays the same.

c) decreases.

d) may increase or decrease.

24.7 Which of the following is (are) proportional to the capacitance of a parallel plate capacitor?

a) the charge stored on each conducting plate

b) the potential difference between the two plates

c) the separation distance between the two plates

d) the area of each plate

e) all of the above

f) none of the above

24.8 A dielectric with the dielectric constant $\kappa = 4$ is inserted into a parallel plate capacitor, filling $\frac{1}{3}$ of the volume, as shown in the figure. If the capacitance of the capacitor without the dielectric is *C,* what is the capacitance of the capacitor with the dielectric?

a) $0.75C$

b) C

c) $2C$

d) $4C$

e) $6C$

24.9 A parallel plate capacitor is connected to a battery for charging. After some time, while the battery is still connected to the capacitor, the distance between the capacitor plates is doubled. Which of the following is (are) true?

a) The electric field between the plates is halved.

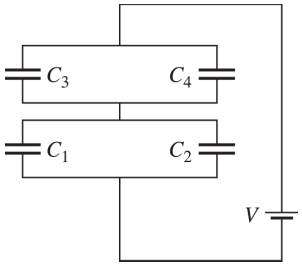
b) The potential difference of the battery is halved.

c) The capacitance doubles.

d) The potential difference across the plates does not change.

e) The charge on the plates does not change.

24.10 Referring to the figure, decide which of the following equations is (are) true. Assume that all of the capacitors have different capacitances. The potential difference across capacitor C_1 is V_1. The potential difference across capacitor C_2 is V_2. The potential difference across capacitor C_3 is V_3. The potential difference across capacitor C_4 is V_4. The charge stored in capacitor C_1 is q_1. The charge stored in capacitor C_2 is q_2. The charge stored in capacitor C_3 is q_3. The charge stored in capacitor C_4 is q_4.



a) $q_1 = q_3$

b) $V_1 + V_2 = V$

c) $q_1 + q_2 = q_3 + q_4$

d) $V_1 + V_2 = V_3 + V_4$

e) $V_1 + V_3 = V$

24.11 You have *N* identical capacitors, each with capacitance *C*, connected in series. The equivalent capacitance of this system of capacitors is

a) NC

b) C/N.

c) N^2C.

d) C/N^2.

e) C.

24.12 You have *N* identical capacitors, each with capacitance *C*, connected in parallel. The equivalent capacitance of this system of capacitors is

a) NC

b) C/N.

c) N^2C.

d) C/N^2.

e) C.

24.13 When a dielectric is placed between the plates of a charged, isolated capacitor, the electric field inside the capacitor

a) increases.

b) decreases.

c) stays the same.

d) increases if the charge on the plates is positive.

e) decreases if the charge on the plates is positive.

24.14 A parallel plate capacitor with a dielectric filling the volume between its plates is charged. The charge is

a) stored on the plates.

b) stored on the dielectric.

c) stored both on the plates and in the dielectric.

CONCEPTUAL QUESTIONS

24.15 Must a capacitor's plates be made of conducting material? What would happen if two insulating plates were used instead of conducting plates?

24.16 Does it take more work to separate the plates of a charged parallel plate capacitor while it remains connected to the charging battery or after it has been disconnected from the charging battery?

24.17 When working on a piece of equipment, electricians and electronics technicians sometimes attach a grounding wire to the equipment even after turning the device off and unplugging it. Why would they do this?

24.18 Table 24.1 does not list a value of the dielectric constant for any good conductor. What value would you assign to it?

24.19 A parallel plate capacitor is charged with a battery and then disconnected from the battery, leaving a certain amount of energy stored in the capacitor. The separation between the plates is then increased. What happens to the energy stored in the capacitor? Discuss your answer in terms of energy conservation.

24.20 You have an electric device containing a $10.0 - \mu F$ capacitor, but an application requires an $18.0 - \mu F$ capacitor. What modification can you make to your device to increase its capacitance to $18.0 - \mu F$?

24.21 Two capacitors with capacitances C_1 and C_2 are connected in series. Show that, no matter what the values of C_1 and C_2 are, the equivalent capacitance is always less than the smaller of the two capacitances.

24.22 Two capacitors, with capacitances C_1 and C_2, are connected in series. A potential difference, V_0, is applied across the combination of capacitors. Find the potential differences V_1 and V_2 across the individual capacitors, in terms of V_0, C_1, and C_2.

24.23 An isolated solid spherical conductor of radius 5.00 cm is surrounded by dry air. It is given a charge and acquires potential *V,* with the potential at infinity assumed to be zero.

a) Calculate the maximum magnitude *V* can have.

b) Explain clearly and concisely *why* there is a maximum.

24.24 A parallel plate capacitor with capacitance *C* is connected to a power supply that maintains a constant potential difference, *V*. A slab of dielectric, with dielectric constant *k*, is then inserted into and completely fills the previously empty space between the plates.

a) What was the energy stored on the capacitor before the insertion of the dielectric?

b) What was the energy stored after the insertion of the dielectric?

c) Was the dielectric pulled into the space between the plates, or did it have to be pushed in? Explain.

24.25 A parallel plate capacitor with square plates of edge length *L* separated by a distance *d* is given a charge *Q,* then disconnected from its power source. A close-fitting square slab of dielectric, with dielectric constant κ, is then inserted into the previously empty space between the plates. Calculate the force with which the slab is pulled into the capacitor during the insertion process.

24.26 A cylindrical capacitor has an outer radius *R* and a separation *d* between the cylinders. Determine what the capacitance approaches in the limit where $d \ll R$. (*Hint:* Express the capacitance in terms of the ratio d/R and then examine what happens as that ratio becomes very small compared to 1.) Explain why the limit on the capacitance makes sense.

24.27 A parallel plate capacitor is constructed from two plates of different areas. If this capacitor is initially uncharged and then connected to a battery, how will the amount of charge on the big plate compare to the amount of charge on the small plate?

24.28 A parallel plate capacitor is connected to a battery. As the plates are moved farther apart, what happens to each of the following?

a) the potential difference across the plates

b) the charge on the plates

c) the electric field between the plates

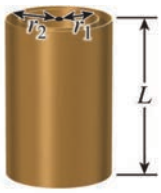
EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 24.3

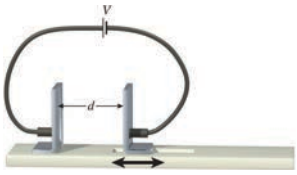
24.29 Supercapacitors, with capacitances of 1.00 F or more, are made with plates that have a spongelike structure with a very large surface area. Determine the surface area of a supercapacitor that has a capacitance of 1.00 F and an effective separation between the plates of $d = 1.00$ mm.

24.30 A potential difference of 100. V is applied across the two collinear conducting cylinders shown in the figure. The radius of the outer cylinder is 15.0 cm, the radius of the inner cylinder is 10.0 cm, and the length of the two cylinders is 40.0 cm. How much charge is applied to each of the cylinders? What is the magnitude of the electric field between the two cylinders?



24.31 What is the radius of an isolated spherical conductor that has a capacitance of 1.00 F?

24.32 A spherical capacitor is made from two thin concentric conducting shells. The inner shell has radius r_1, and the outer shell has radius r_2. What is the fractional difference in the capacitances of this spherical capacitor and a parallel plate capacitor made from plates that have the same area as the inner sphere and the same separation $d = r_2 - r_1$ between them?



24.33 Calculate the capacitance of the Earth. Treat the Earth as an isolated spherical conductor of radius 6371 km.

24.34 Two concentric metal spheres are found to have a potential difference of 900. V when a charge of $6.726 \cdot 10^{-8}$C is applied to

them. The radius of the outer sphere is 0.210 m. What is the radius of the inner sphere?

•**24.35** A capacitor consists of two parallel plates, but one of them can move relative to the other as shown in the figure. Air fills the space between the plates, and the capacitance is 32.0 pF when the separation between plates is $d = 0.500$ cm.

a) A battery supplying a potential difference $V = 9.00$ V is connected to the plates. What is the charge distribution, σ, on the left plate? What are the capacitance, C', and the charge distribution, σ', when d is changed to 0.250 cm?

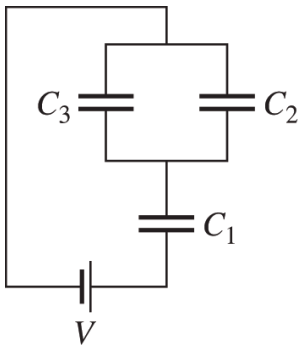
b) With $d = 0.500$ cm, the battery is disconnected from the plates. The plates are then moved so that $d = 0.250$ cm.. What is the potential difference V', between the plates?

Section 24.4

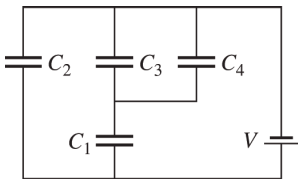
24.36 Determine all the values of equivalent capacitance you can create using any combination of three identical capacitors with capacitance C.

24.37 A large parallel plate capacitor with plates that are square with side length 1.00 cm and are separated by a distance of 1.00 mm is dropped and damaged. Half of the areas of the two plates are pushed closer together to a distance of 0.500 mm. What is the capacitance of the damaged capacitor?

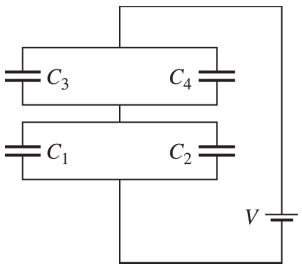
24.38 Three capacitors with capacitances $C_1 = 3.10\ \text{nF},\ C_2 = 1.30\ \text{nF}$, and $C_3 = 3.70\ \text{nF}$ are wired to a battery with $V = 14.9\ \text{V}$. as shown in the figure. What is the potential drop across capacitor C_2?



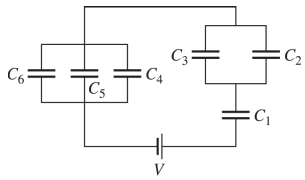
24.39 Four capacitors with capacitances $C_1 = 3.50\ \text{nF}$, $C_2 = 2.10\ \text{nF}$, $C_3 = 1.30\ \text{nF}$, and $C_4 = 4.90\ \text{nF}$ are wired to a battery with $V = 10.0\ \text{V}$. as shown in the figure. What is the equivalent capacitance of this set of capacitors?



24.40 The capacitors in the circuit shown in the figure have capacitances $C_1 = 18.0\ \mu\text{F},\ C_2 = 11.3\ \mu\text{F}, C_3 = 33.0\ \mu\text{F}$, and $C_4 = 44.0\ \mu\text{F}$. The potential difference is $V = 10.0\ \text{V}$. What is the total charge the power source must supply to charge this arrangement of capacitors?



24.41 Six capacitors are connected as shown in the figure.



a) If $C_3 = 2.300$ nF, what does C_2 have to be to yield an equivalent capacitance of 5.000 nF for the combination of the two capacitors?

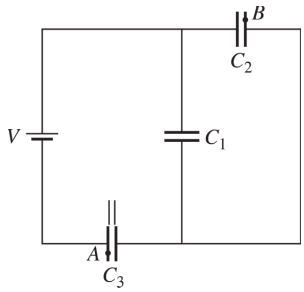
b) For the same values of C_2 and C_3 as in part (a), what is the value of C_1 that will give an equivalent capacitance of 1.914 nF for the combination of the three capacitors?

c) For the same values of C_1, C_2, and C_3 as in part (b), what is the equivalent capacitance of the whole set of capacitors if the values of the other capacitances are $C_4 = 1.300$ nF, $C_5 = 1.700$ nF, and $C_6 = 4.700$ nF?

d) If a battery with a potential difference of 11.70 V is connected to the capacitors as shown in the figure, what is the total charge on the six capacitors?

e) What is the potential drop across C_5 in this case?

• **24.42** A potential difference of $V = 80.0$ V is applied across a circuit with capacitances $C_1 = 15.0$ nF, $C_2 = 7.00$ nF, and $C_3 = 20.0$ nF, as shown in the figure. What is the magnitude and sign of q_{31}, the charge on the left plate of C_3 (marked by point A)? What is the electric potential, V_3, across C_3? What is the magnitude and sign of the charge q_{2r}, on the right plate of C_2 (marked by point B)?



•**24.43** Fifty parallel plate capacitors are connected in series. The distance between the plates is d for the first capacitor, $2d$ for the second capacitor, $3d$ for the third capacitor, and so on. The area of the plates is the same for all the capacitors. Express the equivalent capacitance of the whole set in terms of C_1 (the capacitance of the first capacitor).

•**24.44** A 5.00 nF capacitor charged to 60.0 V and a 7.00-nF capacitor charged to 40.0 V are connected negative plate to negative plate. What is the final charge on the 7.00-nF capacitor?

Section 24.5

24.45 When a capacitor has a charge of magnitude 60.0 μC on each plate, the potential difference across the plates is 12.0 V. How much energy is stored in this capacitor when the potential difference across its plates is 12.0 V?

24.46 The capacitor in an automatic external defibrillator is charged to 7.50 kV and stores 2400. J of energy. What is its capacitance?

24.47 The Earth has an electric field of 150. V/m near its surface. Find the electrical energy contained in each cubic meter of air near the surface.

•**24.48** The potential difference across two capacitors in series is 120. V. The capacitances are $C_1 = 1.00 \cdot 10^3 \mu F$ and $C_2 = 1.50 \cdot 10^3 \mu F$.

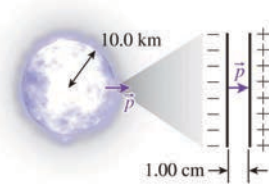
a) What is the total capacitance of this pair of capacitors?

b) What is the charge on each capacitor?

c) What is the potential difference across each capacitor?

d) What is the total energy stored by the capacitors?

•**24.49** Neutron stars are thought to have electric dipole $(\vec{p})$ layers at their surfaces. If a neutron star with a 10.0-km radius has a dipole layer 1.00 cm thick with charge distributions of $+1.00\ \mu C/cm^2$ and $-1.00\ \mu C/cm^2$ on the surface, as indicated in the figure, what is the capacitance of this star? What is the electric potential energy stored in the neutron star's dipole layer?



•**24.50** A $4.00.10^3$ − nF parallel plate capacitor is connected to a 12.0-V battery and charged.

a) What is the charge Q on the positive plate of the capacitor?

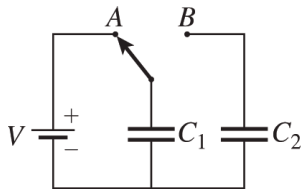
b) What is the electric potential energy stored in the capacitor?

The $4.00.10^3$ – nF capacitor is then disconnected from the 12.0-V battery and used to charge three uncharged capacitors, a 100.-nF capacitor, a 200.-nF capacitor, and a 300.-nF capacitor, connected in series.

c) After charging, what is the potential difference across each of the four capacitors?

d) How much of the electrical energy stored in the $4.00.10^3$ – nF capacitor was transferred to the other three capacitors?

•**24.51** The figure shows a circuit with $V = 12.0$ V, $C_1 = 500.$ pF, and $C_2 = 500.$pF. The switch is closed, to *A,* and the capacitor C_1 is fully charged. Find (a) the energy delivered by the battery and (b) the energy stored in C_1. Then the switch is thrown to *B* and the circuit is allowed to reach equilibrium. Find (c) the total energy stored at C_1 and C_2. (d) Explain the energy loss, if there is any.



•• **24.52** The Earth is held together by its own gravity. But it is also a charge-bearing conductor.

a) The Earth can be regarded as a conducting sphere of radius 6371 km, with electric field $\vec{E} = (-150.\ \text{V/m})\hat{r}$ at its surface, where $\hat{r}$ is a unit vector directed radially outward. Calculate the total electric potential energy associated with the Earth's electric charge and field.

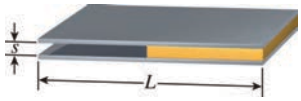
b) The Earth has gravitational potential energy, akin to the electric potential energy. Calculate this energy, treating the Earth as a uniform solid sphere. $(Hint: dU = -(Gm/r)dm.)$

c) Use the results of parts (a) and (b) to address this question: To what extent do electrostatic forces affect the structure of the Earth?

Section 24.6

24.53 Two parallel plate capacitors have identical plate areas and identical plate separations. The maximum energy each can store is determined by the maximum potential difference that can be applied before dielectric breakdown occurs. One capacitor has air between its plates, and the other has Mylar. Find the ratio of the maximum energy the Mylar capacitor can store to the maximum energy the air capacitor can store.

24.54 A capacitor has parallel plates, with half of the space between the plates filled with a dielectric material of constant k and the other half filled with air as shown in the figure. Assume that the plates are square, with sides of length L, and that the separation between the plates is s. Determine the capacitance as a function of L.



24.55 Calculate the maximum surface charge distribution that can be maintained on any surface surrounded by dry air.

24.56 Thermocoax is a type of coaxial cable used for high-frequency filtering in cryogenic quantum computing experiments. Its stainless-steel shield has an inner diameter of 0.350 mm, and its Nichrome conductor has a diameter of 0.170 mm. Nichrome is used because its resistance doesn't change much in going from room temperature to near absolute zero. The insulating dielectric is magnesium oxide (MgO), which has a dielectric constant of 9.70. Calculate the capacitance per meter of Thermocoax.

24.57 A parallel plate capacitor has square plates of side $L = 10.0$ cm and a distance $d = 1.00$ cm between the plates. Of the space between the plates, $\frac{1}{5}$ is filled with a dielectric with dielectric constant $\kappa_1 = 20.0$. The remaining $\frac{4}{5}$ of the space is filled with a different dielectric, with $\kappa_2 = 5.00$. Find the capacitance of the capacitor.

•**24.58** A $4.0 - \text{nF}$ parallel plate capacitor with a sheet of Mylar ($\kappa = 3.1$) filling the space between the plates is charged to a potential difference of 120 V and is then disconnected.

a) How much work is required to completely remove the sheet of Mylar from the space between the two plates?

b) What is the potential difference between the plates of the capacitor once the Mylar is completely removed?

•**24.59** The volume between the two cylinders of a cylindrical capacitor is half filled with a dielectric whose dielectric constant is k and is connected to a battery with a potential difference ΔV. What is the charge placed on the capacitor? What is the ratio of this charge to the charge placed on an identical capacitor with no dielectric connected in the same way across the same potential drop?

•**24.60** A dielectric slab with thickness d and dielectric constant $\kappa = 2.31$ is inserted in a parallel place capacitor that has been charged by a 110.-V battery and has area $A = 100.\text{cm}^2$ and separation distance $d = 2.50$ cm.

a) Find the capacitance, *C,* the potential difference, *V,* the electric field, *E,* the total charge stored on the capacitor *Q,* and electric potential energy stored in the capacitor, *U,* before the dielectric material is inserted.

b) Find the capacitance, *C,* the potential difference, *V,* the electric field, *E,* the total charge stored on the capacitor *Q,* and electric potential energy stored in the capacitor, *U,* before the dielectric material is inserted.

c) Find *C, V, E, Q,* and *U* when the dielectric slab has been inserted and the battery is still connected.

d) Find *C, V, E, Q,* and *U* when the dielectric slab is in place and the battery is disconnected.

•**24.61** A parallel plate capacitor has a capacitance of 120. pF and a plate area of 100. cm^2. The space between the plates is filled with mica whose dielectric constant is 5.40. The plates of the capacitor are kept at 50.0 V.

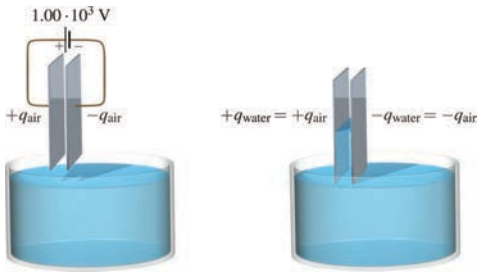
a) What is the strength of the electric field in the mica?

b) What is the amount of free charge on the plates?

c) What is the amount of charge induced on the mica?

•• **24.62** Design a parallel plate capacitor with a capacitance of 47.0 pF and a capacity of 7.50 nC. You have available conducting plates, which can be cut to any size, and Plexiglas sheets, which can be cut to any size and machined to any thickness. Plexiglas has a dielectric constant of 3.40 and a dielectric strength of $3.00 \cdot 10^7 \text{V/m}$. You must make your capacitor as compact as possible. Specify all relevant dimensions. Ignore any fringe field at the edges of the capacitor plates.

•• **24.63** A parallel plate capacitor consisting of a pair of rectangular plates, each measuring 1.00 cm by 10.0 cm, with a separation between the plates of 0.100 mm, is charged by a power supply at a potential difference of $1.00 \cdot 10^3 \text{V}$. The power supply is then removed, and without being discharged, the capacitor is placed in a vertical position over a container holding de-ionized water, with the short sides of the plates in contact with the water, as shown in the figure. Using energy considerations, show that the water will rise between the plates. Neglecting other effects, determine the system of equations that can be used to calculate the height to which the water rises between the plates. You do not have to solve the system.

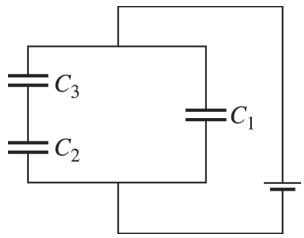


Additional Exercises

24.64 Two circular metal plates of radius 0.610 m and thickness 7.10 mm are used in a parallel plate capacitor. A gap of 2.10 mm is left between the plates, and half of the space (a semicircle) between them is filled with a dielectric for which $\kappa = 11.1$ and the other half is filled with air. What is the capacitance of this capacitor?

24.65 Considering the dielectric strength of air, what is the maximum amount of charge that can be stored on the plates of a capacitor that are a distance of 15 mm apart and have an area of 25 cm^2?

24.66 The figure shows three capacitors in a circuit: $C_1 = 2.00$ nF and $C_2 = C_3 = 4.00$ nF. Find the charge on each capacitor when the potential difference applied is $V = 1.50$ V.



24.67 A capacitor with a vacuum between its plates is connected to a battery and then the gap is filled with Mylar. By what percentage is its energy-storing capacity increased?

24.68 A parallel plate capacitor with a plate area of 12.0 cm^2 and air in the space between the plates, which are separated by 1.50 mm, is connected to a 9.00-V battery. If the plates are pulled back so that the separation increases to 2.75 mm, how much work is done?

24.69 Suppose you want to make a 1.00-F capacitor using two square sheets of aluminum foil. If the sheets of foil are separated by a single piece of paper (thickness of about 0.100 mm and $\kappa = 5.00$. find the size of the sheets of foil (the length of each edge).

24.70 A 4.00-pF parallel plate capacitor has a potential difference of 10.0 V across it. The plates are 3.00 mm apart, and the space between them contains air.

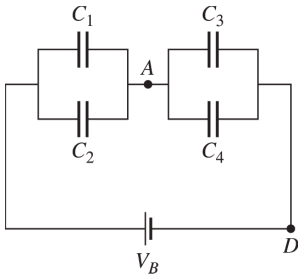
a) What is the charge on the capacitor?

b) How much energy is stored in the capacitor?

c) What is the area of the plates?

d) d) What would the capacitance of this capacitor be if the space between the plates were filled with polystyrene?

24.71 A four-capacitor circuit is charged by a battery, as shown in the figure. The capacitances are $C_1 = 1.00\ \text{mF},\ C_2 = 2.00\ \text{mF},\ C_3 = 3.00\ \text{mF}$, and $C_4 = 4.00\ \text{mF}$, and the battery potential is $V_\text{B} = 1.00\ \text{V}$. When the circuit is at equilibrium, point D has potential $V_D = 0.00\ \text{V}$. What is the potential, V_A, at point A?



24.72 How much energy can be stored in a capacitor with two parallel plates, each with an area of 64.0 cm^2 and separated by a gap of 1.30 mm, filled with porcelain whose dielectric constant is 7.00, and holding equal and opposite charges of magnitude 420. μC?

24.73 A quantum mechanical device known as the *Josephson junction* consists of two overlapping layers of superconducting metal (for example, aluminum at 1.00 K) separated by 20.0 nm of aluminum oxide, which has a dielectric constant of 9.10. If this device has an area of 100. μm^2 and a parallel plate configuration, estimate its capacitance.

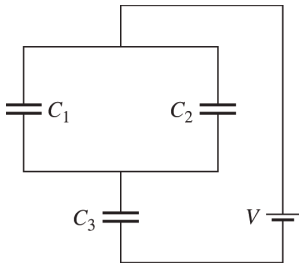
24.74 Three capacitors with capacitances $C_1 = 6.00\ \mu\text{F},\ C_2 = 3.00\ \mu\text{F}$, and $C_3 = 5.00\ \mu\text{F}$ are connected in a circuit as shown in the figure, with an applied potential of V. After the charges on the capacitors have reached their equilibrium

values, the charge Q_2 on the second capacitor is found to be 40.0 μC.

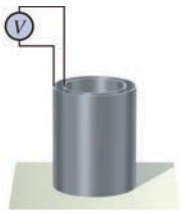
a) What is the charge, Q_1, on capacitor C_1?

b) What is the charge, Q_3, on capacitor C_3?

c) How much voltage, *V,* was applied across the capacitors?



24.75 For a science project, a fourth-grader cuts the tops and bottoms off two soup cans of equal height, 7.24 cm, and with radii of 3.02 cm and 14.16 cm, puts the smaller one inside the larger, and hot-glues them both on a sheet of plastic, as shown in the figure. Then she fills the gap between the cans with a special "soup" (dielectric constant of 63.0). What is the capacitance of this arrangement?



24.76 The Earth can be thought of as a spherical capacitor. If the net charge on the Earth is $-7.80 \cdot 10^5$C, find (a) the capacitance of the Earth and (b) the electric potential energy stored on the Earth's surface.

• **24.77** A parallel plate capacitor with air in the gap between the plates is connected to a 6.00-V battery. After charging, the energy stored in the capacitor is 72.0 nJ. Without disconnecting the capacitor from the battery, a dielectric is inserted into the gap and an additional 317 nj of energy flows from the battery to the capacitor.

a) What is the dielectric constant of the dielectric?

b) If each of the plates has an area of $50.0\ \text{cm}^2$, what is the charge on the positive plate of the capacitor after the dielectric has been inserted?

c) What is the magnitude of the electric field between the plates before the dielectric is inserted?

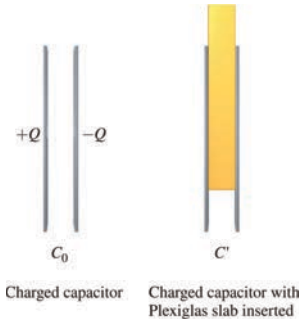
d) What is the magnitude of the electric field between the plates after the dielectric is inserted?

•**24.78** An 8.00-μF capacitor is fully charged by a 240.-V battery, which is then disconnected. Next, the capacitor is connected to an initially uncharged capacitor of capacitance *C,* and the potential difference across it is found to be 80.0 V. What is *C*? How much energy ends up being stored in the second capacitor?

•**24.79** A parallel plate capacitor consists of square plates of edge length 2.00 cm separated by a distance of 1.00 mm. The capacitor is charged with a 15.0 V battery, and the battery is then removed. A 1.00 mm-thick sheet of nylon (dielectric constant of 3.50) is slid between the plates. What is the average force (magnitude and direction) on the nylon sheet as it is inserted into the capacitor?

•**24.80** A proton traveling along the *x*-axis at a speed of $1.00 \cdot 10^6 \text{m/s}$ enters the gap between the plates of a 2.00 cm-wide parallel plate capacitor. The surface charge distributions on the plates are given by $\sigma = \pm 1.00 \cdot 10^{-6} \text{C/m}^2$. How far has the proton been deflected sideways (Δy) when it reaches the far edge of the capacitor? Assume that the electric field is uniform inside the capacitor and zero outside.

•**24.81** A parallel plate capacitor has square plates of side $L = 10.0\ \text{cm}$ separated by a distance $d = 2.50\ \text{mm}$, as shown in the figure. The capacitor is charged by a battery with potential difference $V_0 = 75.0\ \text{V}$; the battery is then disconnected.



a) Determine the capacitance, C_0, and the electric potential energy, U_0, stored in the capacitor at this point.

b) A slab made of Plexiglas ($\kappa = 3.40$) is then inserted so that it fills $\frac{2}{3}$ of the volume between the plates, as shown in the figure. Determine the new capacitance, C', the new potential difference between the plates, V', and the new electric potential energy, U', stored in the capacitor.

c) Neglecting gravity, did the inserter of the dielectric slab have to do work or not?

•**24.82** A typical AAA battery has stored energy of about 3400 J. (Battery capacity is typically listed as 625 mA h, meaning that much charge can be delivered at approximately 1.5 V.) Suppose you want to build a parallel plate capacitor to store this amount of energy, using a plate separation of 1.0 mm and with air filling the space between the plates.

a) Assuming that the potential difference across the capacitor is 1.50 V, what must the area of each plate be?

b) Assuming that the potential difference across the capacitor is the maximum that can be applied without dielectric breakdown occurring, what must the area of each plate be?

c) Is either capacitor a practical replacement for the AAA battery?

•**24.83** Two parallel plate capacitors, C_1 and C_2, are connected in series to a 96.0-V battery. Both capacitors have plates with an area of 1.00 cm^2 and a separation of 0.100 mm; C_1, has air between its plates, and C_2, has that space filled with porcelain (dielectric constant of 7.00 and dielectric strength of 5.70 kV/mm.).

a) After charging, what are the charges on each capacitor?

b) What is the total energy stored in the two capacitors?

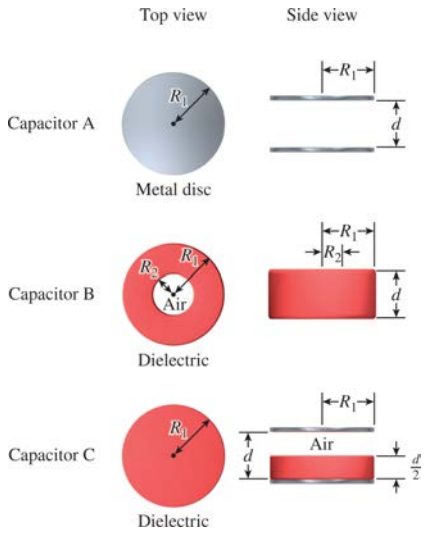
c) What is the electric field between the plates of C_2?

•24.84 The plates of parallel plate capacitor A consist of two metal discs of identical radius, $R_1 = 4.00$ cm, separated by a distance $d = 2.00$ mm, as shown in the figure.

a) Calculate the capacitance of this parallel plate capacitor with the space between the plates filled with air.

b) A dielectric in the shape of a thick-walled cylinder of outer radius $R_1 = 4.00$ cm, inner radius $R_2 = 2.00$ cm, thickness $d = 2.00$ mm, and dielectric constant $\kappa = 2.00$ is placed between the plates, coaxial with them, as shown in the figure. Calculate the capacitance of capacitor B, with this dielectric.

c) The dielectric cylinder is removed, and instead a solid disc of radius R_1 made of the same dielectric is placed between the plates to form capacitor C, as shown in the figure. What is the new capacitance?



•24.85 A 1.00-μF capacitor charged to 50.0 V and a 2.00-μF capacitor charged to 20.0 V are connected, with the positive plate of each connected to the negative plate of the other. What is the final charge on the 1.00-μF capacitor?

•**24.86** The capacitance of a spherical capacitor consisting of two concentric conducting spheres with radii r_1 and $r_2 (r_2 > r_1)$ is given by $C = 4\ p\ \epsilon_0 r_1 r_2/(r_2 - r_1)$. Suppose that the space between the spheres, from r_1 up to a radius $R (r_1 < R < r_2)$ is filled with a dielectric for which $\epsilon = 10\epsilon_0$. Find an expression for the capacitance, and check the limits when $R = r_1$ and $R = r_2$

•**24.87** In the figure, a parallel plate capacitor is connected to a 300.-V battery. With the capacitor connected, a proton is fired with a speed of $2.00 \cdot 10^5 \text{m/s}$ from (through) the negative plate of the capacitor at an angle θ with the normal to the plate.

a) Show that the proton cannot reach the positive plate of the capacitor, regardless of what the angle θ is.

b) Sketch the trajectory of the proton between the plates.

c) Assuming that $V = 0$ at the negative plate, calculate the potential at the point between the plates where the proton reverses its motion in the x-direction.

d) Assuming that the plates are long enough for the proton to stay between them throughout its motion, calculate the speed (magnitude only) of the proton as it collides with the negative plate.

•• **24.88** For the parallel plate capacitor with dielectric shown in the figure, prove that for a given thickness of the dielectric slab, the capacitance does not depend on the position of the slab relative to the two conducting plates (that is, it does not depend on the values of d_1 and d_3

MULTI-VERSION EXERCISES

24.89 The battery of an electric car stores 53.63 MJ of energy. How many supercapacitors, each with capacitance $C = 3.361$ kF, at a potential difference of 2.121 V, are required to supply this amount of energy?

24.90 The battery of an electric car stores 60.51 MJ of energy. If 6990 supercapacitors, each with capacitance $C = 3.423$ kF, are required to supply this amount of energy, what is the potential difference across each supercapacitor?

24.91 The battery of an electric car stores 67.39 MJ of energy. If 6845 supercapacitors, each with capacitance C and charged to a potential difference of 2.377 V, can supply this amount of energy, what is the value of C for each supercapacitor?

24.92 A parallel plate capacitor with vacuum between the plates has a capacitance of 3.547 μF. A dielectric material with $\kappa = 4.617$ is placed between the plates, completely filling the volume between them. The capacitor is then connected to a battery that maintains a potential difference of 10.03 V across the plates. How much work is required to pull the dielectric material out of the capacitor?

24.93 A parallel plate capacitor with vacuum between the plates has a capacitance of 3.607 μF. A dielectric material is placed between the plates, completely filling the volume between them. The capacitor is then connected to a battery that maintains a potential difference of 11.33 V across the plates. The dielectric material is pulled out of the capacitor, which requires $4.804 \cdot 10^{-4}$ J of work. What is the dielectric constant of the material?

24.94 A parallel plate capacitor with vacuum between the plates has a capacitance of 3.699 μF. A dielectric material with $\kappa = 3.533$ is placed between the plates, completely filling the volume between

them. The capacitor is then connected to a battery that maintains a potential difference V across the plates. The dielectric material is pulled out of the capacitor, which requires $7.389 \cdot 10^{-4}$ J of work. What is the potential difference, V?

Electric lighting is so commonplace that you don't even think about it. You walk into a dark room and simply flick on a switch, bringing the room to nearly daytime brightness (Figure 25.1). However, what happens when the switch is flicked depends ultimately on principles of physics and engineering devices that took decades to develop and refine.

FIGURE 25.1 A current flowing through a wire makes this light bulb shine.

Image Source/Superstock

This chapter is the first to focus on electric charges in motion. It presents some of the fundamental concepts that we'll use in Chapter 26 to analyze basic electric circuits, which are integral to all electronics applications. These chapters concentrate on the electrical effects of moving charges, but you should be aware that moving

charges also give rise to other effects, which we'll start to examine in Chapter 27 on magnetism.

WHAT WE WILL LEARN

- Electric current at a point in a circuit is the rate at which net charge moves past that point.
- Direct current is current flowing in a direction that does not change with time. The direction of current is defined as the direction in which positive charge would be moving.
- The current density passing a given point in a conductor is the current per cross-sectional area.
- The conductivity of a material characterizes the ability of that material to conduct current. Its inverse is resistivity.
- The resistance of a device depends on its geometry and on the material of which it is made.
- The resistivity of a conductor increases approximately linearly with temperature.
- Electromotive force (usually referred to as emf) is a potential difference in an electric circuit.
- Ohm's Law states that the potential drop across a device is equal to the current flowing through the device times the resistance of the device.
- A simple circuit consists of a source of emf and resistors connected in series or in parallel.
- In a circuit diagram, an equivalent resistance can replace resistors connected in series or in parallel.
- The power in a circuit is the product of the current and the voltage drop.
- A diode conducts current in one direction but not in the opposite direction.

25.1 Electric Current

Up to this point, our study of electricity has focused on electrostatics, which deals with the properties of stationary electric charges and fields. Electric circuits were introduced in the discussion of capacitors in Chapter 24, but it covered only situations involving fully charged capacitors, where the charge is at rest. If electrostatics were all there was to electricity, it would not be nearly as important to modern society as it is. The world-changing impact of electricity is due to the properties of charges in motion, or electric current. All electrical devices rely on some kind of current for their operation.

Let's start by looking at a few very simple experiments. When you were a kid, you very likely had some toys that ran on batteries, and probably some of them contained small light bulbs. Consider a very simple circuit consisting only of a battery, a switch, and a light bulb (see Figure 25.2). If the switch is open, as in Figure 25.2a, the light bulb does not shine. If the switch is closed, as in Figure 25.2b, the light bulb turns on. We all know why this happens—because a current flows through the closed circuit. In Chapter 24, we saw that the battery provides a potential difference for the circuit. In this chapter, we'll examine what it means for the current to flow, what the physical basis of current is, and how it is related to the potential difference provided by the battery. We'll see that the light bulb acts as a resistor in the circuit, and we'll examine how resistors behave.

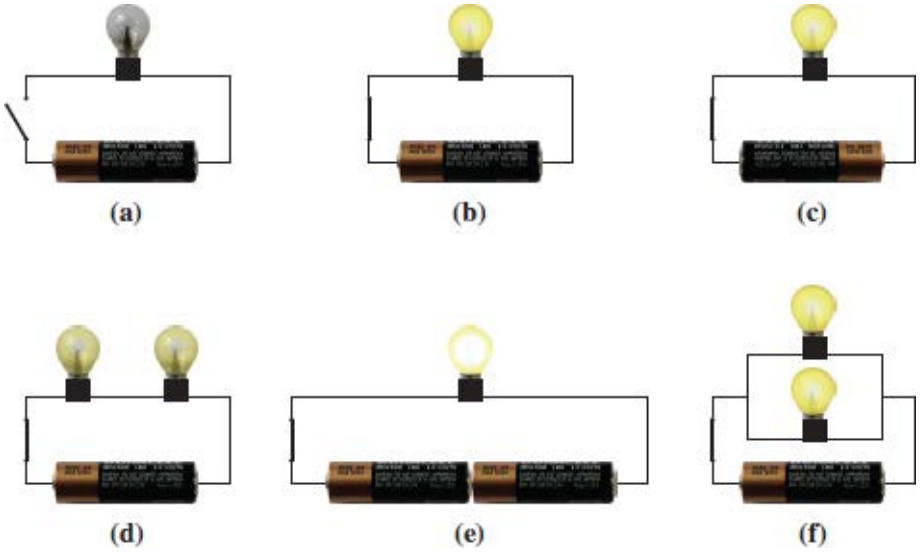

FIGURE 25.2 Experiments with batteries and light bulbs.

a-b: W. Bauer and G. D. Westfall

Let's begin by considering the simple experiment performed in Figure 25.2c, where the battery's orientation is the reverse of what it is in Figure 25.2b. The light bulb shines just the same, despite the fact that the sign of the potential difference provided by the battery is reversed. (The positive terminal of the battery is on the end with the copper color.) In Figure 25.2d, two light bulbs are in the circuit, one behind the other. (Section 25.5 will focus on this arrangement of resistors, which is a connection *in series*.) Each of the two light bulbs shines with significantly less intensity than the single bulb in Figure 25.2c, so the current in the circuit may be smaller than before. On the other hand, two batteries in series, as in Figure 25.2e, double the potential difference in the circuit, and the bulb shines significantly brighter. Finally, if separate wires are used to connect the two light bulbs to a single battery, as shown in Figure 25.2f, the light bulbs shine with about the same intensity as in Figure 25.2b or Figure 25.2c. This way of wiring resistors in a circuit is called a *parallel connection* and will be explored in Section 25.6.

Quantitatively, the **electric current,** i, is the net charge passing a given point in a given time, divided by that time. The random motion of electrons in a conductor is not a current, in spite of the fact

that large amounts of charge are moving past a given point, because no *net* charge flows. If net charge dq passes a point during time dt, the current at that point is, by definition,

$$i = \frac{dp}{dt}. \tag{25.1}$$

The net amount of charge passing a given point in time t is the integral of the current with respect to time:

$$q = \int dp = \int_0^t i \, dt\prime. \tag{25.2}$$

Total charge is conserved, implying that charge flowing in a conductor is never lost. Therefore, the same amount of charge flows into one end of a conductor as emerges from the other end.

The unit of current, coulombs per second, was given the name **ampere** (abbreviated A, or sometimes amp), after the French physicist André Ampère (1775–1836):

$$1\,\mathrm{A} = \frac{1\,\mathrm{C}}{1\,\mathrm{s}}.$$

Some typical currents are 1 A for a light bulb, 200 A for the starter in your car, $1\,\mathrm{mA} = 1 \cdot 10^{-3}\,\mathrm{A}$ to power your MP3 player, 1 nA for the currents in your brain's neurons and synaptic connections, and $10{,}000\,\mathrm{A} = 10^4\,\mathrm{A}$ in a lightning strike (for a short time). The smallest currents that can be measured are those from individual electrons tunneling in scanning tunneling microscopes and are on the order of 10 pA. The largest current in the Solar System is the solar wind, which is in the GA range. Other examples of the broad range of currents are shown in Figure 25.3.

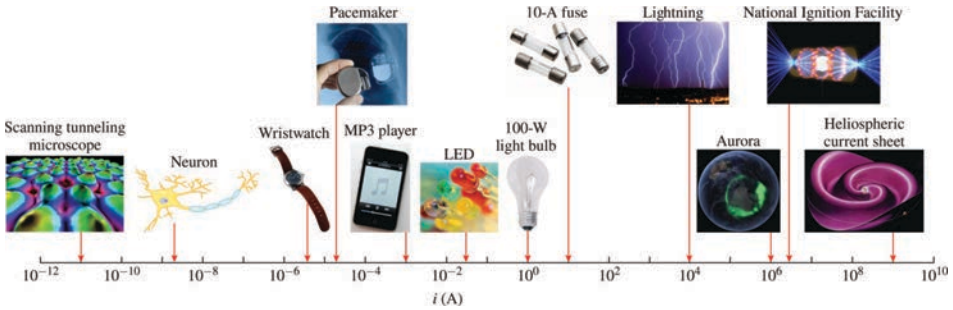

FIGURE 25.3 Examples of electrical currents ranging from 1 pA 1 pA to 10 GA.

You should remember this handy safety rule related to the orders of magnitudes of currents: 1-10-100. That is, 1 mA of current flowing through a human body can be felt (as a tingle, usually), 10 mA of current makes muscles contract to the point that the person cannot let go of the wire carrying the current, and 100 mA is sufficient to stop the heart.

A current that flows in only one direction, which does not change with time, is called **direct current.** (Current that flows first in one direction and then in the opposite direction is called *alternating current* and will be discussed in Chapter 30.) In this chapter, the direction of the current flowing in a conductor is indicated by an arrow.

Physically, the charge carriers in a conductor are electrons, which are negatively charged. However, by convention, positive current is defined as flowing from the positive to the negative terminal. The reason for this counterintuitive definition of current direction is that the definition originated in the second half of the 19th century, when

it was not known that electrons are the charge carriers responsible for current. And so the current direction was simply defined as the direction in which the positive charges would flow.

Self-Test Opportunity 25.1

A typical rechargeable AA battery is rated at 700 mAh. How long can this battery provide a current of 100 μA?

EXAMPLE 25.1 Iontophoresis

There are three ways to administer anti-inflammatory medication. The painless way is the oral one—simply swallowing the drug. However, this method typically leads to a small amount of the drug in the affected tissue, on the order of 1 μg. The second way is to have the drug injected locally with a needle. This hurts but can deposit on the order of 10 mg of the drug in the affected tissue—four orders of magnitude more than with the oral method. However, since the 1990s, a third method has been available, which is also painless and can deposit on the order of 100 μg of a drug in the area where it is needed. This method, called *iontophoresis*, uses (very weak) electrical currents that are sent through the patient's tissue (Figure 25.4). The iontophoresis device consists of a battery and two electrodes (plus other electronic circuitry that allows the nurse to control the strength of the current applied). The anti-inflammatory drug, usually dexamethasone, is applied to the underside of the negatively charged electrode. A current flows through the patient's skin and deposits the drug in the tissue to a depth of up to 1.7 cm.

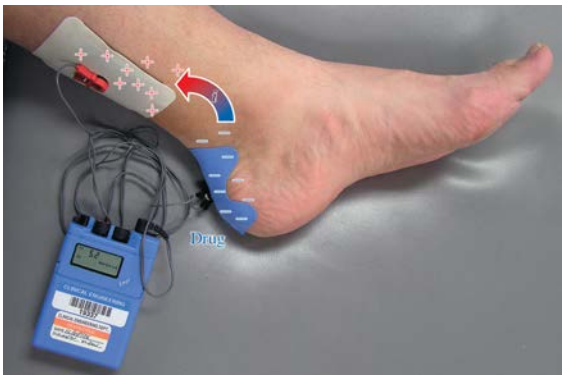

FIGURE 25.4 Iontophoresis is the application of medication under the skin with the aid of electrical current.

W. Bauer and G. D. Westfall

PROBLEM

A nurse wants to administer 80 μg of dexamethasone to the heel of an injured soccer player. If she uses an iontophoresis device that applies a current of 0.14 mA, as shown in Figure 25.4, how long does the administration of the dose take? Assume that the instrument has an application rate of 650 μg/C and that the current flows at a constant rate.

SOLUTION

If the drug application rate is 650 μg/C, to apply 80 μg requires a total charge of

$$q = \frac{80\ \mu\text{g}}{650\ \mu\text{g/C}} = 0.123\ \text{C}.$$

Page 777

The current flows at a constant rate, so the integral in equation 25.2 is simply

$$q = \int_0^t i\, dt\prime = it.$$

Solving for t and inserting the numbers, we find

$$q = it \Rightarrow t = \frac{q}{t} = \frac{0.123\ \text{C}}{0.14 \cdot 10^{-3}\ \text{A}} = 880\ \text{s}.$$

The iontophoresis treatment of the athlete will take approximately 15 min.

25.2 Current Density

Consider a current flowing in a conductor. For a perpendicular plane through the conductor, the current per unit area flowing through the conductor at that point (the cross-sectional area A in Figure 25.5) is the **current density,** $\vec{J}$. The direction of $\vec{J}$ is defined as the direction of the velocity of the positive charges (or opposite to the direction of negative charges) crossing the plane. The current flowing through the plane is

$$i = \int \vec{J} \bullet d\vec{A}, \tag{25.3}$$

FIGURE 25.5 Segment of a conductor (wire), with a perpendicular plane intersecting it and forming a cross-sectional area *A*.

where $d\vec{A}$ is the differential area element of the perpendicular plane, as indicated in Figure 25.5. If the current is uniform and perpendicular to the plane, then $i = JA$, and the magnitude of the current density can be expressed as

$$J = \frac{i}{\mathrm{A}}. \tag{25.4}$$

In a conductor that is not carrying current, the conduction electrons move randomly. When current flows through the conductor, electrons still move randomly but also have an additional **drift velocity,** $\vec{v}_{\mathrm{d}}$, in the direction opposite to that of the electric field

driving the current. The magnitude of the velocity of random motion is on the order of 10^6m/s, while the magnitude of the drift velocity is on the order of 10^{-4}m/s or even less. With such a slow drift velocity, you might wonder why a light comes on almost immediately after you turn on a switch. The answer is that the switch establishes an electric field almost immediately throughout the circuit (with a speed on the order of $3 \cdot 10^8 \text{m/s}$), causing the free electrons in the entire circuit (including in the light bulb) to move almost instantly.

The current density is related to the drift velocity of the moving electrons. Consider a conductor with cross-sectional area A and electric field $\vec{E}$ applied to it. Suppose the conductor has n conduction electrons per unit volume, and assume that all the electrons have the same drift velocity and that the current density is uniform. The negatively charged electrons will drift in a direction opposite to that of the electric field. In a time interval dt, each electron moves a net distance $v_\text{d} dt$. The volume of electrons passing a cross section of the conductor in time dt is then $A v_\text{d} dt$, and the number of electrons in this volume is $n A v_\text{d} dt$. Each electron has charge $-e$, so the charge dq that flows through the area in time dt is

$$dp = -n e v_\text{d} A \, dt. \tag{25.5}$$

Therefore, the current is

$$i = \frac{dq}{dt} = -n e v_\text{d} A. \tag{25.6}$$

The resulting current density is

$$J = \frac{i}{A} = -n e v_\text{d}. \tag{25.7}$$

Equation 25.7 was derived in one spatial dimension, as is appropriate for a wire. However, it can be readily generalized to arbitrary directions in three-dimensional space:

$$\vec{J} = -(ne)\vec{v}_{\mathrm{d}}.$$

You can see that the drift velocity vector is antiparallel to the current density vector, as stated before.

Figure 25.6 shows a schematic drawing of a wire carrying a current. The physical current carriers are negatively charged electrons. In Figure 25.6, these electrons are moving to the left with drift velocity $\vec{v}_{\mathrm{d}}$. However, the electric field, the current density, and the current are all directed to the right because of the convention that these quantities refer to positive charges. You may find this convention somewhat confusing, but you'll need to keep it in mind.

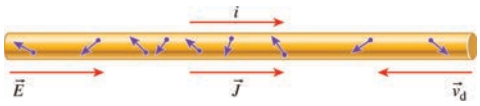

FIGURE 25.6 Electrons moving in a wire from right to left, causing a current in the direction from left to right.

SOLVED PROBLEM 25.1 Drift Velocity of Electrons in a Copper Wire

PROBLEM

You are playing "Galactic Destroyer" on your video game console. Your game controller operates at 12 V and is connected to the main box with an 18-gauge copper wire of length 1.5 m. As you fly your spaceship into battle, you hold the joystick in the forward position for 5.3 s, sending a current of 0.78 mA to the console. How far have the electrons in the wire moved during those few seconds, while on the screen your spaceship crossed half of a star system?

SOLUTION

THINK

To find out how far electrons in a wire move during a given time interval, we need to calculate their drift velocity. To determine the drift velocity for electrons in a copper wire carrying a current, we need to find the density of charge-carrying electrons in copper. Then, we can apply the definition of the charge density to calculate the drift velocity.

SKETCH

A copper wire with cross-sectional area A carrying a current, i, is shown in Figure 25.7, which also shows that, by convention, the electrons drift in the direction opposite to the direction of the current.

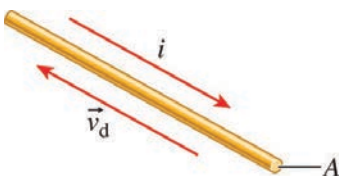

FIGURE 25.7 A copper wire with cross-sectional area A carrying a current, i.

RESEARCH

We obtain the distance x traveled by the electrons during time t from

$$x = v_{\mathrm{d}} t,$$

where v_{d} is the magnitude of the drift velocity of the electrons. The drift velocity is related to the current density via equation 25.7:

$$\frac{i}{\mathrm{A}} = -nev_{\mathrm{d}} \qquad \textbf{(i)}$$

where i is the current, A is the cross-sectional area ($0.823\,\mathrm{mm}^2$ for an 18-gauge wire), n is the density of electrons, and $-e$ is the charge of an electron. The density of electrons is defined as

$$n = \frac{\text{number of conduction electrons}}{\text{volume}}.$$

We can calculate the density of electrons by assuming there is one conduction electron per copper atom. The density of copper is

$$\rho_{\mathrm{Cu}} = 8.96\,\mathrm{g/cm}^3 = 8960\,\mathrm{kg/m}^3.$$

One mole of copper has a mass of 63.5 g and contains $6.02 \cdot 10^{23}$ atoms. Thus, the density of electrons is

$$n = \left(\frac{1\text{ electron}}{1\text{ atom}}\right)\left(\frac{6.02 \cdot 10^{23}\text{ atoms}}{63.5\text{ g}}\right)\left(\frac{8.96\text{ g}}{1\text{ cm}^3}\right)\left(\frac{10^6\text{ cr}}{1\text{ cm}}\right.$$

SIMPLIFY

We solve equation (i) for the magnitude of the drift velocity:

$$v_{\mathrm{d}} = \frac{i}{neA}.$$

Thus, the distance traveled by the electrons is

$$x = v_{\mathrm{d}}t = \frac{i}{neA}t.$$

CALCULATE

Putting in the numerical values, we get

$$\begin{aligned} x = v_{\mathrm{d}}t = \frac{it}{neA} &= \frac{\left(0.78 \cdot 10^{-3}\ \mathrm{A}\right)(5.3\ \mathrm{s})}{\left(8.49 \cdot 10^{28}\ \mathrm{m}^{-3}\right)\left(1.602 \cdot 10^{-19}\ \mathrm{C}\right)(0.8} \\ &= \left(6.96826 \cdot 10^{-8}\ \mathrm{m/s}\right)(5.3\ \mathrm{s}) \\ &= 3.69318 \cdot 10^{-7}\ \mathrm{m}. \end{aligned}$$

ROUND

We report our results to two significant figures:

$$v_{\mathrm{d}} = 7.0 \cdot 10^{-8}\mathrm{m/s},$$

and

$$x = 3.7 \cdot 10^{-7}\ \mathrm{m} = 0.37\ \mu\mathrm{m}.$$

DOUBLE-CHECK

Our result for the magnitude of the drift velocity turns out to be a stunningly small number. Earlier, it was stated that typical drift velocities are on the order of $10^{-4}\mathrm{m/s}$ or smaller. Since the current is proportional to the drift velocity, a relatively small current implies a relatively small drift velocity. An 18-gauge wire can carry a current of several amperes, so the current specified in the problem statement is less than 1% of the maximum current. Therefore, the fact that our calculated drift velocity is less than

1% of 10^{-4}m/s, a typical drift velocity for high currents, is reasonable.

The distance we calculated for the movement of the electrons is less than 0.001 of the thickness of a fingernail, a very small distance compared to the length of the wire. This result provides a valuable reminder that the electromagnetic field moves with nearly the speed of light (in vacuum) inside a conductor and causes all conduction electrons to drift basically at the same time. Therefore, the signal from your game controller arrives almost instantaneously at the console, despite the incredibly slow pace of the individual electrons.

25.3 Resistivity and Resistance

Some materials conduct electricity better than others. Applying a given potential difference across a good conductor results in a relatively large current; applying the same potential difference across an insulator produces little current. The **resistivity,** ρ, is a measure of how strongly a material opposes the flow of electric current. The **resistance,** R, is a material's opposition to the flow of electric current.

If a known electric potential difference, ΔV, is applied across a conductor (some physical device or material that conducts current) and the resulting current, i, is measured, the resistance of that conductor is given by

$$R = \frac{\Delta V}{i}. \tag{25.8}$$

The units of resistance are volts per ampere, a combination that was given the name **ohm** and the symbol Ω (the capital Greek letter omega), in honor of the German physicist Georg Simon Ohm (1789–1854):

$$1\Omega = \frac{1\ \text{V}}{1\ \text{A}}.$$

Rearrangement of equation 25.8 results in

$$i = \frac{\Delta \text{V}}{R}, \tag{25.9}$$

which states that for a given potential difference, ΔV, the current, i, is inversely proportional to the resistance, R. This equation is

commonly referred to as **Ohm's Law.** A rearrangement of equation 25.9, $\Delta V = iR$, is sometimes also referred to as Ohm's Law.

Sometimes devices are described in terms of the **conductance, *G*,** defined as

$$G = \frac{i}{\Delta \mathrm{V}} = \frac{1}{R}.$$

Conductance has the SI derived unit of siemens (S), in honor of German inventor and industrialist Ernst Werner von Siemens (1816–1892):

$$1\,\mathrm{S} = \frac{1\,\mathrm{A}}{1\,\mathrm{V}} = \frac{1}{1\Omega}.$$

In some conductors, the resistivity depends on the direction in which the current is flowing. This chapter assumes that the resistivity of a material is uniform for all directions of the current.

The resistance of a device depends on the material of which the device is made as well as its geometry. As stated earlier, the resistivity of a material characterizes how much it opposes the flow of current. The resistivity is defined in terms of the magnitude of the applied electric field, E, and the magnitude of the resulting current density, J:

$$\rho = \frac{E}{J}. \qquad \textbf{(25.10)}$$

The units of resistivity are

$$[\rho] = \frac{[E]}{[J]} = \frac{\mathrm{V/m}}{\mathrm{A/m^2}} = \frac{\mathrm{Vm}}{\mathrm{A}} = \Omega\,\mathrm{m}.$$

Table 25.1 lists the resistivities of some representative conductors at 20 °C. As you can see, typical values for the resistivity of metal

conductors used in wires are on the order of $10^{-8}\Omega\,\mathrm{m}$. For example, copper has a resistivity of about $2 \cdot 10^{-8}\Omega\,\mathrm{m}$. Several metal alloys listed in Table 25.1 have useful properties. For example, wire made from Nichrome (80% nickel and 20% chromium) is often used as a heating element in devices such as toasters. The next time you are toasting an English muffin, look inside the toaster. The glowing elements are probably Nichrome wires. The resistivity of Nichrome $\left(108 \cdot 10^{-8}\Omega\,\mathrm{m}\right)$ is about 50 times that of copper. Thus, when current is run through the Nichrome wires of the toaster, the wires dissipate power and heat up until they glow with a dull red color, while the copper wires of the electrical cord that connects the toaster to the wall remain cool.

Table 25.1 The Resistivity and the Temperature Coefficient of the Resistivity for Some Representative Conductors

Material	Resistivity, ρ, at $20^\circ C \left(10^{-8} \Omega\, m\right)$	Temperature Coefficient, $\alpha \left(10^{-3} K^{-1}\right)$
Silver	1.62	3.8
Copper	1.72	3.9
Gold	2.44	3.4
Aluminum	2.82	3.9
Brass	3.9	2
Tungsten	5.51	4.5
Nickel	7	5.9
Iron	9.7	5
Steel	11	5
Tantalum	13	3.1
Lead	22	4.3
Constantan	49	0.01
Stainless steel	70	1
Mercury	95.8	0.89
Nichrome	108	0.4

The values for steel and stainless steel depend strongly on the type of steel.

Sometimes materials are specified in terms of their **conductivity, σ**, rather than their resistivity, ρ; conductivity is defined as

$$\sigma = \frac{1}{\rho}.$$

The units of conductivity are $(\Omega\,\mathrm{m})^{-1}$.

The resistance of a conductor can be found from its resistivity and its geometry. For a homogeneous conductor of length L and constant cross-sectional area A, the equation $\Delta V = -\int \vec{E} \bullet d\vec{s}$ from Chapter 23 can be used to relate the electric field, E, and the electric potential difference, ΔV, across the conductor:

$$E = \frac{\Delta V}{L}.$$

Note that in contrast to electrostatics, where the surface of any conductor is an equipotential surface and has no electric field inside and no current flowing through it, the conductor in this situation has $\Delta V \neq 0$ and $\vec{E} \neq 0$, causing a current to flow. The magnitude of the current density is the current divided by the cross-sectional area:

$$J = \frac{i}{A}.$$

From the definition of resistivity (equation 25.10) and using $J = i/A$ and Ohm's Law (equation 25.8), we obtain

$$\rho = \frac{E}{J} = \frac{\Delta V/L}{i/A} = \frac{\Delta V}{i}\frac{A}{L} = \frac{iR}{i}\frac{A}{L} = R\frac{A}{L}.$$

Rearranging terms yields an expression for the resistance of a conductor in terms of the resistivity of its constituent material, the length, and the cross-sectional area:

$$R = \rho \frac{L}{A}. \tag{25.11}$$

Note that in the limit $A \to \infty$, equation 25.11 implies that $R \to 0$. Therefore, the equation is only an approximation, because the conduction electrons will still encounter some resistance in traveling through some length L of a material of density ρ. However, for all wires in actual use, equation 25.11 is an excellent approximation.

Size Convention for Wires

The American Wire Gauge (AWG) size convention for wires specifies diameters and thus cross-sectional areas on a logarithmic scale. The AWG size convention is shown in Table 25.2. The wire gauge is related to the diameter: The higher the gauge number, the thinner the wire. For large-diameter wires, gauge numbers consist of one or more zeros, as shown in Table 25.2. A 00-gauge wire is equivalent to a –1-gauge, a 000-gauge wire is equivalent to a –2-gauge, and so on. By definition, a 36-gauge wire has a diameter of exactly 0.005 in, and a 0000-gauge wire has a diameter of exactly 0.46 in. (These sizes appear in red in Table 25.2.) There are 39 gauge values from 0000-gauge to 36-gauge, and the gauge number is a logarithmic representation of the wire diameter. Therefore, the formula to convert from the AWG gauge to the wire diameter, in inches, is $d = (0.005)92^{(36-n)/39}$, where n is the gauge number. Typical residential wiring uses 12-gauge to 10-gauge wires. An important rule of thumb is that a reduction by 3 gauges doubles the cross-sectional area of the wire. Examining equation 25.11, you can see that to cut the resistance of a given length of wire in half, you have to reduce the gauge number by 3.

Table 25.2 Wire Diameters and Cross-Sectional Areas as Defined by the American Wire Gauge Convention

EXAMPLE 25.2 Resistance of a Copper Wire

Standard wires that electricians put into residential housing have fairly low resistance.

PROBLEM

What is the resistance of the 100.0-m standard 12-gauge copper wire that is typically used in wiring household electrical outlets?

SOLUTION

A 12-gauge copper wire has a diameter of 2.053 mm (see Table 25.2). Its cross-sectional area is then

$$A = 3.31\ \text{mm}^2.$$

Using the value for the resistivity of copper from Table 25.1 and equation 25.11, we find

$$R = \rho\frac{L}{A} = \left(1.72 \cdot 10^{-8}\Omega\ \text{m}\right)\frac{100.0\ \text{m}}{3.31 \cdot 10^{-6}\ \text{m}^2} = 0.520\ \Omega.$$

Concept Check 25.1

If the diameter of the wire in Example 25.2 is doubled, its resistance will

a) increase by a factor of 4.

b) increase by a factor of 2.

c) stay the same.

d) decrease by a factor of 2.

e) decrease by a factor of 4.

Resistor Codes

In many applications, circuit design calls for a range of resistances in various parts of a circuit. Commercially available resistors, such as those shown in Figure 25.8, have a wide range of resistances. Resistors are commonly made of carbon enclosed in a plastic cover that looks like a medicine capsule, with wires sticking out at the ends for electrical connection. The value of the resistance is indicated by three or four color bands on the plastic covering. The first two bands indicate numbers for the mantissa, the third represents a power of 10, and the fourth indicates a tolerance for the range of values. For the mantissa and power of 10, the numbers associated with the colors are black $= 0$, brown $= 1$, red $= 2$, orange $= 3$, yellow $= 4$, green $= 5$, blue $= 6$, purple $= 7$, gray $= 8$, and white $= 9$, For the tolerance, brown means 1%, red means 2%, gold means 5%, silver means 10%, and no band at all means 20%.

FIGURE 25.8 Selection of resistors with various resistances.

Sergiy Kuzmin/123RF

Temperature Dependence and Superconductivity

The values of resistivity and resistance vary with temperature. For metals, this dependence on temperature is linear over a broad range of temperatures. An empirical relationship for the temperature dependence of the resistivity of a metal is

$$\rho - \rho_0 = \rho_0 \alpha (T - T_0), \tag{25.12}$$

where ρ is the resistivity at temperature T, ρ_0 is the resistivity at temperature T_0, and α is the **temperature coefficient of electric resistivity** for the particular conductor.

In everyday applications, the temperature dependence of the resistance is often important. Equation 25.11 states that the resistance of a device depends on its length and cross-sectional area. These quantities depend on temperature, as we saw in Chapter 17; however, the temperature dependence of linear expansion is much smaller than the temperature dependence of resistivity for a particular conductor. Thus, the temperature dependence of the resistance of a conductor can be approximated as

$$R - R_0 = R_0 \alpha (T - T_0). \tag{25.13}$$

Note that equations 25.12 and 25.13 deal with temperature differences, so the temperatures can be expressed in degrees Celsius or kelvins (but not in degrees Fahrenheit!). Also note that T_0 does not necessarily have to be room temperature.

Values of α for representative conductors are listed in Table 25.1. Note that common metal conductors such as copper have a temperature coefficient of electric resistivity on the order of $4 \cdot 10^{-3} \mathrm{K}^{-1}$. However, one metal alloy, constantan (60% copper and 40% nickel), has the special characteristic that its temperature coefficient of electric resistivity is very small: $\alpha = 1 \cdot 10^{-5} \mathrm{K}^{-1}$. The name of this alloy comes from shortening the phrase “constant resistance.” The small temperature coefficient of constantan combined with its relatively high resistivity of $4.9 \cdot 10^{-7} \Omega\,\mathrm{m}$ makes it

useful for precision resistors whose resistances have little dependence on temperature. Note also that Nichrome has a relative small temperature coefficient, $4 \cdot 10^{-4}\text{K}^{-1}$, which makes it suitable for the construction of heating elements, as noted earlier.

Concept Check 25.2

If the temperature of a copper wire with a resistance of 100 Ω is increased by 25 K, the resistance will

a) increase by approximately 10 Ω.

b) increase by approximately 4 mΩ.

c) decrease by approximately 4 mΩ.

d) decrease by approximately 10 Ω.

e) stay the same.

According to equation 25.12, most materials have a resistivity that varies linearly with temperature under ordinary circumstances. However, some materials do not follow this rule at low temperatures. At very low temperatures, the resistivity of some materials goes to exactly zero. These materials are called **superconductors.** Superconductors have applications in the construction of magnets for devices such as magnetic resonance imagers (MRI). Magnets constructed with superconductors use less power and can produce stronger magnetic fields than magnets constructed with conventional resistive conductors. A more extensive discussion of superconductivity will be presented in Chapter 28.

The resistance of some semiconducting materials actually decreases as the temperature increases, which implies a negative temperature coefficient of electric resistivity. These materials are often employed in high-resolution detectors for optical measurements or in particle detectors. Such devices must be kept cold to keep their resistance high, which is accomplished with refrigerators or liquid nitrogen.

A *thermistor* is a semiconductor whose resistance depends strongly on temperature. Thermistors are used to measure temperature. The temperature dependence of the resistance of a

typical thermistor is shown in Figure 25.9a. Here you can see that the resistance of a thermistor falls with increasing temperature. This drop is in contrast to the increase in resistance of a copper wire over the same temperature range, shown in Figure 25.9b.

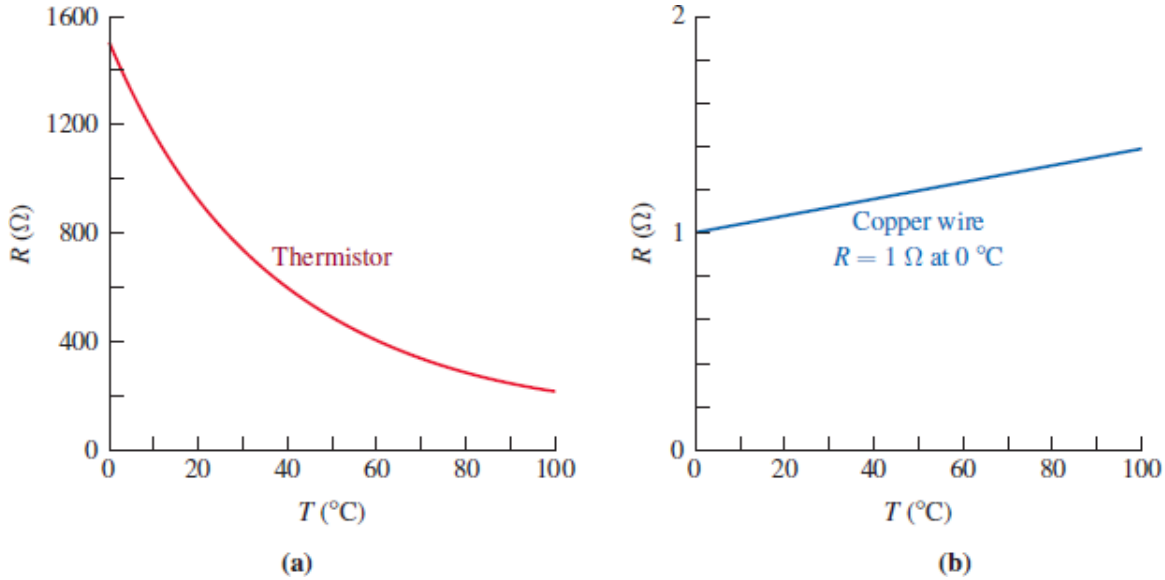

FIGURE 25.9 (a) The temperature dependence of the resistance of a thermistor. (b) The temperature dependence of the resistance of a copper wire that has a resistance of 1 Ω at $T = 0\ ^\circ\mathrm{C}$.

Microscopic Basis of Conduction in Solids

Conduction of current through solids results from the motion of electrons. In a metal conductor such as copper, the atoms of the metal form a regular array called a *crystal lattice*. The outermost electrons of each atom are essentially free to move randomly in this lattice. When an electric field is applied, the electrons drift in the direction opposite to that of the electric field. Resistance to drift occurs when electrons interact with the metal atoms in the lattice. When the temperature of the metal is increased, the motion of the atoms in the lattice increases. This, in turn, increases the probability that electrons will interact with the atoms, effectively increasing the resistance of the metal. A detailed discussion of the interaction between the lattice atoms and the conduction electrons is beyond the scope of this book. The approximate relations given by equations 25.12 and 25.13, which result from this interaction, are sufficient for our purposes.

The atoms of a semiconductor are also arranged in a crystal lattice. However, the outermost electrons of the atoms of the semiconductor are not free to move about within the lattice. To move about, the electrons must be given enough energy to attain an energy state where they can move freely. Thus, a typical semiconductor has a higher resistance than a metal conductor because it has many fewer conduction electrons. In addition, when a semiconductor is heated, many more electrons gain enough energy to move freely; thus, the resistance of the semiconductor decreases as its temperature increases.

25.4 Electromotive Force and Ohm's Law

For current to flow through a resistor, a potential difference must be established across the resistor. This potential difference, supplied by a battery or other device, is termed an **electromotive force,** abbreviated **emf.** (Electromotive force is not a force at all, but rather a potential difference. The term is still in widespread use but mainly in the form of its abbreviation, pronounced "ee-em-eff.") A device that maintains a potential difference is called an *emf device* and does work on the charge carriers. The potential difference created by the emf device is represented as V_{emf}. This text assumes that emf devices have terminals to which a circuit can be connected. The emf device is assumed to maintain a constant potential difference, V_{emf}, between these terminals.

Examples of emf devices are batteries, electric generators, and solar cells. **Batteries,** discussed in Chapters 23 and 24, produce emf through chemical reactions. Electric generators create emf from mechanical motion. Solar cells convert light energy from the Sun to electric energy. If you examine a battery, you will find its potential difference (sometimes colloquially called "voltage") written on it. This "voltage" is the potential difference (emf) that the battery can provide to a circuit. (Note that a battery is a source of constant emf, it does *not* supply constant current to a circuit.) Rechargeable batteries also display a rating in mAh (milliampere-hour), which provides information on the total charge the battery can deliver when fully charged. The mAh is another unit of charge:

$$1\,\text{mAh} = \left(10^{-3}\,\text{A}\right)(3600\,\text{s}) = 3.6\,\text{As} = 3.6\,\text{C}.$$

Electrical components in a circuit can be sources of emf, capacitors, resistors, or other electrical devices. These components are connected with conducting wires. At least one component must be a

source of emf because the potential difference created by the emf device is what drives the current through the circuit. You can think of an emf device as the pump in a water pipeline; without the pump, the water sits in the pipe and doesn't move. Once the pump is turned on, the water moves through the pipe in a continuous flow.

An electric circuit starts and ends at an emf device. Since the emf device maintains a constant potential difference, V_{emf}, between its terminals, positive current leaves the device at the higher potential of its positive terminal and enters its negative terminal at a lower potential. This lower potential is conventionally set to zero.

Consider a simple circuit of the form shown in Figure 25.10, where a source of emf provides a potential difference, $V_{\text{emf},}$ across a resistor with resistance *R*. Note an important convention for circuit diagrams: A resistor is always symbolized by a zigzag line, and it is assumed that all of the resistance, *R,* is concentrated there. The wires connecting the different circuit elements are represented by straight lines; it is implied that they do not have a resistance. Physical wires do, of course, have some resistance, but it is assumed to be negligible for the purpose of the diagram.

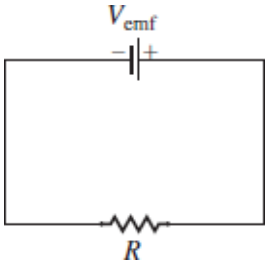

FIGURE 25.10
Simple circuit containing a source of emf and a resistor.

For a circuit like the one shown in Figure 25.10, the emf device provides the potential difference that creates the current flowing through the resistor. Therefore, in this case, Ohm's Law (equation 25.9) can be written in terms of the external emf as

$$V_{\text{emf}} = iR. \qquad \textbf{(25.14)}$$

Note that, unlike Newton's law of gravitation or the law of conservation of energy, Ohm's Law is not a law of nature. It is not even obeyed by all resistors. For many resistors, called *ohmic resistors,* the current is directly proportional to the potential difference across the resistor over a wide range of temperatures and a wide range of applied potential differences. For other resistors, called *non-ohmic resistors,* current and potential difference are not directly proportional at all. Non-ohmic resistors include many kinds of transistors, which means that many modern electronic devices do not obey Ohm's Law. We'll take a closer look at one of these devices, the diode, in Section 25.8. Nevertheless, a large class of materials and devices (such as conventional wires, for example) do obey Ohm's Law, and thus it is worth devoting attention to its consequences. The remainder of this chapter (with the exception of Section 25.8) treats resistors as ohmic devices; that is, devices that obey Ohm's Law.

The current, i, that flows through the resistor in Figure 25.10 also flows through the source of emf and the wires connecting the components. Because the wires are assumed to have zero resistance (as previously noted), the change in potential of the current must occur in the resistor, according to Ohm's Law. This change is referred to as the **potential drop** across the resistor. Thus, the circuit shown in Figure 25.10 can be represented in a different way, making it clearer where the potential drop happens and showing which parts of the circuit are at which potential. Figure 25.11a shows the circuit in Figure 25.10. Figure 25.11b shows the same circuit but with the vertical dimension representing the value of the electric potential at different points around the circuit. The potential difference is supplied by the source of emf, and the entire potential drop occurs across the single resistor. (Remember, the convention is that the lines connecting the circuit elements in a circuit diagram represent wires with no resistance. Therefore, these connecting wires are represented in Figure 25.11b by horizontal lines, signifying that the entire wire is at exactly the same potential.) Ohm's Law applies for the potential drop across the resistor, and the current in the circuit can be calculated using equation 25.9.

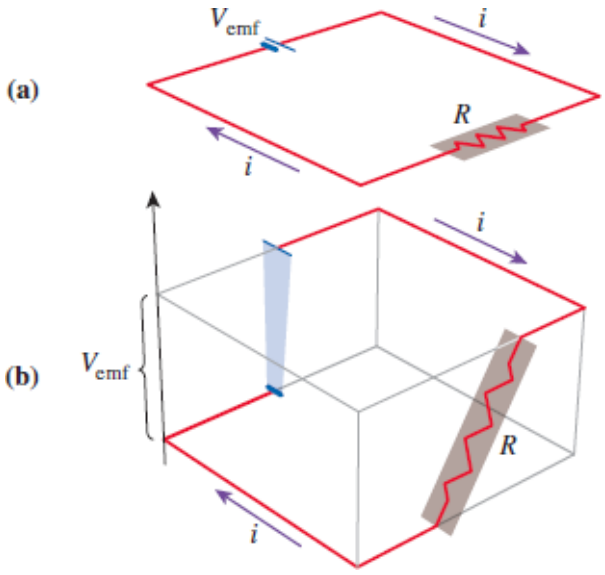

FIGURE 25.11 (a) Conventional representation of a simple circuit with a resistor and a source of emf. (b) Three-dimensional representation of the same circuit, displaying the potential at each point in the circuit. The current in the circuit is shown for both views.

Figure 25.11 illustrates an important point about circuits. Sources of emf add potential difference to a circuit, and potential drops through resistors reduce potential in the circuit. However, the total potential difference on any closed path around the complete circuit must be zero. This is a straightforward consequence of the law of conservation of energy. An analogy with gravity may help: You can gain and lose potential energy by moving up and down in a gravitational field (for example, by climbing up and down hills), but if you arrive back at the same point from which you started, the net energy gained or lost is exactly zero. The same holds for current flowing in a circuit: It does not matter how many potential drops or

sources of emf are encountered on any closed loop; a given point always has the same value of the electric potential. The current can flow through the loop in either direction with the same result.

Self-Test Opportunity 25.2

A resistor with $R = 10.0\,\Omega$ is connected across a source of emf with potential difference $V_{\text{emf}} = 1.50\,\text{V}$. What is the current flowing though the circuit?

Resistance of the Human Body

This short introduction of resistance and Ohm's Law leads to a point about electrical safety. It was mentioned earlier that currents above 100 mA can be deadly if they flow through human heart muscle. Ohm's Law makes it clear that the resistance of the human body determines whether a given potential difference—say, from a car battery—can be dangerous. Since we usually handle tools with our hands, the most relevant measure for the human body's resistance, R_{body}, is the resistance along a path from the fingertips of one hand to the fingertips of the other hand. (Note that the heart is pretty much in the middle of this path!) For most people this resistance is in the range $500\,\text{K}\Omega < R_{\text{body}} < 2\,\text{M}\Omega$. Most of this resistance comes from the skin, in particular, the layers of dead skin on the outside. However, if the skin is wet, its conductivity is drastically increased, and consequently, the body's resistance is drastically lowered. For a given potential difference, Ohm's Law implies that the current then drastically increases. Handling electrical devices in wet environments or touching them with your tongue is thus a very bad idea.

Wires in a circuit can have sharp points where they are cut. If these points penetrate the skin at the fingertips, the resistance of the skin is eliminated, and the fingertip-to-fingertip resistance is very drastically lowered. If a wire penetrates a blood vessel, the human body's resistance decreases even further, because blood has a high salinity and is thus a good conductor. In this case, even relatively small potential differences from batteries can have a deadly effect.

25.5 Resistors in Series

A circuit can contain more than one resistor and/or more than one source of emf. The analysis of circuits with multiple resistors requires different techniques. Let's first examine resistors connected in series.

Two resistors, R_1 and R_2 are connected in series with one source of emf with potential difference V_{emf} in the circuit shown in Figure 25.12. The potential drop across resistor R_1 is denoted by ΔV_1, and the potential drop across resistor R_2 by ΔV_2. The two potential drops must sum to the potential difference supplied by the source of emf:

$$V_{\text{emf}} = \Delta V_1 + \Delta V_2.$$

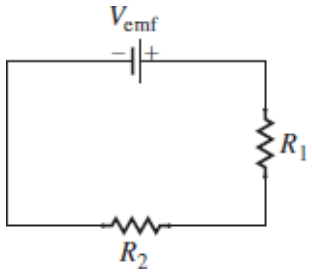

FIGURE 25.12
Circuit with two resistors in series with one source of emf.

The crucial insight is that the same current must flow through all the elements of the circuit. How do we know this? Remember, at the beginning of this chapter, current was defined as the rate of change of the charge in time: $i = dq/dt$. Current has to be the same everywhere along a wire, and also in a resistor, because charge is conserved everywhere. No charge is lost or gained along the wire, and so the current is the same everywhere around the loop in Figure 25.12.

To clear up a common misconception, note that *there is no such thing as current getting "used up" in a resistor*. No matter how many resistors are connected in series, the current that flows into the first

one is the same current that flows out of the last one. An analogy to water flowing in a pipe may help: No matter how long the pipe is and how many bends it may have, all water that flows into one end has to come out the other end.

Thus, the current flowing through each resistor in Figure 25.12 is the same. For each resistor, we can apply Ohm's Law and get

$$V_{\text{emf}} = iR_1 + iR_2.$$

An equivalent resistance, R_{eq}, can replace the two individual resistances:

$$V_{\text{emf}} = iR_1 + iR_2 = iR_{\text{eq}},$$

where

$$R_{\text{eq}} = R_1 + R_2.$$

Thus, two resistors in series can be replaced with an equivalent resistance equal to the sum of the two resistances. Figure 25.13 illustrates the potential drops in the series circuit of Figure 25.12, using a three-dimensional view.

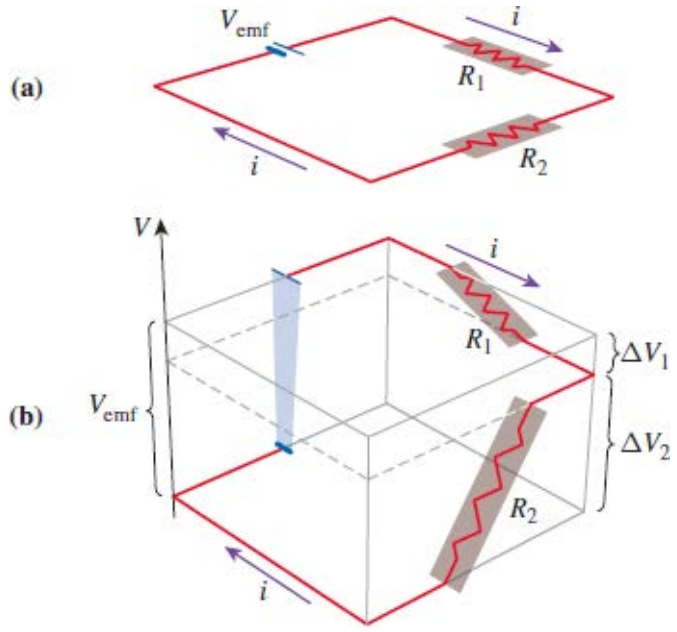

FIGURE 25.13 (a) Conventional representation of a simple circuit with two resistors in series and a source of emf. (b) Three-dimensional representation of the same circuit, displaying the potential at each point in the circuit. The current in the circuit is shown for both views.

The expression for the equivalent resistance of two resistors in series can be generalized to a circuit with n resistors in series:

$$R_{\text{eq}} = \sum_{i=1}^{n} R_{\text{i}} \quad (\text{for resistors in series}). \qquad \textbf{(25.15)}$$

That is, if resistors are connected in a single path so that the same current flows through all of them, their total resistance is just the sum of their individual resistances.

Concept Check 25.3

What are the relative magnitudes of the two resistances in Figure 25.13?

a) $R_1 < R_2$

b) $R_1 = R_2$

c) $R_1 > R_2$

d) Not enough information is given in the figure to compare the resistances.

EXAMPLE 25.3 Internal Resistance of a Battery

When a battery is not connected in a circuit, the potential difference across its terminals is V_t. When the battery is connected in series with a resistor with resistance R, current i flows through the circuit. When the current is flowing, the potential difference, V_{emf}, across the terminals of the battery is less than V_t. This drop occurs because the battery has an internal resistance, R_i, which can be thought of as being in series with the external resistor (Figure 25.14). That is,

$$V_t = iR_{eq} = i(R + R_i).$$

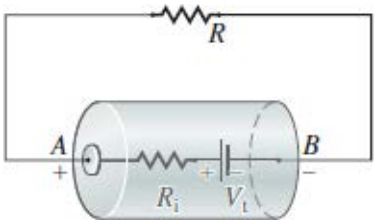

FIGURE 25.14 Battery (gray cylinder) with internal resistance R_i connected to an external resistor, R.

The battery is depicted by the gray cylinder in Figure 25.14. The terminals of the battery are represented by points A and B.

PROBLEM

Consider a battery that has $V_t = 12.0$ V when it is not connected to a circuit. When a 10.0-Ω resistor is connected with the battery, the potential difference across the battery's terminals drops to 10.9 V. What is the internal resistance of the battery?

SOLUTION

The current flowing through the external resistor is given by

$$i = \frac{\Delta V}{R} = \frac{10.9\ \text{V}}{10.0\ \Omega} = 1.09\ \text{A}.$$

The current flowing in the complete circuit, including the battery, must be the same as the current flowing in the external resistor. Thus, we have

$$\begin{aligned} V_\text{t} = iR_\text{eq} &= i(R + R_\text{i}) \\ (R + R_\text{i}) &= \frac{V_\text{t}}{i} \\ R_\text{i} &= \frac{V_\text{t}}{i} - R = \frac{12.0\ \text{V}}{1.09\ \text{A}} - 10.0\ \Omega = 1.00\ \Omega. \end{aligned}$$

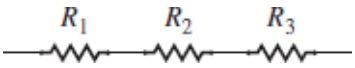
The internal resistance of the battery is 1.00 Ω. Batteries with internal resistance are said to be *nonideal*. Unless otherwise specified, batteries in circuits will be assumed to have zero internal resistance. Such batteries are said to be *ideal*. An ideal battery maintains a constant potential difference between its terminals, independent of the current flowing.

Page 787

Whether a battery can still provide energy cannot be determined by simply measuring the potential difference across the terminals. Instead, you must place a resistance on the battery and then measure the potential difference. If the battery is no longer functional, it may still provide its rated potential difference when not connected, but its potential difference may drop to zero when connected to an external resistance. Some brands of batteries have built-in devices to measure the functioning potential difference simply by pressing on a particular spot on the battery and observing an indicator.

Concept Check 25.4

Three identical resistors, R_1, R_2, and R_3, are wired together as shown in the figure. An electric current is flowing through the three resistors. The current through R_2



a) is the same as the current through R_1 and R_3.

b) is a third of the current through R_1 and R_3.

c) is twice the sum of the current through R_1 and R_3.

d) is three times the current through R_1 and R_3.

e) cannot be determined.

Resistor with a Nonconstant Cross Section

Up to now the discussion has assumed that a resistor has the same cross-sectional area, A, and the same resistivity, ρ, everywhere along its length (this was the implicit assumption in the derivation leading to equation 25.11). This is, of course, not always the case. How do we handle the analysis of a resistor whose cross-sectional area is a function of the position x along the resistor, $A(x)$, and/or whose resistivity can change as a function of position, $\rho(x)$? We simply divide the resistor into many very short pieces of length Δx and sum over all of them, since equation 25.15 says that the total resistance is the sum of all of the resistances of the individual short pieces; then we take the limit $\Delta x \to 0$. If this sounds like an integration to you, you are right. The general formula for computing the resistance of a resistor of length L with a nonuniform cross-sectional area, $A(x)$, is

$$R = \int_0^L \frac{\rho(x)}{A(x)} dx. \qquad \textbf{(25.16)}$$

A concrete example will help clarify this equation.

SOLVED PROBLEM 25.2 Brain Probe

Chapter 22 mentioned the technique of electrocorticography (ECoG), which researchers use to measure the electric field generated by neurons in the brain. Some of these measurements can only be done by inserting very thin wires into the brain in order to probe directly into neurons. These wires are insulated, with only a very short tip exposed, which is pulled into a very fine conical tip. ECoG is being used to treat an epilepsy patient in Figure 25.15.

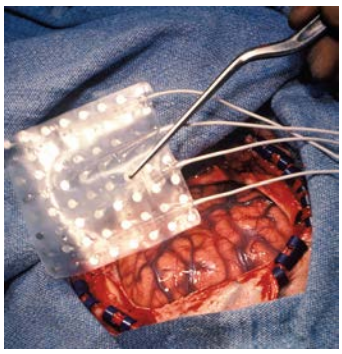


FIGURE 25.15 Electrocorticography performed with electrode grids on the cerebral cortex of an epilepsy patient.

Joe McNally/Getty Images

PROBLEM

If the wire used for ECoG is made of tungsten and has a diameter of 0.74 mm and the tip has a length of 2.0 mm and is sharpened to a diameter of 2.4 μm at the end, what is the resistance of the tip? (The resistivity of tungsten is listed in Table 25.1 as $5.51 \cdot 10^{-8}\ \Omega\,\text{m}$.)

SOLUTION

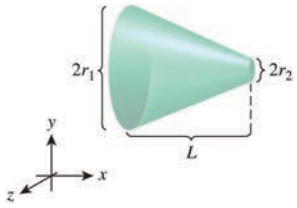
THINK

First, why might one want to know the resistance? To measure electrical fields or potential differences in neurons, probes with a large resistance, say, on the order of kilo-ohms, cannot be used because the fields or differences will not be detectable. However, since resistance is inversely proportional to the cross-sectional area, a very small area means a relatively large resistance. The problem statement says that the probe has a very fine tip, much pointier than any sewing needle. Hence the need to find out the resistance of the probe before inserting it into the brain!

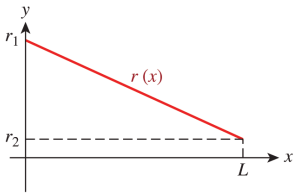
Clearly, we are dealing with a case of nonconstant cross-sectional area, and so we will need to perform the integration of equation 25.16. However, since the tip is entirely made of tungsten, the resistivity is constant throughout its volume, which will simplify the task.

SKETCH

Figure 25.16a shows a three-dimensional view of the tip, and Figure 25.16b presents a cut through its symmetry plane and the integration path.



(a)



(b)

FIGURE 25.16 (a) Shape of the tip of the probe. (b) Coordinate system for the integration.

RESEARCH

The research part is quite simple for this problem, because we already know which equation we need to use. However, equation 25.16 needs to be altered to reflect the fact that the resistivity is constant throughout the tip:

$$R = \rho \int_0^L \frac{1}{A(x)} dx, \qquad \textbf{(i)}$$

where $A(x)$ is the area of a circle, $r(x) = \pi[r(x)]^2$. The radius of the circle falls linearly from r_1 to r_2 (see Figure 25.16b):

$$r(x) = r_1 + \frac{(r_2 - r_1)x}{L}. \qquad \textbf{(ii)}$$

SIMPLIFY

We substitute the expression for the radius from equation (ii) into the formula for the area and then substitute the resulting expression for $A(x)$ into equation (i). We arrive at

$$R = \rho \int_0^L \frac{1}{\pi(r_1 + (r_2 - r_1)x/L)^2}\, dx.$$

This integral may look daunting at first sight, but except for x all the other quantities are constants. We consult an integration table or software and find

$$R = -\frac{\rho L}{\pi(r_{12} - r_1)(r_1 + (r_2 - r_1)x/L)}\bigg|_0^L = \frac{\rho L}{\pi r_1 r_2}.$$

CALCULATE

Putting in the numerical values, we get

$$R = \frac{\left(5.5 \cdot 10^{-8} \Omega\,\mathrm{m}\right)\left(2.0 \cdot 10^{-3}\,\mathrm{m}\right)}{\pi\left(0.37 \cdot 10^{-3}\,\mathrm{m}\right)\left(1.2 \cdot 10^{-6}\,\mathrm{m}\right)} = 7.90039 \cdot 10^{-2} \Omega.$$

ROUND

We report our result to the two significant figures to which the geometric properties of the tip were given:

$$R = 7.9 \cdot 10^{-2}\ \Omega.$$

DOUBLE-CHECK

The value of 79 mΩ seems a very small resistance to a current that has to pass through a tip that is sharpened to a diameter of 2.4 μm. On the other hand, the tip has a very small length, which argues for a small resistance. An additional confidence builder is the fact that the units worked out properly.

However, there are also a few tests we can perform to convince ourselves that at least the asymptotic limits of the solution to $R = \rho L/(\pi r_1 r_2)$ are reasonable. First, as the length approaches zero, so does the resistance, as expected. Second, as the radius of either end of the tip approaches zero, the formula predicts an infinite resistance, which is also expected.

25.6 Resistors in Parallel

Instead of being connected in series, which causes all the current to pass through both resistors, two resistors can be connected in parallel, which divides the current between them, as shown in Figure 25.17. Again, to better illustrate the potential drops, Figure 25.18 shows the same circuit in a three-dimensional view.

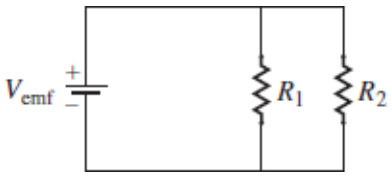


FIGURE 25.17 Circuit with two resistors connected in parallel and a single source of emf.

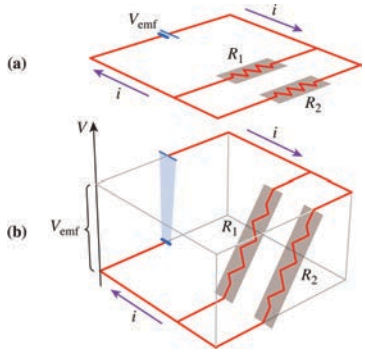

FIGURE 25.18 (a) Conventional representation of a simple circuit with two resistors in parallel and a source of emf. (b) Three-dimensional representation of the same circuit, displaying the potential at each point in the circuit.

In this case, the potential drop across each resistor is equal to the potential difference provided by the source of emf. Using Ohm's Law (equation 25.14) for the current i_1 in R_1 and the current i_2 in R_2, we have

$$i_1 = \frac{V_{\text{emf}}}{R_1}$$

and

$$i_2 = \frac{V_{\text{emf}}}{R_2}.$$

The total current from the source of emf, i, must be

$$i = i_1 + i_2.$$

Inserting the expressions for i_1 and i_2, we obtain

$$i = i_1 + i_2 = \frac{V_{\text{emf}}}{R_1} + \frac{V_{\text{emf}}}{R_2} = V_{\text{emf}}\left(\frac{1}{R_1} + \frac{1}{R_2}\right).$$

Ohm's Law (equation 25.14) can be rewritten as

$$i = V_{\text{emf}}\left(\frac{1}{R_{\text{eq}}}\right).$$

Thus, two resistors connected in parallel can be replaced with an equivalent resistance given by

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_1} + \frac{1}{R_2}.$$

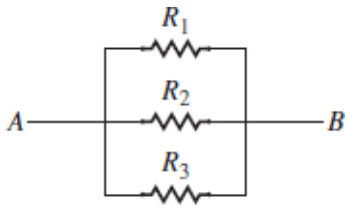
In general, the equivalent resistance for n resistors connected in parallel is given by

$$\frac{1}{R_{\text{eq}}} = \sum_{i=1}^{n} \frac{1}{R_{\text{i}}} \quad \text{(resistors in parallel)}. \qquad \textbf{(25.17)}$$

Clearly, combining resistors in series and in parallel to form equivalent resistances allows circuits with various combinations of resistors to be analyzed in a way analogous to the analysis of combinations of capacitors performed in Chapter 24.

Concept Check 25.5

Three identical resistors, R_1, R_2, and R_3, are wired together as shown in the figure. An electric current is flowing from point *A* to point *B*. The current flowing through R_2



a) is the same as the current through R_1 and R_3.

b) is a third of the current through R_1 and R_3.

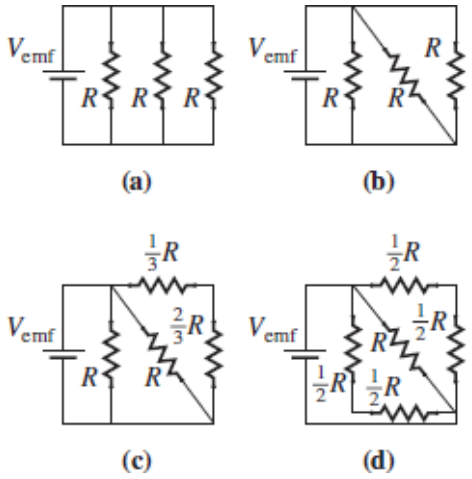
c) is twice the sum of the current through R_1 and R_3.

d) is three times the current through R_1 and R_3.

e) cannot be determined.

Concept Check 25.6

Which combination of resistors has the highest equivalent resistance?



a) combination (a)

b) combination (b)

c) combination (c)

d) combination (d)

e) The equivalent resistance is the same for all four.

EXAMPLE 25.4 Equivalent Resistance in a Circuit with Six Resistors

PROBLEM

Figure 25.19a shows a circuit with six resistors, R_1 through R_6. What is the current flowing through resistors R_2 and R_3 in terms of V_{emf} and R_1 through R_6?

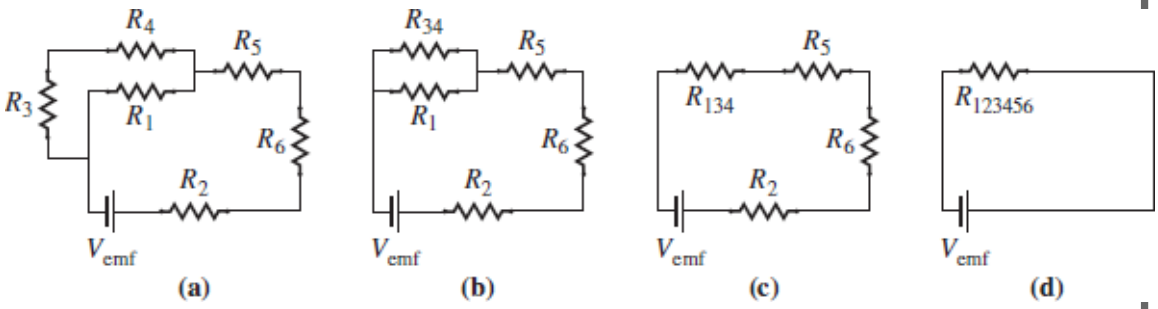


FIGURE 25.19 (a) Circuit with six resistors. (b)–(d) Steps in combining these resistors to determine the equivalent resistance.

SOLUTION

We begin by identifying parts of the circuit that are clearly wired in parallel or in series. The current flowing through R_2 is the current flowing from the source of emf. We note that R_3 and R_4 are in series. Thus, we can write

$$R_{34} = R_3 + R_4. \qquad \textbf{(i)}$$

This substitution is made in Figure 25.19b. This figure shows us that R_{34} and R_1 are in parallel. We can then write

$$\frac{1}{R_{134}} = \frac{1}{R_1} + \frac{1}{R_{34}},$$

or

$$R_{124} = \frac{R_1 R_{34}}{R_1 + R_{34}}. \qquad \textbf{(ii)}$$

This substitution is depicted in Figure 25.19c. From this figure, we can see that R_2, R_5, R_6, and R_{134} are in series. Thus, we can write

$$R_{123456} = R_2 + R_5 + R_6 + R_{134}. \qquad \textbf{(iii)}$$

This substitution is shown in Figure 25.19d. We substitute for R_{34} and R_{134} from equations (i) and (ii) into equation (iii):

$$R_{123456} = R_2 + R_5 + R_6 + \frac{R_1 R_{34}}{R_1 + R_{34}} = R_2 + R_5 + R_6 +$$

Thus, i_2, the current flowing through R_2, is given by

$$i_2 = \frac{V_{\text{emf}}}{R_{123456}}.$$

Now we turn to the determination of the current flowing through R_3. Current i_2 is also flowing through the equivalent resistance R_{134} that contains R_3 (see Figure 25.19c). Thus, we can write

$$V_{134} = i_2 R_{134},$$

where V_{134} is the potential drop across the equivalent resistance R_{134}. The resistor R_1 and the equivalent resistance R_{34} are in parallel. Thus, V_{34}, the potential drop across R_{34}, is the same as the potential drop across R_{134} which is V_{134}. The resistors R_3 and R_4 are in series, and thus, i_3, the current flowing through R_3, is the same as i_{34}, the current flowing through R_{34}. We can thus write

$$V_{34} = V_{134} = i_{34}R_{34} = i_3 R_{34}.$$

Now we can express i_3 in terms of V and R_1 through R_6:

$$i_3 = \frac{V_{134}}{R_{34}} = \frac{i_2 R_{134}}{R_{34}} = \frac{\left(\frac{V_{\text{emf}}}{R_{123456}}\right) R_{134}}{R_{34}} = \frac{V_{\text{emf}} R_{134}}{R_{34} R_{123456}} =$$

or

$$i_3 = \frac{V_{\text{emf}} R_1}{\left(R_2 + R_5 + R_6 + \frac{R_1(R_3 + R_4)}{R_1 + R_3 + R_4}\right)(R_1 + R_3 + R_4)}$$

SOLVED PROBLEM 25.3 Potential Drop across a Resistor in a Circuit

PROBLEM

The circuit shown in Figure 25.20a has four resistors and a battery with $V_{\text{emf}} = 149\,\text{V}$. The values of the four resistors are $R_1 = 17.0\,\Omega$, $R_2 = 51.0\,\Omega$, $R_3 = 114.0\,\Omega$, and $R_4 = 55.0\,\Omega$. What is the magnitude of the potential drop across R_2?

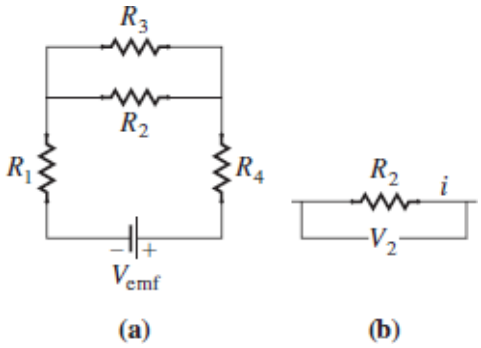

FIGURE 25.20 (a) A circuit with four resistors and a battery. (b) Potential drop across resistor R_2.

SOLUTION

THINK

The resistors R_2 and R_3 are in parallel and can be replaced with an equivalent resistance, R_{23}. The resistors R_1 and R_4 are in series with R_{23}. The current flowing through R_1, R_4, and R_{23} is the same because they are in series. We can obtain the current in the circuit by calculating the equivalent resistance for R_1, R_4, and R_{23} and using Ohm's Law. The potential drop across R_{23} is equal to the current flowing in the circuit times R_{23}. The potential drop across R_2 is the same as the potential drop across R_{23} because R_2 and R_3 are in parallel.

SKETCH

The potential drop across resistor R_2 is illustrated in Figure 25.20b.

RESEARCH

The equivalent resistance for R_2 and R_3 can be calculated using equation 25.17:

$$\frac{1}{R_{23}} = \frac{1}{R_2} + \frac{1}{R_3}. \qquad \textbf{(i)}$$

The equivalent resistance of the three resistors in series can be found using equation 25.15:

$$R_{\text{eq}} = \sum_{i=1}^{n} R_i = R_1 + R_{23} + R_4.$$

Finally, we obtain the current in the circuit using Ohm's Law:

$$V_{\text{emf}} = iR_{\text{eq}} = i(R_1 + R_{23} + R_4).$$

SIMPLIFY

The potential drop, V_2, across R_2 is equal to the potential drop, V_{23}, across the equivalent resistance R_{23}:

$$V_2 = V_{23} = iR_{23} = \frac{V_{\text{emf}}}{R_1 + R_{23} + R_4} R_{23} = \frac{R_{23} V_{\text{emf}}}{R_1 + R_{23} +}$$

We can solve equation (i) for R_{23} to obtain

$$R_{23} = \frac{R_2 R_3}{R_2 + R_3}.$$

We can then use equation (ii) to determine the potential drop V_2 as

$$V_2 = \frac{\left(\frac{R_2 R_3}{R_2 + R_3}\right) V_{\text{emf}}}{R_1 + \left(\frac{R_2 R_3}{R_2 + R_3}\right) + R_4} = \frac{R_2 R_3 V_{\text{emf}}}{R_1(R_2 + R_3) + R_2 R_3 +}$$

which we can rewrite as

$$V_2 = \frac{R_2 R_3 V_{\text{emf}}}{(R_1 + R_4)(R_2 + R_3) + R_2 R_3}.$$

CALCULATE

Putting in the numerical values, we get

$$\begin{aligned} V_2 &= \frac{R_2 R_3 V_{\text{emf}}}{(R_1 + R_4)(R_2 + R_3) + R_2 R_3} \\ &= \frac{(51.0\,\Omega)(114.0\,\Omega)(149\,\text{V})}{(17.0\,\Omega + 55.0\,\Omega)(51.0\,\Omega + 114.0\,\Omega) + (51.0\,\Omega)(1} \\ &= 48.9593\,\text{V}. \end{aligned}$$

ROUND

We report our result to three significant figures:

$$V = 49.0\,\text{V}.$$

DOUBLE-CHECK

You may be tempted to avoid completing the analytic solution as we've done here. Instead, you may want to insert numbers earlier, for example, into the expression for R_{23}. So, to double-check our result, let's calculate the current in the circuit explicitly

and then calculate the potential drop across R_{23} using that current. The equivalent resistance for R_2 and R_3 in parallel is

$$R_{23} = \frac{R_2 R_3}{R_2 + R_3} = \frac{(51.0\,\Omega)(114.0\,\Omega)}{51.0\,\Omega + 114.0\,\Omega} = 35.2\,\Omega.$$

The current in the circuit is then

$$i = \frac{V_{\text{emf}}}{R_1 + R_{23} + R_4} = \frac{149.0\text{ V}}{17.0\,\Omega + 35.2\,\Omega + 55.0\,\Omega} = 1.39\text{ A}$$

The potential drop across R_2 is then

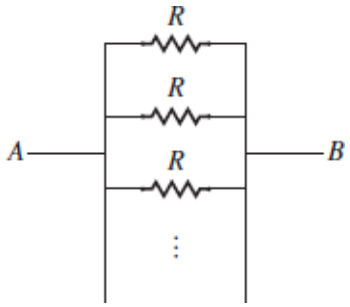
$$V_2 = iR_{23} = (1.39\text{ A})(35.0\,\Omega) = 48.9\text{ V},$$

which agrees with our result within rounding error. It is reassuring that both methods lead to the same answer.

We can also check that the potential drops across R_1, R_{23}, and R_4 sum to V_{emf}, as they should since R_1, R_{23}, and R_4 are in series. The potential drop across R_1 is $V_1 = iR_1 = (1.39\text{ A})\,(17.0\,\Omega) = 23.6\text{ V}$. The potential drop across R_4 is $V_4 = iR_4 = (1.39\text{ A})(55.0\,\Omega) = 76.5\text{ V}$. So the total potential drop is $V_{\text{total}} = V_1 + V_{23} + V_4 = (23.6\text{ V}) + (48.9\text{ V}) + (76.5\text{ V}) = 149\text{ V}$, which is equal to V_{emf}. Thus, our answer is consistent.

Concept Check 25.7

As more identical resistors, *R,* are added to the circuit shown in the figure, the resistance between points *A* and *B* will



a) increase.

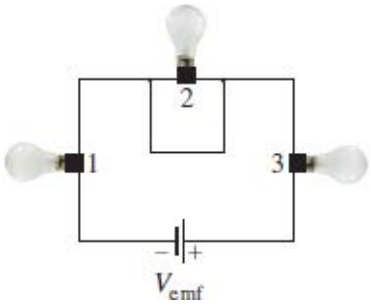
b) stay the same.

c) decrease.

d) change in an unpredictable manner.

Concept Check 25.8

Three light bulbs are connected in series with a battery that delivers a constant potential difference, V_{emf}. When a wire is connected across light bulb 2 as shown in the figure, light bulbs 1 and 3



a) burn just as brightly as they did before the wire was connected.

b) burn more brightly than they did before the wire was connected.

c) burn less brightly than they did before the wire was connected.

d) go out.

25.7 Energy and Power in Electric Circuits

Consider a simple circuit in which a source of emf with potential difference ΔV causes a current, i, to flow. The work required from the emf device to move a differential amount of charge, dq, from the negative terminal to the positive terminal (within the emf device) is equal to the increase in electric potential energy of that charge, dU:

$$dU = dq\Delta V.$$

Remembering that current is defined as $i = dq/dt$, we can rewrite the differential electric potential energy as

$$dU = i\,dt\,\Delta V.$$

Using the definition of power, $P = dU/dt$, and substituting into it the expression for the differential potential energy, we obtain

$$P = \frac{dU}{dt} = \frac{i\,dt\Delta V}{dt} = i\Delta V.$$

Thus, the product of the current times the potential difference gives the power supplied by the source of emf. By conservation of energy, this power is equal to the power dissipated in a circuit containing one resistor. In a more complicated circuit, each resistor will dissipate power at the rate given by this equation, where i and ΔV refer to the current through and potential difference across that resistor. Ohm's Law (equation 25.9) leads to different formulations of the power:

$$P = i\Delta V = i^2R = \frac{(\Delta V)^2}{R}. \qquad \textbf{(25.18)}$$

The unit of power (as noted in Chapter 5) is the watt (W). Electrical devices, such as light bulbs, are rated in terms of how much power they consume. Your electric bill depends on how much electrical

energy your appliances consume, and this energy is measured in kilowatt-hours (kWh).

Where does this energy go? This question will be addressed quantitatively in Chapter 30 when alternating currents are discussed. Qualitatively, much or most of the energy dissipated in resistors is converted into heat. This phenomenon is employed in incandescent lighting, where heating a metal filament to a very high temperature causes it to emit light. The heat dissipated in electrical circuits is a huge problem for large-scale computer systems and server farms for the biggest Internet databases. These computer systems use thousands of processors for computing applications that can be parallelized. All of these processors emit heat, and very expensive cooling has to be provided to offset it. It turns out that the cost of cooling is one of the most stringent boundary conditions limiting the maximum size of these supercomputers.

Some of the power dissipated in circuits can be converted into mechanical energy by motors. The functioning of electric motors requires an understanding of magnetism and will be covered later.

EXAMPLE 25.5 Temperature Dependence of a Light Bulb's Resistance

A 100-W light bulb is connected in series to a source of emf with $V_{\text{emf}} = 100\ \text{V}$. When the light bulb is lit, the temperature of its tungsten filament is 2520°C.

PROBLEM

What is the resistance of the light bulb's tungsten filament at room temperature (20°C)?

SOLUTION

The resistance of the filament when the light bulb is lit can be obtained using equation 25.18:

$$P = \frac{V_{\text{emf}}^2}{R}.$$

Page 793

We rearrange this equation and substitute the numerical values to get the resistance of the filament:

$$R = \frac{V_{\text{emf}}^2}{P} = \frac{(100\ \text{V})^2}{100\ \text{W}} = 100\ \Omega.$$

The temperature dependence of the filament's resistance is given by equation 25.13:

$$R - R_0 = R_0\alpha(T - T_0).$$

We solve for the resistance at room temperature, R_0:

$$R = R_0 + R_0\alpha(T - T_0) = R_0\left[1 + \alpha(T - T_0)\right]$$

$$R_0 = \frac{R}{1 + \alpha(T - T_0)}.$$

Using the temperature coefficient of resistivity for tungsten from Table 25.1, we get

$$R_0 = \frac{R}{1 + \alpha(T - T_0)} = \frac{100\,\Omega}{1 + \left(4.5 \cdot 10^{-3}\ ^\circ\mathrm{C}^{-1}\right)(2520\ ^\circ\mathrm{C} - 2}$$

High-Voltage Direct Current Power Transmission

The transmission of electrical power from power-generating stations to users of electricity is of great practical interest. Often, electrical power-generating stations are located in remote areas, and thus the power must be transmitted long distances. This is particularly true for clean power sources, such as hydroelectric dams and large solar farms in deserts.

The power, *P*, transmitted to users is the product of the current, *i,* and the potential difference, ΔV, in the power line: $P = i\Delta V$. Thus, the current required for a given power is $i = P/\Delta V$, and a higher potential difference means a lower current in the power line. Equation 25.18 indicates that the power dissipated in an electrical power transmission line, P_{loss}, is given by $P_{\text{loss}} = i^2R$. The resistance, *R*, of the power line is fixed; thus, decreasing the power lost during transmission means reducing the current carried in the transmission line. This reduction is accomplished by transmitting the power using a very high potential difference and a very low current. Looking at equation 25.18, you might argue that we could also write $P_{\text{loss}} = (\Delta V)^2/R$ and that a high potential difference means a large power loss instead of a small power loss. However, ΔV in this equation is the potential drop across the power line, not the potential difference at which the electrical power is being transmitted. The potential drop across the power line is $V_{\text{drop}} = iR$, which is much lower than the high potential difference used to transmit the electrical power. The expressions for the transmitted power and the dissipated power can be combined to give $P_{\text{loss}} = (P/\Delta V)^2R = P^2R/(\Delta V)^2$, which means that for a given amount of power, the dissipated power decreases as the square of the potential difference used to transmit the power.

Normally, electrical power generation and transmission use alternating currents. As we'll see in Chapter 30, alternating currents have the advantage that it is easy to raise or lower the potential difference via transformers. However, alternating currents have the inherent disadvantage of high power losses. High-voltage direct current (HVDC) transmission lines do not have this problem and suffer only power losses due to the resistance of the power line. However, HVDC transmission lines have the extra requirement that

alternating current must be converted to direct current for transmission and the direct current must be converted back to alternating current at the destination.

Chapter 5 mentioned the electrical energy produced by the Itaipú Dam on the Paraná River in Brazil and Paraguay. Part of the power produced by this hydroelectric plant is transmitted via the world's largest HVDC transmission line a distance of about 800 km from the Itaipú Dam to São Paulo, Brazil, one of the ten largest metropolitan areas in the world. The transmission line carries 6300 MW of electrical power using direct current with a potential difference of $\pm$600 kV. The station at the Itaipú Dam that converts the alternating current to direct current is shown in Figure 25.21a. The station in São Paulo that converts the transmitted direct current back to alternating current is shown in Figure 25.21b.

(a)

(b)

FIGURE 25.21 (a) The station that converts alternating current to direct current at the Itaipú Dam on the Paraná River in Brazil and Paraguay. (b) The station that converts the transmitted direct current back to alternating current in São Paulo, Brazil.

a: Pulsar Imagens/Alamy Stock Photo; **b:** Travel Pix/Alamy Stock Photo

Future applications of HVDC power transmission include the transmission of power from solar power stations located in remote areas in the southwest United States to densely populated areas, such as large cities in California and Texas. Some of the most promising research on power transmission is focusing on the use of superconducting wires for this purpose. As mentioned earlier, once a

material becomes superconducting, its resistance approaches zero. Therefore, it can transmit electrical power without significant losses. The most promising materials for superconducting power transmission wires are *high-temperature superconductors*, discovered only in 1986. These wires have to be cooled with liquid nitrogen, but we are approaching the point where their widespread use in long-distance power transmission can become a reality.

Self-Test Opportunity 25.3

Consider a battery with internal resistance R_i. What external resistance, R, will undergo the maximum heating when connected to this battery?

SOLVED PROBLEM 25.4 Size of Wire for a Power Line

PROBLEM

Imagine you are designing the HVDC power line from the Itaipú Dam on the Paraná River in Brazil and Paraguay to the city of São Paulo in Brazil. The power line is 800 km long and transmits 6300 MW of power at a potential difference of 1.20 MV. (Figure 25.22 shows an HVDC line.)

FIGURE 25.22
HVDC power transmission line.

K Arun Singh/Shutterstock

The electric company requires that no more than 25% of the power be lost in transmission. If the line consists of one wire made out of copper and having a circular cross section, what is the minimum diameter of the wire?

SOLUTION

THINK

Knowing the power transmitted and the potential difference with which it is transmitted, we can calculate the current carried in the line. We can then express the power lost in terms of the resistance of the transmission line. With the current and the resistance of the wire, we can write an expression for the power lost during transmission. The resistance of the wire is a function of the diameter of the wire, the length of the wire, and the resistivity of copper. We can then solve for the diameter of the wire that will keep the power loss within the specified limit.

SKETCH

A sketch of a copper wire of length L and diameter d is shown in Figure 25.23.

FIGURE 25.23 An HVDC transmission line consisting of a copper conductor (not to scale).

RESEARCH

The power, P, carried in the line is related to the current, i, and the potential difference, ΔV : $P = i\Delta V$. The power lost in transmission, P_{lost}, can be related (see equation 25.18) to the current in the wire and the resistance, R, of the wire:

$$P_{\text{lost}} = i^2 R. \qquad \textbf{(i)}$$

The resistance of the wire is given by equation 25.11:

$$R = \rho_{\text{Cu}} \frac{L}{A}, \qquad \textbf{(ii)}$$

where ρ_{Cu} is the resistivity of copper, L is the length of the wire, and A is the cross-sectional area of the wire.

The cross-sectional area of the wire is the area of a circle:

$$A = \pi \left(\frac{d}{2} \right)^2 = \frac{\pi d^2}{4},$$

where d is the diameter of the wire. Thus, with the area of a circle substituted for A, equation (ii) becomes

$$R = \rho_{\text{cu}} \frac{L}{\pi d^2/4}. \qquad \textbf{(iii)}$$

SIMPLIFY

We can solve $P = i\Delta V$ for the current in the wire:

$$i = \frac{P}{\Delta V}.$$

Substituting this expression for the current and that for the resistance from equation (iii) into equation (i) for the lost power gives

$$P_{\text{lost}} = \left(\frac{P}{\Delta V}\right)^2 \left(\rho_{\text{Cu}} \frac{L}{\pi d^2/4}\right) = \frac{4P^2 \rho_{\text{Cu}} L}{\pi (\Delta V)^2 d^2}.$$

The fraction of lost power relative to total power, f, is

$$\frac{P_{\text{lost}}}{P} = \frac{\left(\dfrac{4P^2 \rho_{\text{Cu}} L}{\pi (\Delta V)^2 d^2}\right)}{P} = \frac{4P \rho_{\text{Cu}} L}{\pi (\Delta V)^2 d^2} = f.$$

Solving this equation for the diameter of the wire gives

$$d = \sqrt{\frac{4P \rho_{\text{Cu}} L}{f \pi (\Delta V)^2}}.$$

CALCULATE

Putting in the numerical values gives us

$$d = \sqrt{\frac{4\left(6300.10^{6}\text{W}\right)\left(1.72 \cdot 10^{-8}\Omega\,\text{m}\right)\left(800 \cdot 10^{3}\,\text{m}\right)}{(0.25)\pi\left(1.20 \cdot 10^{6}\,\text{V}\right)^{2}}} = 0.0$$

ROUND

Rounding to three significant figures gives us the minimum diameter of the copper wire:

$$d = 1.75\,\text{cm}.$$

DOUBLE-CHECK

To double-check our result, let's calculate the resistance of this transmission line. Using our calculated value for the diameter, we can find the cross-sectional area and then, using equation 25.11, obtain

$$R = \rho_{\text{Cu}}\frac{L}{\pi d^2/4} = \frac{4\rho_{\text{Cu}}L}{\pi d^2} = \frac{4\left(1.72 \cdot 10^{-8}\Omega\,\text{m}\right)\left(800 \cdot 10^{3}\right.}{\pi\left(1.75 \cdot 10^{-2}\,\text{m}\right)^{2}}$$

The current transmitted is

$$i = \frac{P}{V} = \frac{6300 \cdot 10^{6}\,\text{W}}{1.20 \cdot 10^{6}\,\text{V}} = 5250\,\text{A}.$$

The power lost is then

$$P = i^2R = (5250\,\text{A})^2(57.2\,\Omega) = 1580\,\text{MW},$$

which is close (within rounding error) to 25% of the total power of 6300 MW. Thus, our result seems reasonable.

25.8 Diodes: One-Way Streets in Circuits

Section 25.4 stated that many resistors obey Ohm's Law. It was noted, however, that there are also non-ohmic resistors that do not obey Ohm's Law. A very common and extremely useful example is a diode. A *diode* is an electronic device that is designed to conduct current in one direction and not in the other direction. Remember that Figure 25.2c showed that a light bulb was still shining with the same intensity when the battery it was connected to was reversed. If a diode (represented by the symbol ⟶|⟵) is added to the same circuit, the diode prevents the current from flowing when the potential difference delivered by the battery is reversed; see Figure 25.24. The diode acts like a one-way street for the current.

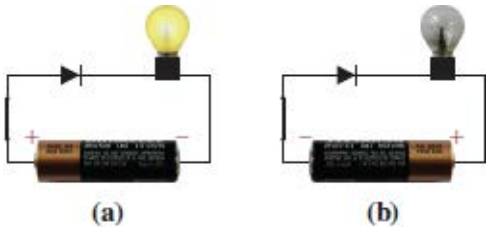


FIGURE 25.24 (a) The circuit of Figure 25.2c, but with a diode included. (b) Reversing the potential difference from the battery causes the current to stop flowing and the light bulb to stop shining.

a-b: W. Bauer and G. D. Westfall

Figure 25.25 shows current versus potential difference for a 3-Ω ohmic resistor and a silicon diode. The resistor obeys Ohm's Law, with the current flowing in the opposite direction when the potential difference is negative. The plot of current versus potential difference for the resistor is a straight line with a slope of $\frac{1}{3}\Omega$. The silicon diode is wired so that it will not conduct any current when there is a negative potential difference. This silicon diode, like most, will conduct current if the potential difference is above 0.7 V. For potential differences above this threshold, the diode is essentially a conductor; below this threshold, the diode will not conduct current. The turn-on of the diode above the threshold potential difference increases exponentially; it can be close to instantaneous, as is visible in Figure 25.25.

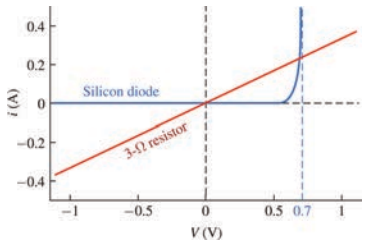

FIGURE 25.25
Current as a function of potential difference for a resistor (red) and a diode (blue).

Diodes are very useful for converting alternating current to direct current, as we'll see in Chapter 30. The fundamental physics principles that underlie the functioning of diodes require an understanding of quantum mechanics.

One particularly useful kind of diode is the light-emitting diode (LED), which not only regulates current in a circuit but also emits light of a single wavelength in a very controlled way. LEDs that emit light of many different wavelengths have been manufactured, and they emit light much more efficiently than conventional incandescent bulbs do. Light intensity is measured in lumens (lm). Light sources

can be compared in terms of how many lumens they produce per watt of electrical power. During the last decade, intensive research into LED technology has resulted in huge increases in LED output efficiency, which has reached values of 130 to 170 lm/W. This compares very favorably with conventional incandescent lights (which are in the range from 5 to 20 lm/W), halogen lights (20 to 30 lm/W), and even fluorescent high-efficiency lights (30 to 95 lm/W). Prices for LEDs (in particular, "white" LEDs) are still comparatively high but are expected to decrease significantly. In 2020, the United States used over 200 billion kWh of electrical energy for lighting alone, which was approximately 6% of the total U.S. electricity consumption. Universal use of LED lighting could save 70% to 90% of those 200 billion kWh, approximately the annual energy output of 20 power plants ($\sim$ 1 GW power each).

LEDs are also used in large display screens, where high light output is desirable. Perhaps the most impressive of these is the Infinity Screen (Figure 25.26) at SoFi Stadium in Los Angeles, CA. The screen has a viewing area of 6500 m^2 and a total of 8 million individual LEDs.

FIGURE 25.26
Giant LED screen at SoFi Stadium in Los Angeles, CA.

Self-Test Opportunity 25.4

Suppose the battery in Figure 25.24 has a potential difference of 1.5 V across its terminals and the diode is a silicon diode like the one in Figure 25.25. What are the potential drops across the diode and the light bulb in parts (a) and (b) of Figure 25.24?

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- Current, i, is defined as the rate at which charge, q, flows past a particular point: $i = \frac{dq}{dt}$.
- The magnitude of the average current density, J, at a given cross-sectional area, A, in a conductor is given by $J = \frac{i}{A}$.
- The magnitude of the current density, J, is related to the magnitude of the drift velocity, v_{d}, of the current-carrying charges, $-e$, by $J = \frac{i}{A} = -nev_d$, where n is the number of charge carriers per unit volume.
- The resistivity, ρ, of a material is defined in terms of the magnitudes of the electric field applied across the material, E, and the resulting current density, J: $\rho = \frac{E}{J}$.
- The resistance, R, of a specific device having resistivity ρ, length L, and constant cross-sectional area A, is $R = \rho\frac{L}{A}$.
- The temperature dependence of the resistivity of a material is given by $\rho - \rho_0 = \rho_0\alpha(T - T_0)$, where ρ is the final resistivity, ρ_0 is the initial resistivity, α is the temperature coefficient of electric resistivity, T is the final temperature, and T_0 is the initial temperature.
- The electromotive force, or emf, is a potential difference created by a device that drives current through a circuit.
- Ohm's Law states that when a potential difference, ΔV, appears across a resistor, R, the current, i, flowing through the resistor is $i = \frac{\Delta V}{R}$.
- Resistors connected in series can be replaced with an equivalent resistance, R_{eq}. given by the sum of the resistances of the resistors: $R_{\text{eq}} = \sum_{i=1}^{n} R_i$.

- Resistors connected in parallel can be replaced with an equivalent resistance, R_{eq}, given by $\frac{1}{R_{\text{eq}}} = \sum_{i=1}^{n} \frac{1}{R_i}$.
- The power, P, dissipated by a resistor, R, through which a current, i, flows is given by $P = i\Delta V = i^2 R = \frac{(\Delta V)^2}{R}$, where ΔV is the potential drop across the resistor.

ANSWERS TO SELF-TEST OPPORTUNITIES

25.1 $\dfrac{700\ \text{mAh}}{0.1\ \text{mA}} = 7000\ \text{h} \approx 292\ \text{days}.$

25.2 $\Delta V = iR \Rightarrow i = \dfrac{\Delta V}{R} = \dfrac{1.50\ \text{V}}{10.0\ \Omega} = 0.150\ \text{A}.$

25.3 The maximum heating of the external resistance occurs when the external resistance is equal to the internal resistance.

$$V_\text{t} = V_\text{emf} + iR_\text{i} = i(R + R_\text{i})$$

$$P_\text{heat} = i^2 R = \frac{V_\text{t}^2 R}{(R + R_\text{i})^2}$$

$$\frac{dP_\text{heat}}{dR} = -\frac{2V_\text{t}^2 R}{(R + R_\text{i})^3} + \frac{V_\text{t}^2}{(R + R_\text{i})^2} = 0 \text{ at extremum.}$$

From this, it follows that $R = R_\text{i}$.

You can check that this extremum is a maximum by taking the second derivative at $R = R_\text{i}$:

$$\left.\frac{d^2 P_\text{heat}}{dR^2}\right|_{R=R_\text{i}} = V_\text{t}^2\left(\frac{6}{16R^3} - \frac{5}{8R^3}\right) = -\frac{V_\text{t}^2}{R^3}\left(\frac{1}{2}\right) < 0.$$

25.4 The sum of the two potential drops, across the diode and across the light bulb, has to equal 1.5 V, the potential difference supplied by the battery. In part (b), the diode prevents any current from flowing; therefore, the potential drop across the diode is 1.5 V and that across the light bulb is zero. In part (a), the potential drop across the diode is 0.7 V (see Figure 25.25), and therefore that across the light bulb is $1.5\ \text{V} - 0.7\ \text{V} = 0.8\ \text{V}$.

PROBLEM-SOLVING GUIDELINES

1. If a circuit diagram is not given as part of the problem statement, draw one yourself and label all the given values and unknown components. Indicate the direction of the current, starting from the emf source. (Don't worry about getting the direction of the current wrong in your diagram; if you guess wrong, your final answer for the current will be a negative number.)

2. Sources of emf supply potential to a circuit, and resistors reduce potential in the circuit. However, be careful to check the direction of the potential of the emf source relative to that of the current; a current flowing in the direction opposite to the potential of an emf device picks up a negative potential difference.

3. The sum of the potential drops across resistors in a circuit equals the net amount of emf supplied to the circuit. (This is a consequence of the law of conservation of energy.)

4. In any given wire segment, the current is the same everywhere. (This is a consequence of the law of conservation of charge.)

MULTIPLE-CHOICE QUESTIONS

25.1 If the current through a resistor is increased by a factor of 2, how does this affect the power that is dissipated?

a) It decreases by a factor of 4.

b) It increases by a factor of 2.

c) It decreases by a factor of 8.

d) It increases by a factor of 4.

25.2 You make a parallel connection between two resistors, resistor A having a very large resistance and resistor B having a very small resistance. The equivalent resistance for this combination will be

a) slightly greater than the resistance of resistor A.

b) slightly less than the resistance of resistor A.

c) slightly greater than the resistance of resistor B.

d) slightly less than the resistance of resistor B.

25.3 Two cylindrical wires, 1 and 2, made of the same material, have the same resistance. If the length of wire 2 is twice that of wire 1, what is the ratio of their cross-sectional areas, A_1 and A_2?

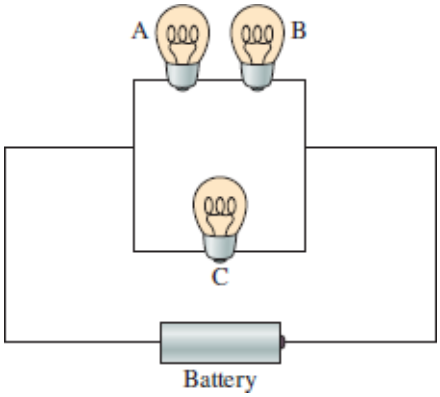
a) $A_1/A_2 = 2$

b) $A_1/A_2 = 4$

c) $A_1/A_2 = 0.5$

d) $A_1/A_2 = 0.25$

25.4 All three light bulbs in the circuit shown in the figure are identical. Which of the three shines the brightest?



a) A

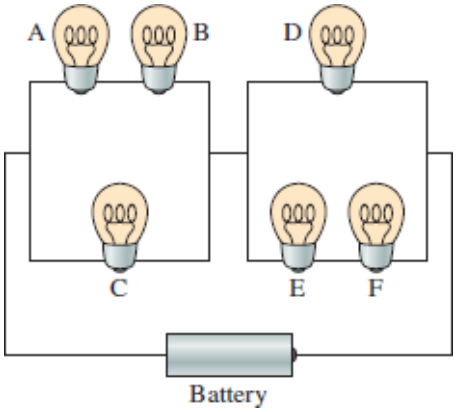
b) B

c) C

d) A and B

e) All three are equally bright.

25.5 All of the six light bulbs in the circuit shown in the figure are identical. Which ordering correctly expresses the relative brightness of the bulbs? (*Hint:* The more current flowing through a light bulb, the brighter it is!)



a) $A = B > C = D > E = F$

b) $A = B = E = F > C = D$

c) $C = D > A = B = E = F$

d) $A = B = C = D = E = F$

25.6 Which of the arrangements of three identical light bulbs shown in the figure draws the most current from the battery?

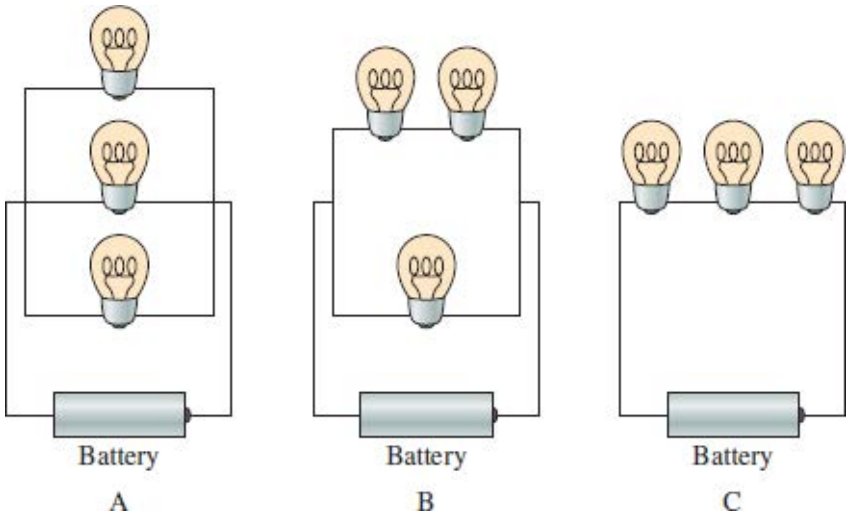
a) A

b) B

c) C

d) All three draw equal current.

e) A and C are tied for drawing the most current.



25.7 Which of the arrangements of three identical light bulbs shown in the figure has the highest resistance?

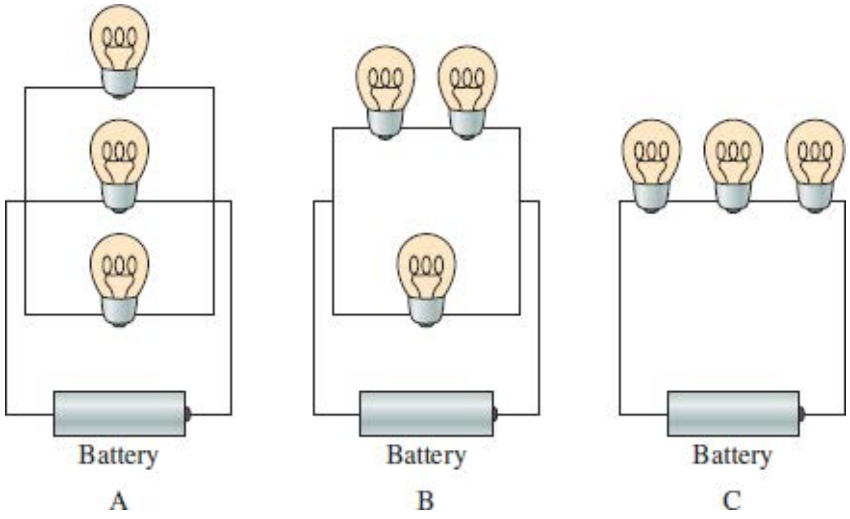
a) A

b) B

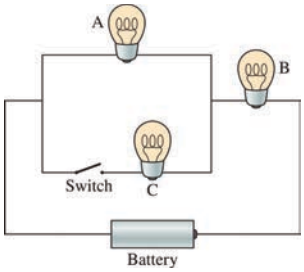
c) C

d) All three have equal resistance.

e) A and C are tied for having the highest resistance.



25.8 Three identical light bulbs are connected as shown in the figure. Initially the switch is closed. When the switch is opened (as shown in the figure), bulb C goes off. What happens to bulbs A and B?



a) Bulb A gets brighter, and bulb B gets dimmer.

b) Both bulbs A and B get brighter.

c) Both bulbs A and B get dimmer.

d) Bulb A gets dimmer, and bulb B gets brighter.

25.9 Which of the following wires has the largest current flowing through it?

a) a 1-m-long copper wire of diameter 1 mm connected to a 10-V battery

b) a 0.5-m-long copper wire of diameter 0.5 mm connected to a 5-V battery

c) a 2-m-long copper wire of diameter 2 mm connected to a 20-V battery

d) a 1-m-long copper wire of diameter 0.5 mm connected to a 5-V battery

e) All of the wires have the same current flowing through them.

25.10 Ohm's Law states that the potential difference across a device is equal to

a) the current flowing through the device times the resistance of the device.

b) the current flowing through the device divided by the resistance of the device.

c) the resistance of the device divided by the current flowing through the device.

d) the current flowing through the device times the cross-sectional area of the device.

e) the current flowing through the device times the length of the device.

25.11 A constant electric field is maintained inside a semiconductor. As the temperature is lowered, the magnitude of the current density inside the semiconductor

a) increases.

b) stays the same.

c) decreases.

d) may increase or decrease.

25.12 Which of the following is an incorrect statement?

a) The currents through electronic devices connected in series are equal.

b) The potential drops across electronic devices connected in parallel are equal.

c) More current flows across the smaller resistance when two resistors are connected in parallel.

d) More current flows across the smaller resistance when two resistors are connected in series.

25.13 Identical batteries are connected in three different arrangements to the same light bulb as shown in the figure. Assume that the batteries have no internal resistance. In which arrangement will the light bulb shine the brightest?

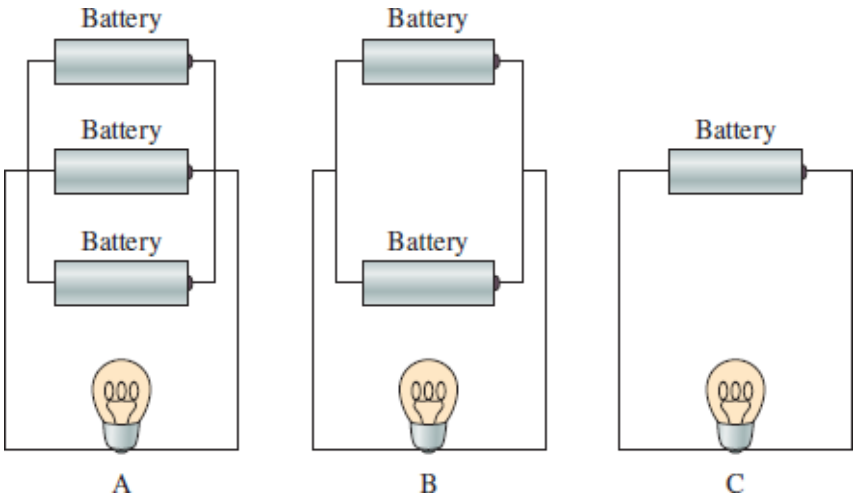
a) A

b) B

c) C

d) The bulb will have the same brightness in all three arrangements.

e) The bulb will not light in any of the arrangements.



25.14 Identical batteries are connected in three different arrangements to the same light bulb as shown in the figure. Assume that the batteries have no internal resistance. In which arrangement will the light bulb shine the brightest?

a) A

b) B

c) C

d) The bulb will have the same brightness in all three arrangements.

e) The bulb will not light in any of the arrangements.

CONCEPTUAL QUESTIONS

25.15 What would happen to the drift velocity of electrons in a wire if the resistance due to collisions between the electrons and the atoms in the crystal lattice of the metal disappeared?

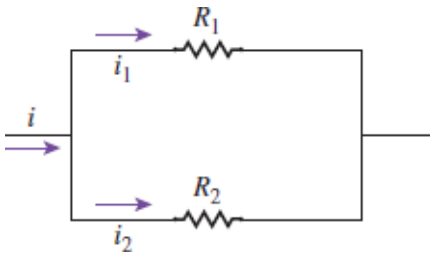
25.16 Why do light bulbs typically burn out just as they are turned on rather than while they are lit?

25.17 Two identical light bulbs are connected to a battery. Will the light bulbs be brighter if they are connected in series or in parallel?

25.18 Two resistors with resistances R_1 and R_2 are connected in parallel. Demonstrate that, no matter what the actual values of R_1 and R_2 are, the equivalent resistance is always less than the smaller of the two resistances.

25.19 Show that for resistors connected in series, it is always the highest resistance that dissipates the most power, while for resistors connected in parallel, it is always the lowest resistance that dissipates the most power.

25.20 For the connections shown in the figure, determine the current i_1 in terms of the total current, i, and R_1 and R_2.



25.21 An infinite number of resistors are connected in parallel. If $R_1 = 10\,\Omega$, $R_2 = 10^2\,\Omega$, $R_3 = 10^3\,\Omega$, and so on, show that $R_{\text{eq}} = 9\,\Omega$

25.22 You are given two identical batteries and two pieces of wire. The red wire has a higher resistance than the black wire. You place the red wire across the terminals of one battery and the black wire across the terminals of the other battery. Which wire gets hotter?

25.23 Should light bulbs (ordinary incandescent bulbs with tungsten filaments) be considered ohmic resistors? Why or why not? How would this be determined experimentally?

25.24 A charged-particle beam is used to inject a charge, Q_0, into a small, irregularly shaped region (not a cavity, just some region within the solid block) in the interior of a block of ohmic material with conductivity σ and permittivity ϵ at time $t = 0$. Eventually, all the injected charge will move to the outer surface of the block, but how quickly?

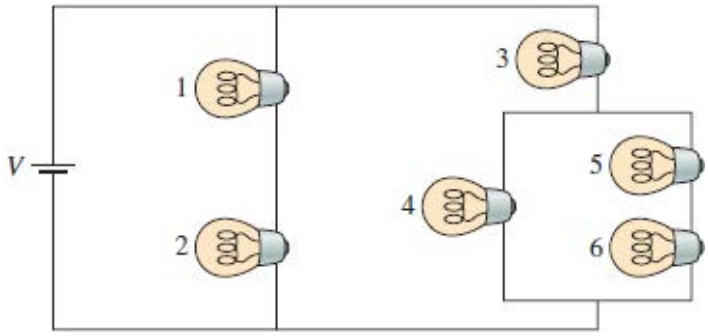
a) Derive a differential equation for the charge, $Q(t)$, in the injection region as a function of time.

b) Solve the equation from part (a) to find $Q(t)$ for all $t \geq 0$.

c) For copper, a good conductor, and for quartz (crystalline SiO_2), an insulator, calculate the time for the charge in the injection region to decrease by half. Look up the necessary values. Assume that the effective "dielectric constant" of copper is 1.00000.

25.25 Show that the drift speed of free electrons in a wire does not depend on the cross-sectional area of the wire.

25.26 Rank the brightness of the six identical light bulbs in the circuit in the figure. Each light bulb may be treated as an identical resistor with resistance R.



25.27 Two conductors of the same length and radius are connected to the same emf device. If the resistance of one is twice that of the other, to which conductor is more power delivered?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Sections 25.1 and 25.2

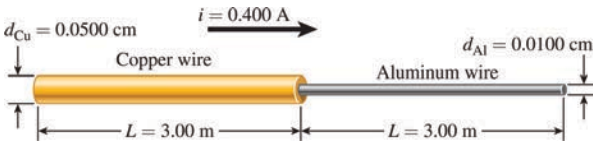
25.28 How many protons are in the beam traveling close to the speed of light in the Tevatron at Fermilab, which is carrying 11 mA of current around the 6.3-km circumference of the main Tevatron ring?

25.29 What is the current density in an aluminum wire having a radius of 1.00 mm and carrying a current of 1.00 mA? What is the drift speed of the electrons carrying this current? The density of aluminum is $2.70 \cdot 10^3\ \text{kg/m}^3$, and 1 mole of aluminum has a mass of 26.98 g. There is one conduction electron per atom in aluminum.

•**25.30** A copper wire has a diameter $d_{\text{Cu}} = 0.0500$ cm, is 3.00 m long, and has a charge-carrier density of $8.50 \cdot 10^{28}\text{electrons/m}^3$. As shown in the figure, the copper wire is attached to an equal length of aluminum wire with a diameter $d_{\text{Al}} = 0.0100$ cm and a charge-carrier density of $6.02 \cdot 10^{28}\text{electrons/m}^3$. A current of 0.400 A flows through the copper wire.

a) What is the ratio of the current densities in the two wires, $J_{\text{Cu}}/J_{\text{Al}}$?

b) What is the ratio of the drift velocities in the two wires, $v_{\text{d-Cu}}/v_{\text{d-Al}}$?



•**25.31** A current of 0.123 mA flows in a silver wire whose cross-sectional area is $0.923\ \text{mm}^2$.

a) Find the density of electrons in the wire, assuming that there is one conduction electron per silver atom.

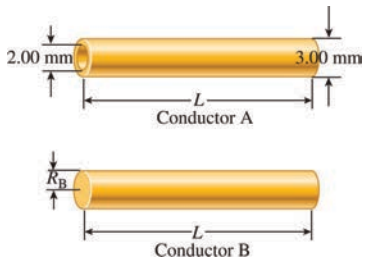
b) Find the current density in the wire assuming that the current is uniform.

c) Find the electrons' drift speed.

Section 25.3

25.32 What is the resistance of a copper wire of length $l = 10.9\,\text{m}$ and diameter $d = 1.30\,\text{mm}$? The resistivity of copper is $1.72 \cdot 10^{-8}\,\Omega\,\text{m}$.

25.33 Two conductors are made of the same material and have the same length L. Conductor A is a hollow tube with inside diameter 2.00 mm and outside diameter 3.00 mm; conductor B is a solid wire with radius R_B. What value of R_B is required for the two conductors to have the same resistance measured between their ends?



25.34 A copper coil has a resistance of 0.100 Ω at room temperature (20.0 °C). What is its resistance when it is cooled to −100. °C?

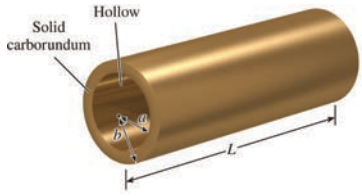
25.35 What gauge of aluminum wire will have the same resistance per unit length as 12-gauge copper wire?

25.36 A rectangular wafer of pure silicon, with resistivity $\rho = 2300\,\Omega\,\text{m}$, measures 2.00 cm by 3.00 cm by 0.0100 cm. Find the maximum resistance of this rectangular wafer between any two faces.

•**25.37** A copper wire that is 1.00 m long and has a radius of 0.500 mm is stretched to a length of 2.00 m. What is the fractional change in resistance, $\Delta R/R$ as the wire is stretched? What is $\Delta R/R$, for a wire of the same initial dimensions made out of aluminum?

•**25.38** The most common material used for sandpaper, silicon carbide, is also widely used in electrical applications. One common device is a tubular resistor made of a special grade of silicon carbide called *carborundum*. A particular carborundum resistor (see the figure) consists of a thick-walled cylindrical shell (a pipe) of inner radius $a = 1.50$ cm, outer radius $b = 2.50$ cm, and length

$L = 60.0$ cm. The resistance of this carborundum resistor at 20.0 °C is 1.00 Ω.



a) Calculate the resistivity of carborundum at room temperature. Compare this to the resistivities of the most commonly used conductors (copper, aluminum, and silver).

b) Carborundum has a high temperature coefficient of resistivity: $\alpha = 2.14 \cdot 10^{-3}\ \mathrm{K}^{-1}$. If, in a particular application, the carborundum resistor heats up to 300. °C, what is the percentage change in its resistance between room temperature (20.0 °C) and this operating temperature?

•• **25.39** As illustrated in the figure, a current, i, flows through the junction of two materials with the same cross-sectional area and with conductivities σ_1 and σ_2. Show that the total amount of charge at the junction is $\varepsilon_0 i(1/\sigma_2 - 1/\sigma_1)$.

Section 25.4

25.40 A potential difference of 12.0 V is applied across a wire of cross-sectional area $4.50\,\text{mm}^2$ and length 1000. km. The current passing through the wire is $3.20 \cdot 10^{-3}$ A.

a) What is the resistance of the wire?

b) What type of wire is this?

25.41 One brand of 12.0-V automotive battery used to be advertised as providing "600 cold-cranking amps." Assuming that this is the current the battery supplies if its terminals are shorted, that is, connected to negligible resistance, determine the internal resistance of the battery. (*IMPORTANT:* **Do not** attempt such a connection as it could be lethal!)

25.42 A copper wire has radius $r = 0.0250$ cm, is 3.00 m long, has resistivity $\rho = 1.72 \cdot 10^{-8}\ \Omega\,\text{m}$, and carries a current of 0.400 A. The wire has a charge-carrier density of $8.50 \cdot 10^{28}$ electrons/m^3.

a) What is the resistance, R, of the wire?

b) What is the electric potential difference, ΔV, across the wire?

c) What is the electric field, E, in the wire?

• **25.43** A 34-gauge copper wire $\left(A = 0.0201\ \text{mm}^2\right)$, with a constant potential difference of 0.100 V applied across its 1.00 m length at room temperature $(20.0\ ^\circ\text{C})$, is cooled to liquid nitrogen temperature $(77\ \text{K} = -196\ ^\circ\text{C})$.

a) Determine the percentage change in the wire's resistance during the drop in temperature.

b) Determine the percentage change in current flowing in the wire.

c) Compare the drift speeds of the electrons at the two temperatures.

Section 25.5

25.44 A resistor of unknown resistance and a 35.0-Ω resistor are connected across a 120.-V emf device in such a way that an 11.0-A current flows. What is the value of the unknown resistance?

25.45 A battery has a potential difference of 14.50 V when it is not connected in a circuit. When a 17.91-Ω resistor is connected across the battery, the potential difference of the battery drops to 12.68 V. What is the internal resistance of the battery?

25.46 When a battery is connected to a 100.-Ω resistor, the current is 4.00 A. When the same battery is connected to a 400.-Ω resistor, the current is 1.01 A. Find the emf supplied by the battery and the internal resistance of the battery.

•**25.47** A light bulb is connected to a source of emf. There is a 6.20 V drop across the light bulb and a current of 4.10 A flowing through the light bulb.

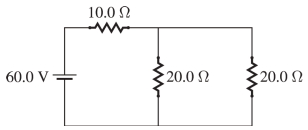
a) What is the resistance of the light bulb?

b) A second light bulb, identical to the first, is connected in series with the first bulb. The potential drop across the bulbs is now 6.29 V, and the current through the bulbs is 2.90 A. Calculate the resistance of each light bulb.

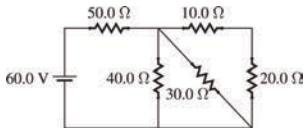
c) Why are your answers to parts (a) and (b) not the same?

Section 25.6

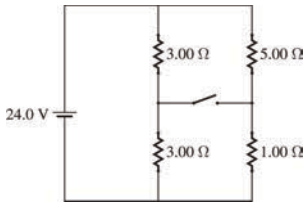
25.48 What is the current in the 10.0- Ω resistor in the circuit in the figure?



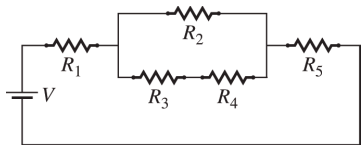
25.49 What is the equivalent resistance of the five resistors in the circuit in the figure?



• **25.50** What is the current in the circuit shown in the figure when the switch is (a) open and (b) closed?



25.51 For the circuit shown in the figure, $R_1 = 6.00\ \Omega$, $R_2 = 6.00\ \Omega$, $R_3 = 2.00\ \Omega$, $R_4 = 4.00\ \Omega$, $R_5 = 3.00\ \Omega$, and the potential difference is 12.0 V.

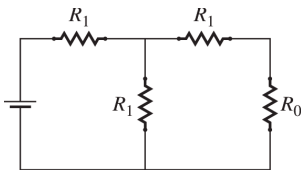


a) What is the equivalent resistance for the circuit?

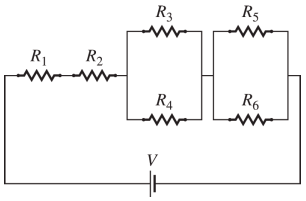
b) What is the current through R_5?

c) What is the potential drop across R_3?

25.52 Four resistors are connected in a circuit as shown in the figure. What value of R_1, expressed as a multiple of R_0, will make the equivalent resistance for the circuit equal to R_0?



•25.53 As shown in the figure, a circuit consists of an emf source with $V = 20.0$ V and six resistors. Resistors $R_1 = 5.00\ \Omega$ and $R_2 = 10.00\ \Omega$ are connected in series. Resistors $R_3 = 5.00\ \Omega$ and $R_4 = 5.00\ \Omega$ are connected in parallel and are in series with R_1 and R_2. Resistors $R_5 = 2.00\ \Omega$ and $R_6 = 2.00\ \Omega$ are connected in parallel and are also in series with R_1 and R_2.



a) What is the potential drop across each resistor?

b) How much current flows through each resistor?

Page 801

• 25.54 When a 40.0-V emf device is placed across two resistors in series, a current of 10.0 A flows through each of the resistors. When the same emf device is placed across the same two resistors in parallel, the current through the emf device is 50.0 A. What is the magnitude of the larger of the two resistances?

Section 25.7

25.55 A voltage spike causes the line voltage in a home to jump rapidly from 110. V to 150. V. What is the percentage increase in the power output of a 100.-W tungsten-filament incandescent light bulb during this spike, assuming that the bulb's resistance remains constant?

25.56 A thundercloud similar to the one described in Example 24.3 produces a lightning bolt that strikes a radio tower. If the lightning bolt transfers 5.00 C of charge in about 0.100 ms and the potential remains constant at 70.0 MV, find (a) the average current, (b) the average power, (c) the total energy, and (d) the effective resistance of the air during the lightning strike.

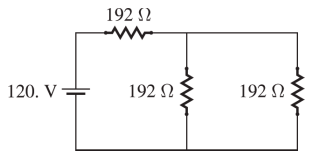
25.57 A hair dryer consumes 1600. W of power and operates at 110. V. (Assume that the current is DC. In fact, these are root-mean-square values of AC quantities, but the calculation is not affected. Chapter 30 covers AC circuits in detail.)

a) Will the hair dryer trip a circuit breaker designed to interrupt the circuit if the current exceeds 15.0 A?

b) What is the resistance of the hair dryer when it is operating?

25.58 How much money will a homeowner owe an electric company if he turns on a 100.00-W incandescent light bulb and leaves it on for an entire year? (Assume that the cost of electricity is $0.12000/kWh and that the light bulb lasts that long.) The same amount of light can be provided by a 26.000-W compact fluorescent light bulb. What would it cost the home-owner to leave one of those on for a year?

25.59 Three resistors are connected across a battery as shown in the figure.



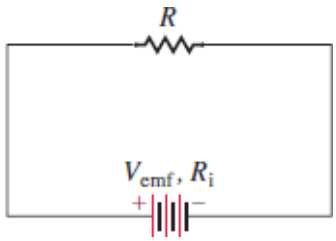
a) How much power is dissipated across the three resistors?

b) Determine the potential drop across each resistor.

25.60 Suppose an AAA battery is able to supply 625 mAh before its potential drops below 1.50 V. How long will it be able to supply

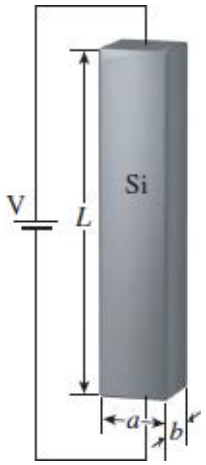
power to a 5.00-W bulb before the potential drops below 1.50 V?

•25.61 Show that the power supplied to the circuit in the figure by the battery with internal resistance R_i is maximum when the resistance of the resistor in the circuit, R, is equal to R_i. Determine the power supplied to R. For practice, calculate the power dissipated by a 12.0-V battery with an internal resistance of 2.00 Ω when $R = 1.00\ \Omega$, $R = 2.00\ \Omega$, and $R = 3.00\ \Omega$.



• **25.62** A water heater consisting of a metal coil that is connected across the terminals of a 15.0-V power supply is able to heat 250 mL of water from room temperature to boiling point in 45.0 s. What is the resistance of the coil?

• **25.63** A potential difference of $V = 0.500$ V is applied across a block of silicon with resistivity $8.70 \cdot 10^{-4}\ \Omega$ m. As indicated in the figure, the dimensions of the silicon block are width $a = 2.00$ mm and length $L = 15.0$ cm. The resistance of the silicon block is 50.0 Ω, and the density of charge carriers is $1.23 \cdot 10^{23}\ \text{m}^{-3}$. Assume that the current density in the block is uniform and that current flows in silicon according to Ohm's Law. The total length of 0.500-mm-diameter copper wire in the circuit is 75.0 cm, and the resistivity of copper is $1.69 \cdot 10^{-8}\ \Omega$ m.



a) What is the resistance, R_w, of the copper wire?

b) What are the direction and the magnitude of the electric current, i, in the block?

c) What is the thickness, b, of the block?

d) On average, how long does it take an electron to pass from one end of the block to the other?

e) How much power, P, is dissipated by the block?

f) As what form of energy does this dissipated power appear?

Additional Exercises

25.64 In an emergency, you need to run a radio that uses 30.0 W of power when attached to a 10.0-V power supply. The only power supply you have access to provides 25.0 kV, but you do have a large number of 25.0-Ω resistors. If you want the power to the radio to be as close as possible to 30.0 W, how many resistors should you use, and how should they be connected (in series or in parallel)?

25.65 A certain brand of hot dog cooker applies a potential difference of 120. V to opposite ends of the hot dog and cooks it by means of the heat produced. If 48.0 kJ is needed to cook each hot dog, what current is needed to cook three hot dogs simultaneously in 2.00 min? Assume a parallel connection.

25.66 A circuit consists of a copper wire of length 10.0 m and radius 1.00 mm connected to a 10.0-V battery. An aluminum wire of length 5.00 m is connected to the same battery and dissipates the same amount of power. What is the radius of the aluminum wire?

25.67 The resistivity of a conductor is $\rho = 1.00 \cdot 10^{-5}\ \Omega\ \text{m}$. If a cylindrical wire is made of this conductor, with a cross-sectional area of $1.00 \cdot 10^{-6}\ \text{m}^2$, what should the length of the wire be for its resistance to be 10.0 Ω?

25.68 Two cylindrical wires of identical length are made of copper and aluminum. If they carry the same current and have the same potential difference across their length, what is the ratio of their radii?

25.69 Two resistors with resistances 200. Ω and 400. Ω are connected (a) in series and (b) in parallel with an ideal 9.00-V battery. Compare the power delivered to the 200.-Ω resistor.

25.70 What are (a) the conductance and (b) the radius of a 3.50-m-long iron heating element for a 110.-V, 1500.-W heater?

25.71 A 100.-W, 240.-V European light bulb is used in an American household, where the electricity is delivered at 120. V. What power will it consume?

25.72 A modern house is wired for 115 V, and the current is limited by circuit breakers to a maximum of 200. A. (For the purpose of this problem, treat these as DC quantities.)

a) Calculate the minimum total resistance the circuitry in the house can have at any time.

b) Calculate the maximum electrical power the house can consume.

•25.73 A 12.0-V battery with an internal resistance $R_i = 4.00\ \Omega$ is attached across an external resistor of resistance R. Find the maximum power that can be delivered to the resistor.

• 25.74 A multiclad wire consists of a zinc core of radius 1.00 mm surrounded by a copper sheath of thickness 1.00 mm. The resistivity of zinc is $\rho = 5.964 \cdot 10^{-8}\ \Omega$ m. What is the resistance of a 10.0-m-long strand of this wire?

• 25.75 The Stanford Linear Accelerator accelerated a beam consisting of $2.0 \cdot 10^{14}$ electrons per second through a potential difference of $2.0 \cdot 10^{10}$ V.

a) Calculate the current in the beam.

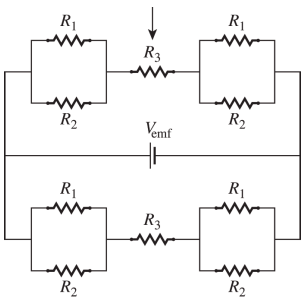
b) Calculate the power of the beam.

c) Calculate the effective ohmic resistance of the accelerator.

• 25.76 In the circuit shown in the figure, $R_1 = 3.00\ \Omega$, $R_2 = 6.00\ \Omega$, $R_3 = 20.0\ \Omega$, and $V_{emf} = 12.0$ V.

a) Determine a value for the equivalent resistance.

b) Calculate the magnitude of the current flowing through R_3 on the top branch of the circuit (marked with a vertical arrow).

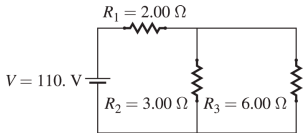


•25.77 Three resistors are connected to a power supply with $V = 110.$ V as shown in the figure.

a) Find the potential drop across R_3.

b) Find the current in R_1.

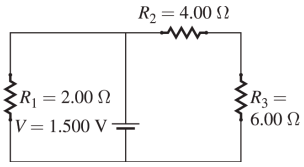
c) Find the rate at which thermal energy is dissipated from R_2.



• **25.78** A battery with $V = 1.500$ V is connected to three resistors as shown in the figure.

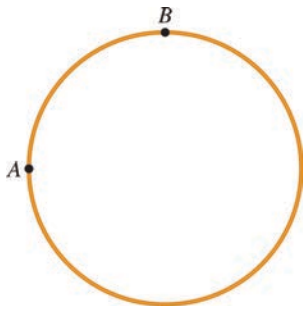
a) Find the potential drop across each resistor.

b) Find the current in each resistor.



• **25.79** A 2.50-m-long copper cable is connected across the terminals of a 12.0-V car battery. Assuming that it is completely insulated from its environment, how long after the connection is made will the copper start to melt? (Useful information: copper has a mass density of 8960 kg/m^3, a melting point of 1359 K, and a specific heat of 386 J/kg/K.)

• **25.80** A piece of copper wire is used to form a circular loop of radius 10.0 cm. The wire has a cross-sectional area of 10.0 mm^2. Points A and B are 90.0° apart, as shown in the figure. Find the resistance between points A and B.



•**25.81** Two conducting wires have identical lengths $L_1 = L_2 = L = 10.0$ km and identical circular cross sections of radius $r_1 = r_2 = r = 1.00$ mm. One wire is made of steel (with

resistivity $\rho_{\text{steel}} = 40.0 \cdot 10^{-8}\ \Omega\ \text{m}$); the other is made of copper (with resistivity $\rho_{\text{copper}} = 1.68 \cdot 10^{-8}\ \Omega\ \text{m}$).

a) Calculate the ratio of the power dissipated by the two wires, $P_{\text{copper}}/P_{\text{steel},}$ when they are connected in parallel and a potential difference of $V = 100.\ \text{V}$ is applied to them.

b) Based on this result, how do you explain the fact that conductors for power transmission are made of copper and not steel?

• **25.82** Before bendable tungsten filaments were developed, Thomas Edison used carbon filaments in his light bulbs. Though carbon has a very high melting temperature $(3599\ ^\circ\text{C})$, its sublimation rate is high at high temperatures. So carbon-filament bulbs were kept at lower temperatures, thereby rendering them dimmer than later tungsten-based bulbs. A typical carbon-filament bulb requires an average power of 40. W, when 110 volts is applied across it, and has a filament temperature of $1800\ ^\circ\text{C}$. Carbon, unlike copper, has a negative temperature coefficient of resistivity: $\alpha = -0.00050\ ^\circ\text{C}^{-1}$. Calculate the resistance at room temperature $(20.\ ^\circ\text{C})$ of this carbon filament.

•• **25.83** A material is said to be *ohmic* if an electric field, $\vec{E}$, in the material gives rise to current density $\vec{J} = \sigma\vec{E}$, where the conductivity, σ, is a constant independent of $\vec{E}$ or $\vec{J}$. (This is the precise form of Ohm's Law.) Suppose in some material an electric field, $\vec{E}$, produces current density, $\vec{J}$, not necessarily related by Ohm's Law; that is, the material may or may not be ohmic.

a) Calculate the rate of energy dissipation (sometimes called *ohmic heating* or *joule heating*) per unit volume in this material, in terms of $\vec{E}$ and $\vec{J}$.

b) Express the result of part (a) in terms of $\vec{E}$ alone and $\vec{J}$ alone, for $\vec{E}$ and $\vec{J}$ related via Ohm's Law, that is, in an ohmic material with conductivity σ or resistivity ρ.

MULTI-VERSION EXERCISES

25.84 A high-voltage direct current (HVDC) transmission line carries electrical power a distance of 643.1 km. The line transmits 7935 MW of power at a potential difference of 1.177 MV. If the HVDC line consists of one copper wire of diameter 2.353 cm, what fraction of the power is lost in transmission?

25.85 A high-voltage direct current (HVDC) transmission line carries 5319 MW of electrical power a distance of 411.7 km. The HVDC line consists of one copper wire of diameter 2.125 cm. The fraction of the power lost in transmission is $7.538 \cdot 10^{-2}$. What is the potential difference in the line?

25.86 A high-voltage direct current (HVDC) transmission line carries 5703 MW of electrical power at a potential difference of 1.197 MV. The HVDC line consists of one copper wire of diameter 1.895 cm. The fraction of the power lost in transmission is $1.166 \cdot 10^{-1}$. How long is the line?

25.87 The reserve capacity (RC) of a car battery is defined as the number of minutes the battery can provide 25.0 A of current at a potential difference of 10.5 V. Thus, the RC indicates how long the battery can power a car whose charging system has failed. How much energy is stored in a car battery with an RC of 110.0?

25.88 The reserve capacity (RC) of a car battery is defined as the number of minutes the battery can provide 25.0 A of current at a potential difference of 10.5 V. Thus, the RC indicates how long the battery can power a car whose charging system has failed. If a car battery stores $1.843 \cdot 10^6$ J of energy, what is its RC?

25.89 A flashlight bulb with a tungsten filament draws 374.3 mA of current when a potential difference of 3.907 V is applied. When the bulb is at room temperature ($20.00\ ^\circ\text{C}$) and is not lit, its resistance is

1.347 Ω. What is the temperature of the tungsten filament when the bulb is lit?

25.90 A flashlight bulb with a tungsten filament draws 420.1 mA when a potential difference of 3.949 V is applied. The temperature of the tungsten filament when the bulb is lit is 1291 $^\circ$C. What is the resistance of the bulb when it is at room temperature (20.00 $^\circ$C) and is not lit?

25.91 When a flashlight bulb with a tungsten filament is lit, the applied potential difference is 3.991 V and the temperature of the tungsten filament is $1.110 \cdot 10^3$ $^\circ$C. The resistance of the bulb when it is at room temperature (20.00 $^\circ$C) and is not lit is 1.451 Ω. What current does the bulb draw when it is lit?

The electric circuit, such as the one shown in Figure 26.1, undoubtedly changed the world. Modern electronics continues to change human society, at a faster and faster pace. It took 38 years for radio to reach 50 million users in the United States. However, it took only 13 years for television to reach that number of users, 10 years for cable TV, 5 years for the Internet, and 3 years for cell phones.

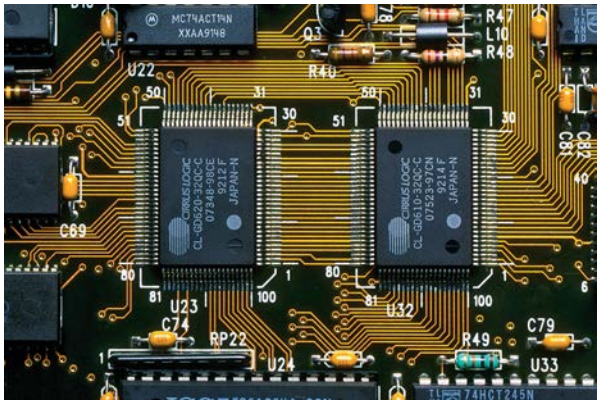

FIGURE 26.1 A circuit board can have hundreds of circuit components connected by metallic conducting paths.

Charles Smith/Getty Images

This chapter examines the techniques used to analyze circuits that cannot be broken down into simple series and parallel connections. Modern electronics design depends on millions of different circuits, each with its own purpose and configuration. However, regardless of how complicated a circuit becomes, the basic rules for analyzing it are the ones presented in this chapter.

Some of the circuits analyzed in this chapter contain not only resistors and emf devices but also capacitors. In these circuits, the current is not steady, but changes with time. Time-varying currents will be covered more thoroughly in later chapters, which introduce additional circuit components.

WHAT WE WILL LEARN

- Some circuits cannot be reduced to a single loop; complex circuits can be analyzed using Kirchhoff's rules.
- Kirchhoff's Junction Rule states that the algebraic sum of the currents at any junction in a circuit must be zero.
- Kirchhoff's Loop Rule states that the algebraic sum of the potential changes around any closed loop in a circuit must be zero.
- Single-loop circuits can be analyzed using Kirchhoff's Loop Rule.
- Multiloop circuits must be analyzed using both Kirchhoff's Junction Rule and Kirchhoff's Loop Rule.
- The current in a circuit that contains a resistor and a capacitor varies exponentially with time, with a characteristic time constant given by the product of the resistance and the capacitance.

26.1 Kirchhoff's Rules

In Chapter 25, we considered several kinds of direct current (DC) circuits, each containing one emf device along with resistors connected in series or in parallel. Some seemingly complicated circuits contain multiple resistors in series or in parallel that can be replaced with an equivalent resistance. However, we did not consider circuits containing multiple sources of emf. In addition, there are single-loop and multiloop circuits with emf devices and resistors that cannot be reduced to simple circuits containing parallel or series connections. Figure 26.2 shows two examples of such circuits. This chapter explains how to analyze these kinds of circuits using **Kirchhoff's rules.**

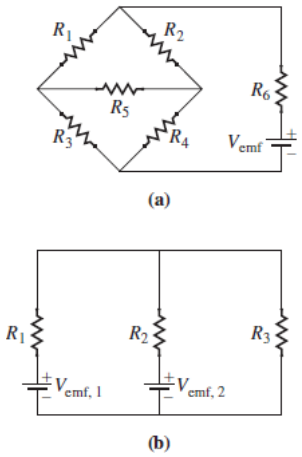

FIGURE 26.2 Two examples of circuits that cannot be reduced to simple combinations of parallel and series resistors.

Kirchhoff's Junction Rule

A **junction** is a place in a circuit where three or more wires are connected to each other. Each connection between two junctions in a circuit is called a **branch.** A branch can contain any number of different circuit elements and the wires between them. Each branch can have a current flowing, and this current is the same everywhere in the branch. This fact leads to **Kirchhoff's Junction Rule:** The sum of the currents entering a junction must equal the sum of the currents leaving the junction.

With a positive sign assigned (arbitrarily) to currents entering the junction and a negative sign to those exiting the junction, Kirchhoff's Junction Rule is expressed mathematically as

$$\text{Junction: } \sum_{k=1}^{n} i_k = 0. \tag{26.1}$$

How do you know which currents enter a junction and which exit the junction when you make a drawing like the one shown in Figure 26.3? You don't; you simply assign a direction for each current along a given wire. If an assigned direction turns out to be wrong, you will obtain a negative number for that particular current in your final solution.

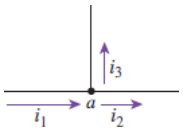

FIGURE 26.3 A single junction from a multiloop circuit.

Kirchhoff's Junction Rule is a direct consequence of the conservation of electric charge. Junctions do not have the capability of storing charge. Thus, charge conservation requires that all charges streaming into a junction also leave the junction, which is exactly what Kirchhoff's Junction Rule states.

According to Kirchhoff's Junction Rule, at each junction in a multiloop circuit, the current flowing into the junction must equal the current flowing out of the junction. For example, Figure 26.3 shows a single junction, *a,* with a current, i_1, entering the junction and two currents, i_2 and i_3, leaving the junction. According to Kirchhoff's Junction Rule, in this case,

$$\sum_{k=1}^{3} i_k = i_1 - i_2 - i_3 = 0 \Rightarrow i_1 = i_2 + i_3.$$

Kirchhoff's Loop Rule

A **loop** in a circuit is any set of connected wires and circuit elements forming a closed path. If you follow a loop, eventually you will get to the same point from which you started. For example, in the circuit diagram shown in Figure 26.2b, three possible loops can be identified. These three loops are shown in different colors (red, green, and blue) in Figure 26.4. The blue loop includes resistors 1 and 2, emf sources 1 and 2, and their connecting wires. The red loop includes resistors 2 and 3, emf source 2, and their connecting wires. Finally, the green loop includes resistors 1 and 3, emf source 1, and their connecting wires. Note that any given wire or circuit element can be and usually is part of more than one loop.

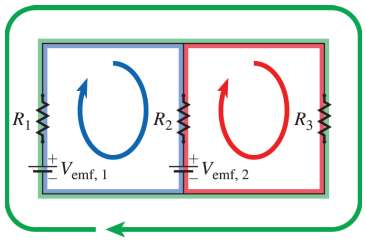

FIGURE 26.4 The three possible loops (indicated in red, green, and blue) for the circuit diagram shown in Figure 26.2b.

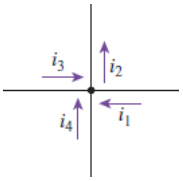
Concept Check 26.1

For the junction shown in the figure, which equation correctly expresses the sum of the currents?



a) $i_1 + i_2 + i_3 + i_4 = 0$
b) $i_1 - i_2 + i_3 + i_4 = 0$
c) $-i_1 + i_2 + i_3 - i_4 = 0$
d) $i_1 - i_2 - i_3 - i_4 = 0$
e) $i_1 + i_2 - i_3 - i_4 = 0$

You can move through any loop in a circuit in either a clockwise or a counterclockwise direction. Figure 26.4 shows a clockwise path through each of the loops, as indicated by the arrows. But the direction of the path taken around the loop is irrelevant as long as your choice is followed consistently all the way around the loop.

Summing the potential differences from all circuit elements encountered along any given loop yields the total potential difference of the complete path along the loop. **Kirchhoff's Loop Rule** then states: The potential difference around a complete circuit loop must sum to zero.

Kirchhoff's Loop Rule is a direct consequence of the fact that electric potential is single-valued. This means that the electric potential energy of a conduction electron at a point in the circuit has one specific value. Suppose this rule were not valid. Then we could analyze the potential changes of a conduction electron in going around a loop and find that the electron had a different potential energy when it returned to its starting point. The potential energy of this electron would change at a

point in the circuit, in obvious contradiction of energy conservation. In other words, Kirchhoff's Loop Rule is simply a consequence of the law of conservation of energy.

Application of Kirchhoff's Loop Rule requires conventions for determining the potential drop across each element of the circuit. This depends on the assumed direction of the current and the direction of the analysis. For emf sources, the rules are straightforward, since minus and plus signs (as well as short and long lines) indicate which side of the emf source is at the higher potential. The potential drop for an emf source is in the direction from minus to plus or from short line to long line. As noted earlier, the assignment of the current directions and the choice of a clockwise or counterclockwise path around a loop are arbitrary. Any direction will give the same information, as long as it is applied consistently around a loop. The conventions used to analyze circuit elements in a loop are summarized in Table 26.1 and Figure 26.5, where the magnitude of the current through the circuit element is i. (The labels in the rightmost column of Table 26.1 correspond to the parts of Figure 26.5.)

Table 26.1 **Conventions Used to Determine the Sign of Potential Changes Around a Single-Loop Circuit Containing Several Resistors and Sources of emf**

Element	Direction of Analysis	Potential Change	
R	Same as current	$-iR$	(a)
R	Opposite to current	$+iR$	(b)
V_{emf}	Same as emf	$+V_{\text{emf}}$	(c)
V_{emf}	Opposite to emf	$-V_{\text{emf}}$	(d)

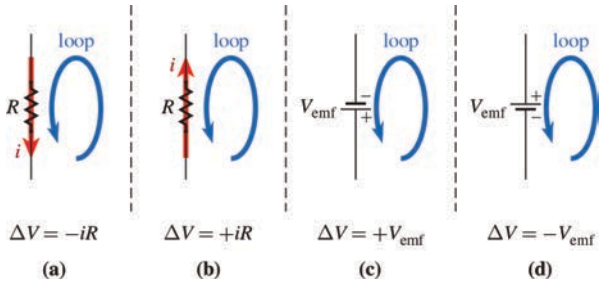


FIGURE 26.5 Sign convention for potential changes in analyzing loops.

If we move around a loop in a circuit in the same direction as the current, the potential changes across resistors will be negative. If we move around the loop in the opposite direction from the current, the potential changes across the resistors will be positive. If we move around a loop in such a way that we pass through an emf source from the negative to the positive terminal, this component contributes a positive potential difference. If we pass through an emf source from the positive to the negative terminal, that component contributes a negative potential difference.

With these conventions, Kirchhoff's Loop Rule is written in mathematical form as

$$\text{Closed loop: } \sum_{j=1}^{m} V_{\text{emf},j} - \sum_{k=1}^{n} i_k R_k = 0. \tag{26.2}$$

To clarify Kirchhoff's Loop Rule, Figure 26.6 shows a loop with two sources of emf and three resistors, using the three-dimensional display employed in Chapters 24 and 25, where the value of the electric potential, *V,* is represented in the vertical dimension. The most important point visualized by Figure 26.6 is that one complete turn around the loop always ends up at the same value of the potential as at the starting point. This is exactly what Kirchhoff's Loop Rule (equation 26.2) claims. An analogy with downhill skiing may help. When you ski, you are moving around in the gravitational potential, up and down the mountain. A ski lift corresponds to a source of emf, lifting you to a higher value of the gravitational potential. A downhill ski run corresponds to a resistor. (The annoying horizontal traverses between runs correspond to the wires in a circuit—both the wires and the horizontal traverses are at constant potential.) Thus, starting at $V_{\text{emf},1}$ and proceeding clockwise around the loop in Figure 26.6 is analogous to a ski outing in which you take two different lifts and ski down three different runs. And the important point, which is obvious in skiing, is that you return to the same altitude (the same value of the gravitational potential) from which you started, once you have completed the round trip.

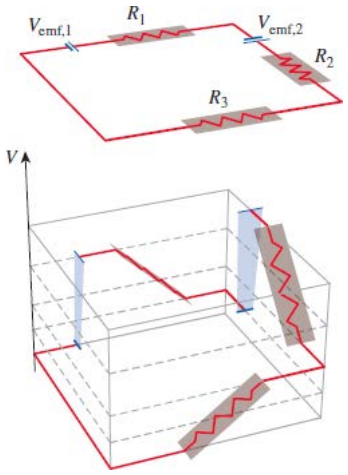

FIGURE 26.6 Loop with multiple sources of emf and multiple resistors.

A final point about loops is illustrated by Figure 26.7. Figure 26.7a reproduces the circuit shown in Figure 26.6 as a single isolated loop. Since this loop does not have junctions and thus has only one branch (which is the entire loop), the same current *i* flows everywhere in the loop. In Figure 26.7b, this loop is connected at four junctions (labeled *a, b, c,* and *d*) to other parts of a more extended circuit. Now this loop has four branches, each of which can have a different current flowing through it, as illustrated by the different-colored arrows in the figure. The point is this: In both parts of the figure, Kirchhoff's Loop Rule holds for the loop shown. The relative values of the electric potential between any two circuit elements in Figure 26.7b are the same as those shown in Figure 26.6, independent of the currents that are forced through the different branches of the loop by the rest of the circuit. (In our downhill skiing analogy, the currents correspond to different numbers of skiers on the lifts and the downhill runs. Obviously the number of skiers on the hill does not have any influence on the steepness of the hill.)

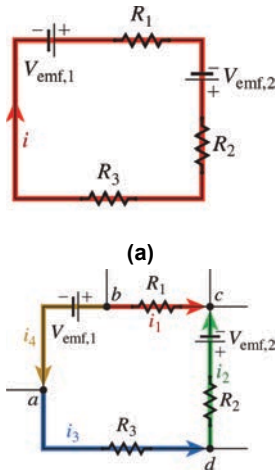

FIGURE 26.7 The same circuit loop as in Figure 26.6: (a) as an isolated single loop; (b) as a loop connected to other circuit branches.

26.2 Single-Loop Circuits

Let's begin analyzing general circuits by considering a circuit containing two sources of emf, $V_{\text{emf},1}$ and $V_{\text{emf},2}$, and two resistors, R_1 and R_2, connected in series in a single loop, as shown in Figure 26.8. Note that $V_{\text{emf},1}$ and $V_{\text{emf},2}$ have opposite polarity. In this single-loop circuit, there are no junctions, and so the entire circuit consists of a single branch. The current is the same everywhere in the loop. To illustrate the potential changes across the components of this circuit, Figure 26.9 shows a three-dimensional view.

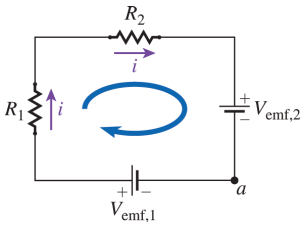

FIGURE 26.8 A single-loop circuit containing two resistors and two sources of emf in series.

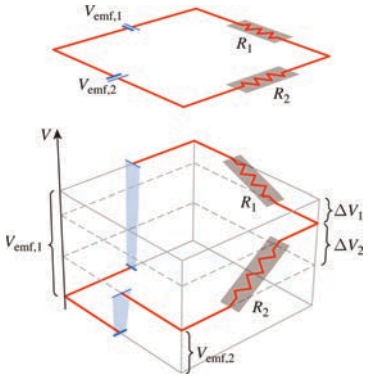

FIGURE 26.9 Three-dimensional representation of the single-loop circuit in Figure 26.8, containing two resistors and two sources of emf in series.

Although we could arbitrarily pick any point in the circuit of Figure 26.8 and assign it the value 0 V (or any other value of the potential, because we can always add a global additive constant to all potential values without changing the physical outcome), we start at point a with $V = 0\ \text{V}$ and proceed around the circuit in a clockwise direction (indicated by blue elliptical arrow in the figure). Because the components of the circuit are in series, the current, i, is the same in each component, and we assume that the current is flowing in the clockwise direction (purple arrows in the figure). The first circuit component along the clockwise path from point a is the source of emf, $V_{\text{emf},1}$, which produces a positive potential gain of $V_{\text{emf},1}$. Next is resistor R_1, which produces a potential drop given by $\Delta V_1 = iR_1$. Continuing around the loop, the next component is resistor R_2, which produces a potential drop given by $\Delta V_2 = iR_2$. Next, we encounter a second source of emf, $V_{\text{emf},2}$. This source of emf is wired into the circuit with its polarity opposite that of $V_{\text{emf},1}$. Thus, this

component produces a potential *drop* with magnitude $V_{\text{emf},2}$, rather than a potential *gain*. We have now completed the loop and are back at $V = 0$ V. Using equation 26.2, we sum the potential changes of this loop as follows:

$$V_{\text{emf},1} - \Delta V_1 - \Delta V_2 - V_{\text{emf},2} = V_{\text{emf},1} - iR_1 - iR_2 - V_{\text{emf},2} = 0.$$

To show that the direction in which we move through a loop, clockwise or counterclockwise, is arbitrary, let's analyze the same circuit in the counterclockwise direction, starting at point a (see Figure 26.10). The first circuit element is $V_{\text{emf},2}$, which produces a positive potential gain. The next element is R_2. Because we have assumed that the current is in the clockwise direction and we are analyzing the loop in the counterclockwise direction, the potential change for R_2 is $+iR_2$, according to the conventions listed in Table 26.1. Proceeding to the next element in the loop, R_1, we use a similar argument to designate the potential change for this resistor as $+iR_1$. The final element in the circuit is $V_{\text{emf},1}$, which is aligned in a direction opposite to that of our analysis, so the potential change across this element is $-V_{\text{emf},1}$. Kirchhoff's Loop Rule then gives us

$$+V_{\text{emf},2} + iR_2 + iR_1 - V_{\text{emf},1} = 0.$$

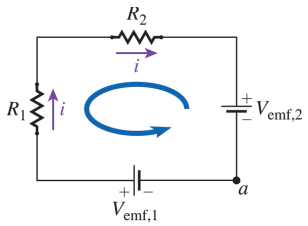

FIGURE 26.10 The same loop as in Figure 26.8, but analyzed in the counterclockwise direction.

You can see that the clockwise and counterclockwise loop directions give the same information, which means that the direction in which we choose to analyze the circuit does not matter.

SOLVED PROBLEM 26.1 Charging a Battery

A 12.0-V battery with internal resistance $R_i = 0.200\ \Omega$ is being charged by a battery charger that is capable of delivering a current of magnitude $i = 6.00$ A.

PROBLEM

What is the minimum emf the battery charger must supply to be able to charge the battery?

SOLUTION

THINK

The battery charger, which is an external source of emf, must have enough potential difference to overcome the potential difference of the battery and the potential drop across the battery's internal resistance. The battery charger must be hooked up so that its positive terminal is connected to the positive terminal of the battery to be charged. We can think of the battery's internal resistance as a resistor in a single-loop circuit that also contains two sources of emf with opposite polarities.

SKETCH

Figure 26.11 shows a diagram of the circuit, consisting of a battery with potential difference V_t and internal resistance R_i connected to an external source of emf, V_e. The yellow shaded area represents the battery's physical dimensions. Note that the positive terminal of the battery charger is connected to the positive terminal of the battery.

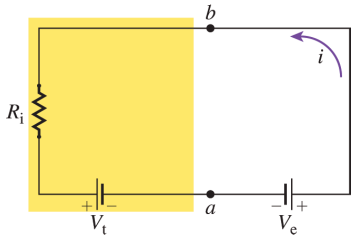

FIGURE 26.11 Circuit consisting of a battery with internal resistance connected to an external source of emf.

RESEARCH

We can apply Kirchhoff's Loop Rule to this circuit. We assume a current flowing counterclockwise around the circuit, as shown in Figure 26.11. The potential changes around the circuit must sum to zero. We sum the potential changes starting at point b and moving in a counterclockwise direction:

$$-iR_i - V_t + V_e = 0.$$

SIMPLIFY

We can solve this equation for the required potential difference of the charger:

$$V_e = iR_i + V_t,$$

where i is the current that the charger supplies.

CALCULATE

Putting in the numerical values gives us

$$V_\mathrm{e} = iR_\mathrm{i} + V_\mathrm{t} = (6.00\ \mathrm{A})(0.200\ \Omega) + 12.0\ \mathrm{V} = 13.20\ \mathrm{V}.$$

ROUND

We report our result to three significant figures:

$$V_\mathrm{e} = 13.2\ \mathrm{V}.$$

DOUBLE-CHECK

Our result indicates that the battery charger has to have a higher potential difference than the specified potential difference of the battery, which is reasonable. A typical charger for a 12-V battery has a potential difference of around 14 V.

26.3 Multiloop Circuits

Analyzing multiloop circuits requires both Kirchhoff's Loop Rule and Kirchhoff's Junction Rule. The procedure for analyzing a multiloop circuit consists of identifying complete loops and junction points in the circuit and applying Kirchhoff's rules to these parts of the circuit separately. Analyzing the single loops in a multiloop circuit with Kirchhoff's Loop Rule and the junctions with Kirchhoff's Junction Rule results in a system of coupled equations in several unknown variables. These equations can be solved for the quantities of interest using various techniques, including direct substitution. Example 26.1 illustrates the analysis of a multiloop circuit.

EXAMPLE 26.1 Multiloop Circuit

Consider the circuit shown in Figure 26.12. This circuit has three resistors, R_1, R_2, and R_3, and two sources of emf, $V_{\text{emf},1}$ and $V_{\text{emf},2}$. The red arrows show the direction of potential drop across the emf sources. This circuit cannot be resolved into simple series or parallel connections. To analyze this circuit, we need to assign directions to the currents flowing through the resistors. We can choose these directions arbitrarily (knowing that if we choose the wrong direction, the resulting current value will be negative). Figure 26.13 shows the circuit with the assigned directions for the currents shown by the purple arrows.

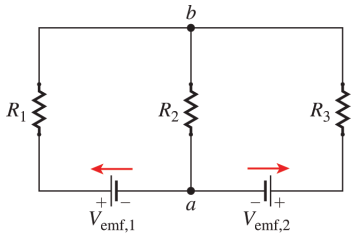

FIGURE 26.12 Multiloop circuit with three resistors and two sources of emf.

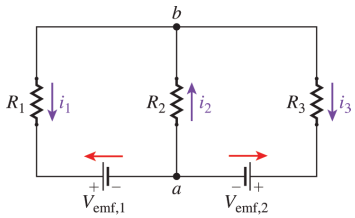

FIGURE 26.13 Multiloop circuit with the assumed direction of the current through the resistors indicated.

Let's consider junction b first. The current entering the junction must equal the current leaving it, so we can write

$$i_2 = i_1 + i_3. \tag{i}$$

Looking at junction a, we again equate the incoming current and the outgoing current to get

$$i_1 + i_3 = i_2,$$

which provides the same information obtained for junction b. Note that this is a typical result: If a circuit has n junctions, it is possible to obtain at most $n - 1$ independent equations from application of Kirchhoff's Junction Rule. (In this case, $n = 2$, so we can get only one independent equation.)

At this point we cannot determine the currents in the circuit because we have three unknown values and only one equation. Therefore, we need two more independent equations. To get these equations, we apply Kirchhoff's Loop Rule. We can identify three loops in the circuit shown in Figure 26.13:

1. the left half of the circuit, including the elements R_1, R_2, and $V_{\text{emf},1}$;
2. the right half of the circuit, including the elements R_2, R_3, and $V_{\text{emf},2}$; and

3. the outer loop, including the elements R_1, R_3, $V_{\text{emf},1}$, and $V_{\text{emf},2}$.

Applying Kirchhoff's Loop Rule to the left half of the circuit, using the assumed directions for the currents and analyzing the loop in a counterclockwise direction starting at junction b, we obtain

$$-i_1R_1 - V_{\text{emf},1} - i_2R_2 = 0,$$

or

$$i_1R_1 + V_{\text{emf},1} + i_2R_2 = 0. \qquad \textbf{(ii)}$$

Applying the Loop Rule to the right half of the circuit, again starting at junction b and analyzing the loop in a clockwise direction, we get

$$-i_3R_3 - V_{\text{emf},2} - i_2R_2 = 0,$$

or

$$i_3R_3 + V_{\text{emf},2} + i_2R_2 = 0. \qquad \textbf{(iii)}$$

Applying the Loop Rule to the outer loop, starting at junction b and working in a clockwise direction, gives us

$$-i_3R_3 - V_{\text{emf},2} + V_{\text{emf},1} + i_1R_1 = 0.$$

This equation provides no new information because we can also obtain it by subtracting equation (iii) from equation (ii). For all three loops, we obtain equivalent information if we analyze them in either a counterclockwise direction or a clockwise direction or if we start at any other point and move around the loops from there.

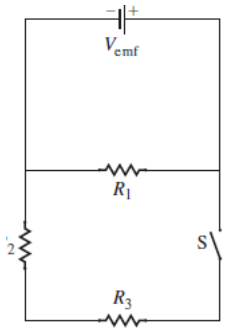
With three equations, (i), (ii), and (iii), and three unknowns, i_1, i_2, and i_3, we can solve for the unknown currents in several ways. For example, we could put the three equations in matrix format and then solve them using Kramer's method on a calculator. This is a recommended method for complicated circuits with many equations and many unknowns. However, for this example, we can proceed by substituting from equation (i) into the other two, thus eliminating i_2. We then solve one of the two resulting equations for i_1 and substitute from that into the other to obtain an expression for i_3. Substituting back then gives solutions for i_2 and i_1:

$$\begin{aligned} i_1 &= -\frac{(R_2 + R_3)V_{\text{emf},1} - R_2V_{\text{emf},2}}{R_1R_2 + R_1R_3 + R_2R_3} \\ i_2 &= -\frac{R_3V_{\text{emf},1} + R_1V_{\text{emf},2}}{R_1R_2 + R_1R_3 + R_2R_3} \\ i_3 &= -\frac{-R_2V_{\text{emf},1} + (R_1 + R_2)V_{\text{emf},2}}{R_1R_2 + R_1R_3 + R_2R_3}. \end{aligned}$$

Note: You do not need to remember this particular solution or the linear algebra used to get there. However, the general method of applying Kirchhoff's rules for loops and junctions, and assigning currents in arbitrary directions is the central idea of circuit analysis.

Concept Check 26.2

In the circuit in the figure, there are three identical resistors. The switch, S, is initially open. When the switch is closed, what happens to the current flowing in R_1?



a) The current in R_1 decreases.

b) The current in R_1 increases.

c) The current in R_1 stays the same.

SOLVED PROBLEM 26.2 The Wheatstone Bridge

The Wheatstone bridge is a particular circuit used to measure unknown resistances. The circuit diagram of a Wheatstone bridge is shown in Figure 26.14. This circuit consists of three known resistances, R_1, R_3, and a variable resistor, R_v, as well as an unknown resistance, R_u. A source of emf, *V,* is connected across junctions *a* and *c*. A sensitive ammeter (a device used to measure current, discussed in Section 26.4) is connected between junctions *b* and *d*. The Wheatstone bridge is used to determine R_u by varying R_v until the ammeter between *b* and *d* shows no current flowing. When the ammeter reads zero, the bridge is said to be balanced.

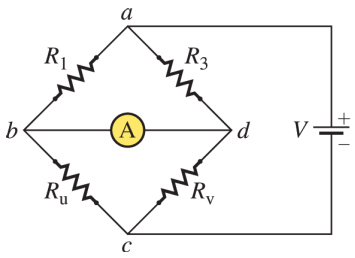


FIGURE 26.14 Circuit diagram of a Wheatstone bridge.

PROBLEM

Determine the unknown resistance, R_u, in the Wheatstone bridge shown in Figure 26.14. The known resistances are $R_1 = 100.0\ \Omega$ and $R_3 = 110.0\ \Omega$, and $R_v = 15.63\ \Omega$ when the current through the ammeter is zero, indicating that the bridge is balanced.

SOLUTION

THINK

The circuit has four resistors and an ammeter, and each component can have a current flowing through it. However, in this case, with $R_v = 15.63\ \Omega$ there is no current flowing through the ammeter. Setting this current to zero leaves four unknown currents through the four resistors, and we therefore need four equations. We can use Kirchhoff's rules to analyze two loops, *adb* and *cbd,* and two junctions, *b* and *d*.

SKETCH

Figure 26.15 shows the Wheatstone bridge with the assumed directions for currents i_1, i_3, i_u, i_v, and i_A.

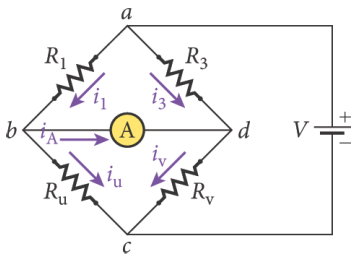

FIGURE 26.15 The Wheatstone bridge with the assumed current directions indicated.

RESEARCH

We first apply Kirchhoff's Loop Rule to loop *adb,* starting at *a* and going clockwise, to obtain

$$-i_3R_3 + i_\mathrm{A}R_\mathrm{A} + i_1R_1 = 0, \tag{i}$$

where R_A is the resistance of the ammeter. We apply Kirchhoff's Loop Rule again to loop *cbd,* starting at *c* and going clockwise, to get

$$+i_\mathrm{u}R_\mathrm{u} - i_\mathrm{A}R_\mathrm{A} - i_\mathrm{v}R_\mathrm{v} = 0. \tag{ii}$$

Now we can use Kirchhoff's Junction Rule at junction *b* to obtain

$$i_1 = i_\mathrm{A} + i_\mathrm{u}. \tag{iii}$$

Another application of Kirchhoff's Junction Rule, at junction *d,* gives

$$i_3 + i_\mathrm{A} = i_\mathrm{v}. \tag{iv}$$

SIMPLIFY

When the current through the ammeter is zero $(i_\mathrm{A} = 0)$, we can rewrite equations (i) through (iv) as follows:

$$i_1R_1 = i_3R_3 \tag{v}$$

$$i_\mathrm{u}R_\mathrm{u} = i_\mathrm{v}R_\mathrm{v} \tag{vi}$$

$$i_1 = i_\mathrm{u} \tag{vii}$$

and

$$i_3 = i_\mathrm{v}. \tag{viii}$$

Dividing equation (vi) by equation (v) gives us

$$\frac{i_\mathrm{u}R_\mathrm{u}}{i_1R_1} = \frac{i_\mathrm{v}R_\mathrm{v}}{i_3R_3},$$

which we can rewrite using equations (vii) and (viii):

$$R_\mathrm{u} = \frac{R_1}{R_3}R_\mathrm{v}.$$

CALCULATE

Putting in the numerical values, we get

$$R_{\mathrm{u}} = \frac{R_1}{R_3} R_{\mathrm{v}} = \frac{100.0\ \Omega}{110.0\ \Omega} 15.63\ \Omega = 14.20901 \Omega.$$

ROUND

We report our result to four significant figures:

$$R_{\mathrm{u}} = 14.21\ \Omega.$$

DOUBLE-CHECK

Our result for the resistance of the unknown resistor is similar to the value for the variable resistor. Thus, our answer seems reasonable, because the other two resistors in the circuit also have resistances that are approximately equal.

Self-Test Opportunity 26.1

Show that when the current through the ammeter is zero, the equivalent resistance for the resistors in the Wheatstone bridge in Figure 26.14 is given by

$$R_{\mathrm{eq}} = \frac{(R_1 + R_{\mathrm{u}})(R_3 + R_{\mathrm{v}})}{R_1 + R_{\mathrm{u}} + R_3 + R_{\mathrm{v}}}.$$

General Observations on Circuit Networks

An important observation about solving circuit problems is that, in general, the complete analysis of a circuit requires knowing the current flowing in each branch of the circuit. We use Kirchhoff's Junction Rule and Loop Rule to establish equations relating the currents, and we need as many linearly independent equations as there are branches to guarantee that we can obtain a solution to the system.

Let's consider the abstract example shown in Figure 26.16, where all circuit components except the wires have been omitted. This circuit has four junctions, shown in blue in Figure 26.16a. Six branches connect these junctions, shown in Figure 26.16b. We therefore need six linearly independent equations relating the currents in these branches. It was noted earlier that not all equations obtained by applying Kirchhoff's rules to a circuit are linearly independent. This fact is worth repeating: If a circuit has n junctions, it is possible to obtain at most $n - 1$ independent equations from application of the Junction Rule. (For the circuit in Figure 26.16, $n = 4$, so we can get only three independent equations.)

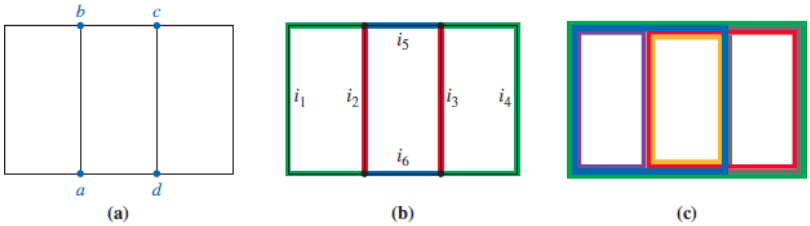

FIGURE 26.16 Circuit network consisting of (a) four junctions, (b) six branches, (c) six possible loops.

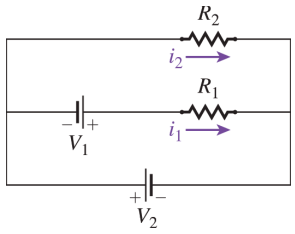
The Junction Rule alone is not enough for the complete analysis of any circuit. It is generally best to write as many equations as possible for junctions and then augment them with equations obtained from loops. Figure 26.16c shows that there are six possible loops in this network, which are marked in different colors. Clearly, there are more loops than we need to analyze to obtain three equations. This is again a general observation: The system of equations that can be set up by considering all possible loops is overdetermined. Thus, you'll always have the freedom to select particular loops to augment the equations obtained from analyzing the junctions. As a general rule of thumb, it is best to choose loops with fewer circuit elements, which often makes the subsequent linear algebra considerably simpler. In particular, if you are asked to find the current in a particular branch of a network, choosing the appropriate loop may allow you to avoid setting up a lengthy set of equations and let you solve the problem with just one equation. So it pays to devote some attention to the selection of loops! Do not write down more equations than you need to solve for the unknowns in any particular problem. This will only complicate the algebra. However, once you have the solution, you can use one or more of the unused loops to check your values.

Concept Check 26.3

In the multiloop circuit shown in the figure, $V_1 = 6.00$ V, $V_2 = 12.0$ V, $R_1 = 10.0\ \Omega$, and $R_2 = 12.0$ V. What is the magnitude of current i_2?



a) 0.500 A

b) 0.750 A

c) 1.00 A

d) 1.25 A

e) 1.50 A

26.4 Ammeters and Voltmeters

A device used to measure current is called an **ammeter.** A device used to measure potential difference is called a **voltmeter.** To measure the current, an ammeter must be wired in a circuit in *series*. Figure 26.17 shows an ammeter connected in a circuit in a way that allows it to measure the current i. To measure the potential difference, a voltmeter must be wired in *parallel* with the component across which the potential difference is to be measured. Figure 26.17 shows a voltmeter placed in the circuit to measure the potential drop across resistor R_1.

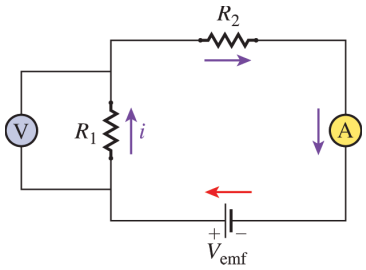


FIGURE 26.17 Placement of an ammeter and a voltmeter in a simple circuit.

It is important to realize that these instruments must be able to make measurements while disturbing the circuit as little as possible. Thus, ammeters are designed to have as low a resistance as possible, usually on the order of 1 Ω, so they do not have an appreciable effect on the currents they measure. Voltmeters are designed to have as high a resistance as possible, usually on the order of $10\ \text{M}\ \Omega\left(10^7\ \Omega\right)$, so they have a negligible effect on the potential differences they are measuring.

In practice, measurements of current and potential difference are made with a digital multimeter that can switch between functioning as an ammeter and functioning as a voltmeter. It displays the results with a numerical digital display, which includes the sign of the potential difference or current. Most digital multimeters can also measure the resistance of a circuit component; that is, they can function as an **ohmmeter.** The digital multimeter performs this task by applying a known potential difference and measuring the resulting current. This test is useful for determining circuit continuity and the status of fuses, as well as measuring the resistance of resistors.

EXAMPLE 26.2 Voltmeter in a Simple Circuit

Consider a simple circuit consisting of a source of emf with voltage $V_{\text{emf}} = 150.\ \text{V}$ and a resistor with resistance $R = 100.\ \text{k}\Omega$ (Figure 26.18). A voltmeter with resistance $R_{\text{V}} = 10.0\ \text{M}\Omega$ is connected across the resistor.

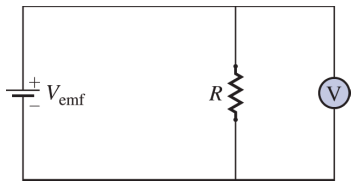

FIGURE 26.18 A simple circuit with a voltmeter connected in parallel across a resistor.

PROBLEM 1

What is the current in the circuit before the voltmeter is connected?

SOLUTION 1

Ohm's Law says that $V = iR$, so we can find the current in the circuit:

$$i = \frac{V_{\text{emf}}}{R} = \frac{150.\ \text{V}}{100. \cdot 10^3 \Omega} = 1.50 \cdot 10^{-3}\ \text{A} = 1.50\ \text{mA}.$$

PROBLEM 2

What is the current in the circuit when the voltmeter is connected across the resistor?

SOLUTION 2

The equivalent resistance of the resistor and the voltmeter connected in parallel is given by

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R} + \frac{1}{R_{\text{V}}}.$$

Solving for the equivalent resistance and putting in the numerical values, we get

$$R_{\text{eq}} = \frac{RR_{\text{V}}}{R + R_{\text{V}}} = \frac{\left(100. \cdot 10^3\ \Omega\right)\left(10.0 \cdot 10^6\ \Omega\right)}{100. \cdot 10^3\ \Omega + 10.0 \cdot 10^6\ \Omega} = 9.90 \cdot 10^4\ \Omega = 99.0\ \text{k}\Omega.$$

The current is then

$$i = \frac{V_{\text{emf}}}{R_{\text{eq}}} = \frac{150.\ \text{V}}{9.90 \cdot 10^4\ \Omega} = 1.52 \cdot 10^{-3}\ \text{A} = 1.52\ \text{mA}.$$

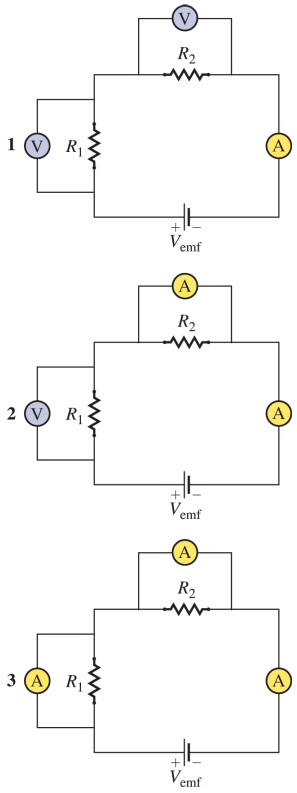
The current in the circuit increases by 0.02 mA when the voltmeter is connected because the parallel combination of the resistor and the voltmeter has a lower resistance than that of the resistor alone. However, the effect is small, even with this relatively large resistance $(R = 100.\ \text{k}\Omega)$.

Self-Test Opportunity 26.2

When the starter of a car is engaged while the headlights are on, the headlights dim. Explain.

Concept Check 26.4

Which of the circuits shown in the figure will not function properly?



a) 1
b) 2
c) 3
d) 1 and 2
e) 2 and 3

SOLVED PROBLEM 26.3 Increasing the Range of an Ammeter

PROBLEM

An ammeter can be used to measure different ranges of current by adding a current divider in the form of a shunt resistor connected in parallel with the ammeter. A *shunt resistor* is simply a resistor with a very small resistance. Its name arises from the fact that when it is connected in parallel with the ammeter, whose resistance is larger, most of the current is shunted through it, bypassing the meter. The sensitivity of the ammeter is therefore decreased allowing it to measure larger currents. Suppose an ammeter produces a full-scale reading when a current of $i_{\text{int}} = 5.10\ \text{mA}$ passes through it. The ammeter has an internal resistance of $R_{\text{i}} = 16.8\ \Omega$. To use this ammeter to measure a maximum current of $i_{\text{max}} = 20.2\ \text{A}$, what should be the resistance of the shunt resistor, R_{s}, connected in parallel with the ammeter?

SOLUTION

THINK

The shunt resistor connected in parallel with the ammeter needs to have a substantially lower resistance than the internal resistance of the ammeter. Most of the current will then flow through the shunt resistor rather than the ammeter.

SKETCH

Figure 26.19 shows a shunt resistor, R_{s}, connected in parallel with an ammeter.

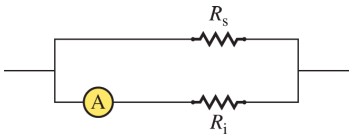


FIGURE 26.19 An ammeter with a shunt resistor connected across it in parallel.

RESEARCH

The two resistors are connected in parallel, so the potential difference across each resistor is the same. The potential difference that gives a full-scale reading on the ammeter is

$$\Delta V_{\text{fs}} = i_{\text{int}} R_{\text{i}}. \tag{i}$$

From Chapter 25, we know that the equivalent resistance of the two resistors in parallel is given by

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_{\text{i}}} + \frac{1}{R_{\text{s}}}. \tag{ii}$$

The voltage drop across the equivalent resistance must equal the voltage drop across the ammeter that gives a full-scale reading when current i_{max} is flowing through the circuit. Therefore, we can write

$$\Delta V_{\text{fs}} = i_{\text{max}} R_{\text{eq}}. \tag{iii}$$

SIMPLIFY

Combining equations (i) and (iii) for the potential difference gives

$$\Delta V_{\text{fs}} = i_{\text{int}} R_{\text{i}} = i_{\text{max}} R_{\text{eq}}. \tag{iv}$$

We can rearrange equation (iv) and substitute for R_{eq} in equation (ii):

$$\frac{i_{\text{max}}}{i_{\text{int}} R_{\text{i}}} = \frac{1}{R_{\text{eq}}} = \frac{1}{R_{\text{i}}} + \frac{1}{R_{\text{s}}}. \tag{v}$$

Solving equation (v) for the shunt resistance gives us

$$\frac{1}{R_{\text{s}}} = \frac{i_{\text{max}}}{i_{\text{int}} R_{\text{i}}} - \frac{1}{R_{\text{i}}} = \frac{1}{R_{\text{i}}} \left(\frac{i_{\text{max}}}{i_{\text{int}}} - 1 \right) = \frac{1}{R_{\text{i}}} \left(\frac{i_{\text{max}} - i_{\text{int}}}{i_{\text{int}}} \right),$$

or

$$R_{\text{s}} = R_{\text{i}} \frac{i_{\text{int}}}{i_{\text{max}} - i_{\text{int}}}.$$

CALCULATE

Putting in the numerical values, we get

$$\begin{aligned} R_{\text{s}} &= R_{\text{i}} \frac{i_{\text{int}}}{i_{\text{max}} - i_{\text{int}}} = (16.8\ \Omega) \frac{5.10 \cdot 10^{-3}\text{A}}{20.0\ \text{A} - 5.10 \cdot 10^{-3}\text{A}} \\ &= 0.00424266\ \Omega. \end{aligned}$$

ROUND

We report our result to three significant figures:

$$R_{\text{s}} = 0.00424\ \Omega.$$

DOUBLE-CHECK

The equivalent resistance of the ammeter and the shunt resistor connected in parallel is given by equation (ii). Solving that equation for the equivalent resistance and putting in the numbers gives

$$R_{\text{eq}} = \frac{R_{\text{i}} R_{\text{s}}}{R_{\text{i}} + R_{\text{s}}} = \frac{(16.8\ \Omega)(0.00424\ \Omega)}{16.8\ \Omega + 0.00424\ \Omega} = 0.00424\ \Omega.$$

Thus, the equivalent resistance of the ammeter and the shunt resistor connected in parallel is approximately equal to the resistance of the shunt resistor. This low equivalent resistance is necessary for a current-measuring instrument, which must be placed in series in a circuit. If the current-measuring device has a high resistance, its presence will disturb the measurement of the current.

26.5 RC Circuits

So far in this chapter, we have dealt with circuits containing sources of emf and resistors. The currents in these circuits do not vary in time. Now we consider circuits that contain capacitors (see Chapter 24), as well as sources of emf and resistors. Called **RC circuits,** these circuits have currents that *do* vary with time. The simplest circuit operations that involve time-dependent currents are the charging and discharging of a capacitor. Understanding these time-dependent processes involves the solution of some simple differential equations. After magnetism and magnetic phenomena are introduced in Chapters 27 through 29, time-dependent currents will be discussed again in Chapter 30, which will build on the techniques introduced here.

Charging a Capacitor

Consider a circuit with a source of emf, V_{emf}, a resistor, R, and a capacitor, C (Figure 26.20). Initially, the switch is open and the capacitor is uncharged, as shown in Figure 26.20a. When the switch is closed (Figure 26.20b), current begins to flow in the circuit, building up opposite charges on the plates of the capacitor and thus creating a potential difference, ΔV, across the capacitor. Current flows because of the source of emf, which maintains a constant voltage. When the capacitor is fully charged (Figure 26.20c), no more current flows in the circuit. The potential difference across the plates is then equal to the voltage provided by the source of emf, and the magnitude of the total charge, q_{tot}, on each plate of the capacitor is $q_{\text{tot}} = CV_{\text{emf}}$.

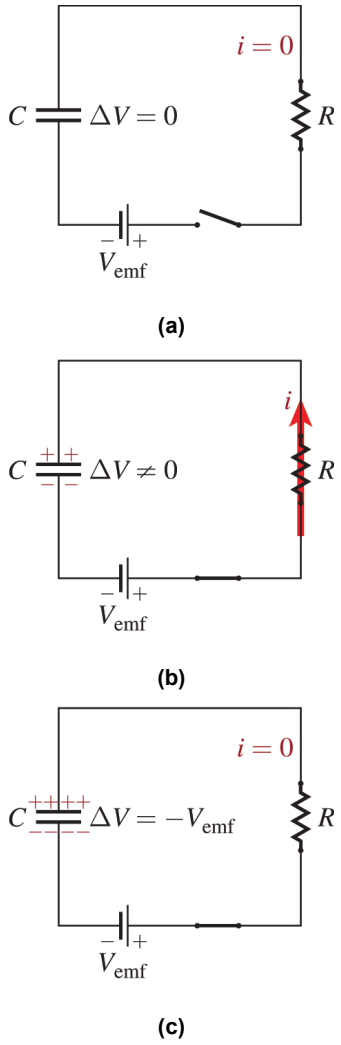

FIGURE 26.20 A basic RC circuit, containing a source of emf, a resistor, and a capacitor: (a) with the switch open; (b) a short time after the switch is closed; (c) a long time after the switch is closed.

While the capacitor is charging, we can analyze the current, i, flowing in the circuit (assumed to flow from the negative to the positive terminal inside the voltage source) by applying Kirchhoff's Loop Rule to the loop in Figure 26.20b in the counterclockwise direction:

$$V_{\text{emf}} - V_{\text{R}} - V_{\text{C}} = V_{\text{emf}} - i(t)R - q(t)/C = 0,$$

where V_C is the potential drop across the capacitor and $q(t)$ is the charge on the capacitor at a given time t. The change of the charge on the capacitor plates due to the current is $i(t) = dq(t)/dt$, and we can rewrite the preceding equation as

$$R\frac{dq(t)}{dt} + \frac{q(t)}{C} = V_{\text{emf}},$$

or

$$\frac{dq(t)}{dt} + \frac{q(t)}{C} = \frac{V_{\text{emf}}}{R}. \tag{26.3}$$

This differential equation relates the charge to its time derivative. The discussion of damped oscillations in Chapter 14 involved similar differential equations. It seems appropriate to try an exponential form for the solution of equation 26.3 because an exponential function is the only type that has the property of having a derivative that is identical to itself. Because equation 26.3 also has a constant term, the trial solution needs to have a constant term. We therefore try a solution with a constant and an exponential and for which $q(0) = 0$:

$$q(t) = q_{\max}\left(1 - e^{-t/\tau}\right),$$

where the constants $q_{\max}$ and τ are to be determined. Substituting this trial solution back into equation 26.3, we obtain

$$q_{\max}\frac{1}{\tau}e^{-t/\tau} + \frac{1}{RC}q_{\max}\left(1 - e^{-t/\tau}\right) = \frac{V_{\text{emf}}}{R}.$$

Now we collect the time-dependent terms on the left-hand side and the time-independent terms on the right-hand side:

$$q_{\max}e^{-t/\tau}\left(\frac{1}{\tau} - \frac{1}{RC}\right) = \frac{V_{\text{emf}}}{R} - \frac{1}{RC}q_{\max}.$$

This equation can only be true for all times if both sides are equal to zero. From the left-hand side, we then find

$$\tau = RC. \tag{26.4}$$

Thus, the constant τ (called the **time constant**) is simply the product of the capacitance and the resistance. From the right-hand side, we find an expression for the constant $q_{\max}$:

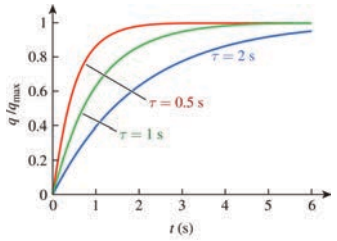
$$q_{\max} = CV_{\text{emf}}.$$

Thus, the differential equation for charging the capacitor (equation 26.3) has the solution

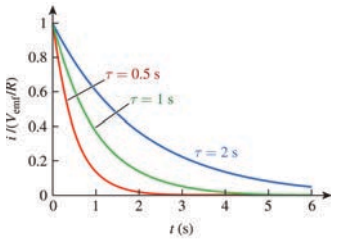
$$q(t) = CV_{\text{emf}}\left(1 - e^{-t/RC}\right). \tag{26.5}$$

Note that at $t = 0, q = 0$, which is the initial condition before the circuit components were connected. At $t = \infty, q = q_{\max} = CV_{\text{emf}}$, which is the steady-state condition in which the capacitor

is fully charged. The time dependence of the charge on the capacitor is shown in Figure 26.21a for three different values of the time constant τ.



(a)



(b)

FIGURE 26.21 Charging a capacitor: (a) charge on the capacitor as a function of time; (b) current flowing through the resistor as a function of time.

The current flowing in the circuit is obtained by differentiating equation 26.5 with respect to time:

$$i = \frac{dq}{dt} = \left(\frac{V_{\text{emf}}}{R}\right) e^{-t/RC}. \qquad \textbf{(26.6)}$$

From equation 26.6, at $t = 0$, the current in the circuit is V_{emf}/R, and at $t = \infty$, the current is zero, as shown in Figure 26.21b.

How do we know that the solution we have found for equation 26.3 is the only solution? This is not obvious from the preceding discussion, but the solution is unique. (A proof is generally provided in a course on differential equations.)

Discharging a Capacitor

Now let's consider a circuit containing only a resistor, *R,* and a fully charged capacitor, *C,* obtained by moving the switch in Figure 26.22 from position 1 to position 2. The charge on the capacitor before the switch is moved is $q_{\max}$. In this case, current will flow in the circuit until the capacitor is completely discharged. While the capacitor is discharging, we can apply Kirchhoff's Loop Rule around the loop in the clockwise direction and obtain

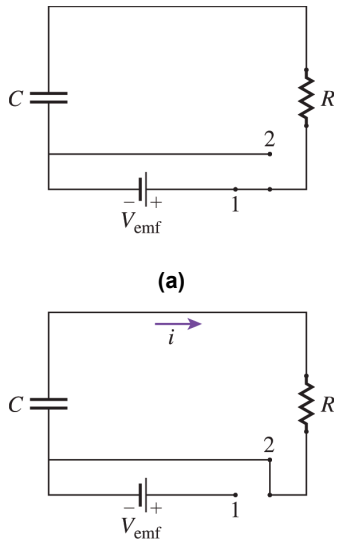


FIGURE 26.22 RC circuit containing an emf source, a resistor, a capacitor, and a switch. The capacitor is (a) charged with the switch in position 1 and (b) discharged with the switch in position 2.

$$-i(t)R - V_C = -i(t)R - \frac{q(t)}{C} = 0.$$

We can rewrite this equation using the definition of current:

$$\frac{Rdq(t)}{dt} + \frac{d(t)}{C} = 0. \tag{26.7}$$

The solution to equation 26.7 is obtained using the same method as for equation 26.3, except that equation 26.7 has no constant term and $q(0) > 0$. Thus, we try a solution of the form $q(t) = q_{\max}e^{-t/\tau}$. which leads to

$$q(t) = q_{\max}e^{-t/RC}. \tag{26.8}$$

At $t = 0$, the charge on the capacitor is $q_{\max}$. At $t = \infty$, the charge on the capacitor is zero.

We can obtain the current by differentiating equation 26.8 as a function of time:

$$i(t)\frac{dq}{dt} = -\left(\frac{q_{\max}}{RC}\right)e^{-t/RC}. \tag{26.9}$$

At $t = 0$, the current in the circuit is $-q_{\max}/RC$. At $t = \infty$, the current in the circuit is zero. Plotting the time dependence of the charge on the capacitor and the current flowing through the resistor for the discharging process would result in exponentially decreasing curves like those in Figure 26.21b.

The equations describing the time dependence of the charging and the discharging of a capacitor all involve the exponential factor $e^{-t/RC}$. Again, the product of the resistance and the capacitance is defined as the time constant of an RC circuit: $\tau = RC$. According to equation 26.5, after an amount of time equal to the time constant, the capacitor will have been charged to 63% of its maximum value. Thus, an RC circuit can be characterized by specifying the time constant. A large time constant means that it takes a long time to charge the capacitor; a small time constant means that it takes a short time to charge the capacitor.

Concept Check 26.5

To discharge a capacitor in an RC circuit very quickly, what should the values of the resistance and the capacitance be?

a) Both should be as large as possible.

b) Resistance should be as large as possible, and capacitance as small as possible.

c) Resistance should be as small as possible, and capacitance as large as possible.

d) Both should be as small as possible.

EXAMPLE 26.3 Time Required to Charge a Capacitor

Consider a circuit consisting of a 12.0-V battery, a 50.0-Ω resistor, and a 100.0-μF capacitor wired in series. The capacitor is initially completely discharged.

PROBLEM

How long after the circuit is closed will it take to charge the capacitor to 90% of its maximum charge?

SOLUTION

The charge on the capacitor as a function of time is given by

$$q(t) = q_{\max}\left(1 - e^{-t/RC}\right),$$

where $q_{\max}$ is the maximum charge on the capacitor. We want to know the time until $q(t)/q_{\max} = 0.90$, which can be obtained from

$$\left(1 - e^{-t/RC}\right) = \frac{q(t)}{q_{\max}} = 0.90,$$

or

$$0.10 = e^{-t/RC}. \qquad \text{(i)}$$

Taking the natural log of both sides of equation (i), we get

$$\ln\ 0.10 = -\frac{t}{RC},$$

or

$$t = -RC \ln 0.10 = -(50.0\ \Omega)(100 \cdot 10^{-6}\ \text{F})(-2.30) = 0.0115\ \text{s} = 11.5\ \text{ms}.$$

Self-Test Opportunity 26.3

A 1.00-mF capacitor is fully charged, and a 100.0-Ω resistor is connected across the capacitor. How long will it take to remove 99.0% of the charge stored in the capacitor?

Pacemaker

A normal human heart beats at regular intervals, sending blood through the body. The heart's own electrical signals regulate its beating. These electrical signals can be measured through the skin using an electrocardiograph. This device produces a graph of potential difference versus time, which is called an *electrocardiogram*, or *ECG* (sometimes *EKG*, from the German word *Electrokardiograph*). Figure 26.23a shows how an ECG would represent four regular heartbeats occurring at a rate of 72 beats per minute. Doctors and medical personnel can use an ECG to diagnose the health of the heart.

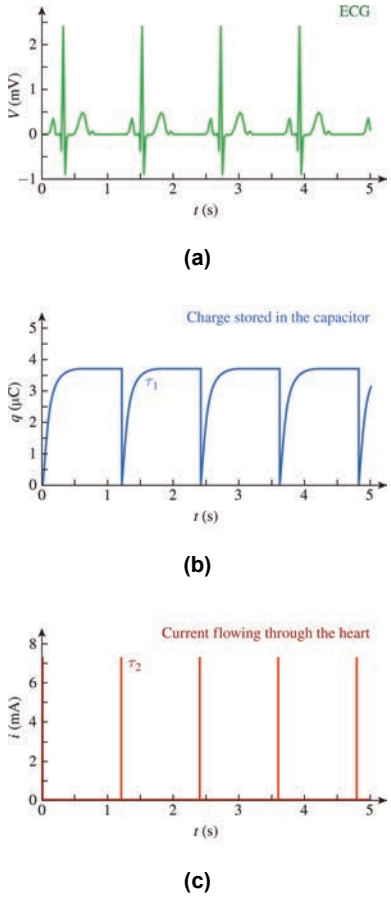

FIGURE 26.23 (a) An electrocardiogram (ECG) showing four regular heartbeats. (b) The charge stored in the pacemaker's capacitor as a function of time. (c) The current flowing through the heart due to the discharging of the pacemaker's capacitor.

Sometimes the heart does not beat regularly and needs help to maintain its proper rhythm. This help can be provided by a pacemaker, an electrical circuit that sends electrical pulses to the heart at regular intervals, replacing the heart's usual electrical signals and stimulating the heart to beat at prescribed intervals. A pacemaker is implanted in the patient and connected directly to the heart, as illustrated in Figure 26.24.

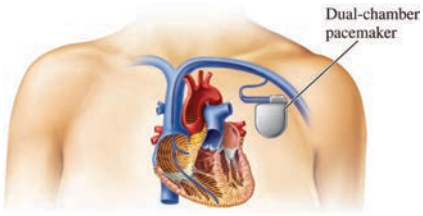

FIGURE 26.24 A modern pacemaker implanted in a patient. The pacemaker sends electrical pulses to two chambers of the heart to help keep it beating regularly.

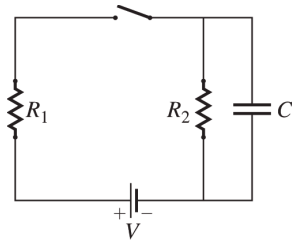
Concept Check 26.6

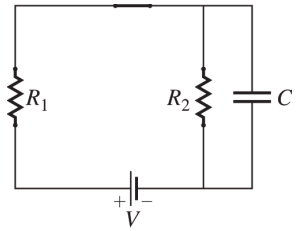
In the circuit shown in the figure, the capacitor, C, is initially uncharged. Immediately after the switch is closed,



a) the current flowing through R_1 is zero.
b) the current flowing through R_1 is larger than that through R_2.
c) the current flowing through R_2 is larger than that through R_1.
d) the current flowing through R_1 is the same as that through R_2.

Concept Check 26.7

In the circuit shown in the figure, the switch is closed. After a long time,



a) the current through R_1 is zero.
b) the current flowing through R_1 is larger than that through R_2.
c) the current flowing through R_2 is larger than that through R_1.
d) the current flowing through R_1 is the same as that through R_2.

EXAMPLE 26.4 Circuit Elements of a Pacemaker

Let's analyze the circuit shown in Figure 26.25, which simulates the function of a pacemaker. This pacemaker circuit operates by charging a capacitor, C, for some time using a battery with voltage V_{emf} and a resistor R_1, as illustrated in Figure 26.25a, where the switch is open. Closing the switch, as in Figure 26.25b, shorts the capacitor across the heart, and the capacitor discharges through the heart in a short time to stimulate the heart to beat. Thus, this circuit operates as a pacemaker by keeping the switch open for the time between heartbeats, closing the switch for a short time to stimulate a heartbeat, and then opening the switch again.

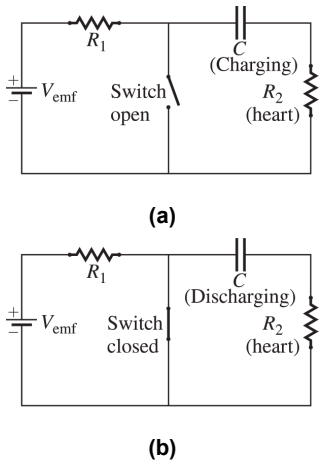


FIGURE 26.25 (a) A simplified pacemaker circuit in charging mode. (b) The pacemaker circuit in discharging mode.

PROBLEM

What values of the capacitance, C, and the resistance, R_1, should be used in a pacemaker?

SOLUTION

We assume that the heart acts as a resistor with a value $R_2 = 500\ \Omega$ and that the source of emf is a lithium ion battery (discussed in Chapter 23). Such a battery has a very high energy density and a voltage of 3.7 V. A normal heart rate is in the range from 60 to 100 beats per minute. However, the pacemaker might need to stimulate the heart to beat faster, so it should be capable of running at 180 beats per minute, which means that the capacitor may be charged up to 180 times a minute. Thus, the minimum time between discharges, t_{min}, is

$$t_{\text{min}} = \frac{1}{180\ \text{beats/min}} = \left(\frac{1\ \text{min}}{180}\right)\left(\frac{60\ \text{s}}{1\ \text{min}}\right) = 0.333\ \text{s}.$$

Equation 26.5 gives the charge, q, as a function of time, t, for the maximum charge, q_{max}, for a given time constant, $\tau_1 = R_1 C$:

$$q = q_{\text{max}}\left(1 - e^{-t/\tau_1}\right).$$

Rearranging this equation gives us

$$\frac{q}{q_{\text{max}}} = f = 1 - e^{-t/\tau_1},$$

where f is the fraction of the charge capacity of the capacitor. Let's assume the capacitor must be charged to 95% of its maximum charge in time t_{min}. Solving for the time constant gives us

$$\tau_1 = R_1 C = -\frac{t_{\text{min}}}{\ln(1-f)} = -\frac{0.333 \text{ s}}{\ln\left(1-0.95\right)} = 0.111 \text{ s}.$$

Thus, the time constant for the charging should be $\tau_1 = R_1 C = 100$ ms. The time constant for discharging, τ_2, needs to be small to produce short pulses of a high current to stimulate the heart. Letting $\tau_2 = 0.500$ ms, which is on the order of the narrow electrical pulse in the ECG, we have

$$\tau_2 = R_2 C = 0.500 \text{ ms}.$$

We can solve for the required capacitance and substitute the value 500 Ω for R_2:

$$C = \frac{0.000500 \text{ s}}{500\ \Omega} = 1.00\ \mu\text{F}.$$

The resistance required for the charging circuit can now be related to the time constant for the charging and the value of the capacitance we just calculated:

$$\tau_1 = R_1 C = 0.100 \text{ s} = R_1(1.00\ \mu\text{F}),$$

which gives us

$$R_1 = \frac{0.100 \text{ s}}{1.00 \cdot 10^{-6} \text{ F}} = 100 \text{ k}\Omega.$$

Figure 26.23b shows the charge in the capacitor of the simulated pacemaker as a function of time for a heart rate of 72 heartbeats per minute. You can see that the capacitor charges to nearly full capacity before it is discharged. Figure 26.23c shows the current that flows through the heart when the capacitor discharges. The current pulse is narrow, lasting less than a millisecond. This pulse stimulates the heart to beat, as illustrated by the ECG in Figure 26.23a. The rate at which the heart beats is controlled by the rate at which the pacemaker's switch is closed and opened, which is controlled by a microprocessor. Since 2018, smartwatch owners also have the opportunity to perform their own ECG measurements. Shown in Figure 26.26 is an ECG produced with an Apple Watch. Note that the pulse shape of this measured ECG is very similar to the simulated one of Figure 26.23a.

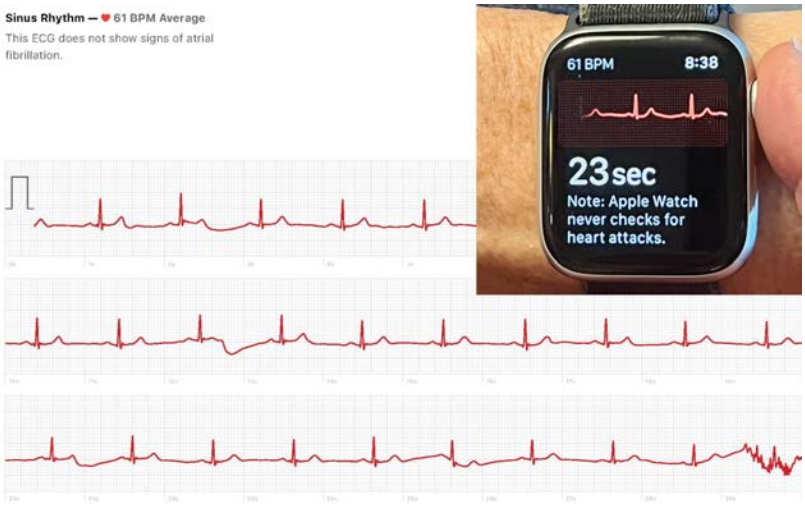

FIGURE 26.26 ECG as measured with an Apple Watch.

Wolfgang Bauer

Neuron

The type of cell responsible for transmitting and processing signals in the nervous systems and brains of humans and other animals is a neuron (Figure 26.27). The neuron conducts the necessary currents by electrochemical means, via the movement of ions (mainly Na^+, K^+, and Cl^-). Neurons receive signals from other neurons through dendrites and send signals to other neurons through an axon. The axon can be quite long (for example, in the spinal cord) and is covered with an insulating myelin sheath. The signals are received from and sent to other neurons or cells in the sense organs and other tissues. All of this, and much more, can be learned in an introductory biology or physiology course. Here we'll take a look at a neuron as a basic circuit that processes signals.

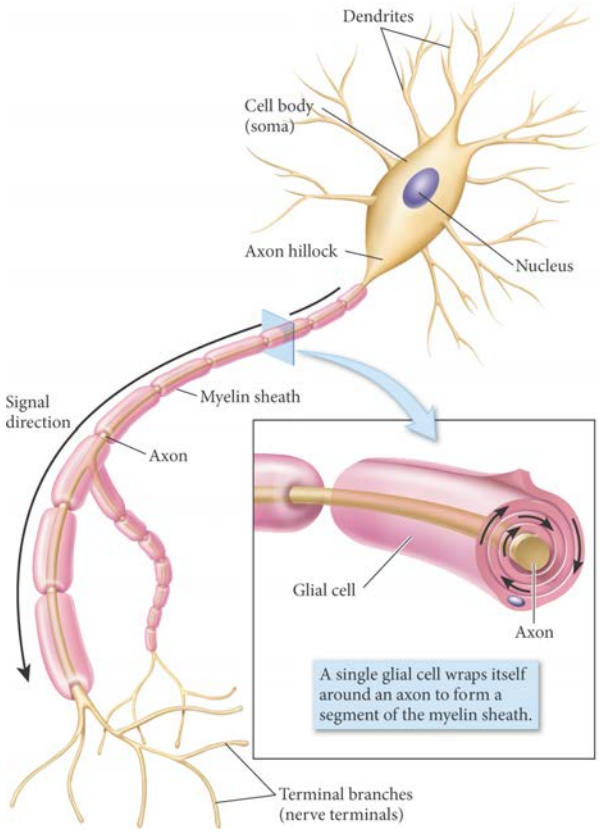

FIGURE 26.27 The main components of a neuron.

An input signal has to be strong enough to get a neuron to fire, that is, to send an output signal down the axon. It is a crude but reasonable approximation to represent the main cell body of a neuron, the soma, as a basic RC circuit that processes these signals. A diagram of this RC circuit is shown in Figure 26.28. A capacitor and a resistor are connected in parallel to an input and an output potential. The typical potential values for neurons are on the order of $\pm 50\ \text{mV}$ relative to the background of the surrounding tissue. If $\Delta V = V_{\text{in}} - V_{\text{out}} \neq 0$, a current flows through the circuit. Part of this current flows through the resistor, but part of the current simultaneously charges the capacitor until it reaches the potential difference between input and output potentials. The potential difference between the capacitor plates rises exponentially, according to $V_C(t) = (V_{\text{in}} - V_{\text{out}})(1 - e^{-t/RC})$, just as for the process of charging a capacitor in an RC circuit. (The time constant, $\tau = RC$, is on the order of 10 ms, assuming a capacitance of 1 nF and a resistance of 10 MΩ.) If the external source of potential difference is then removed from the circuit, the capacitor discharges with the same time constant, and the potential across the capacitor decays exponentially, according to $V_C(t) = V_0 e^{-t/RC}$. This simple time dependence captures the basic response of a neuron. Figure 26.29 shows the potential difference across the capacitor of this model neuron, while it is charged for 30 ms and then discharged.

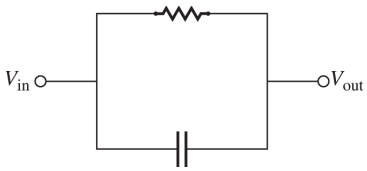

FIGURE 26.28 Simplified model of a neuron as an RC circuit.

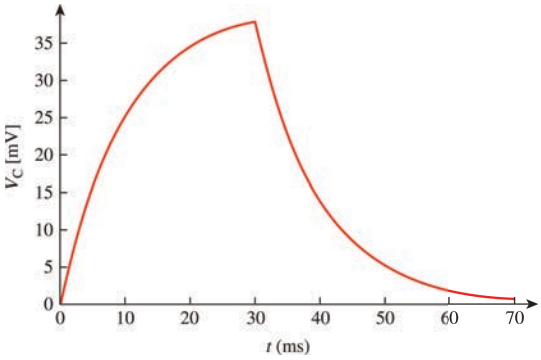

FIGURE 26.29 Potential difference on the capacitor in a model neuron.

SOLVED PROBLEM 26.4 Rate of Energy Storage in a Capacitor

A resistor with $R = 2.50\ \text{M}\Omega$ and a capacitor with $C = 1.25\ \mu\text{F}$ are connected in series with a battery for which $V_{\text{emf}} = 12.0\ \text{V}$. At $t = 2.50\ \text{s}$ after the circuit is closed, what is the rate at which energy is being stored in the capacitor?

THINK

When the circuit is closed, the capacitor begins to charge. The rate at which energy is stored in the capacitor is given by the time derivative of the amount of energy stored in the capacitor, which is a function of the charge on the capacitor.

SKETCH

Figure 26.30 shows a diagram of the series circuit containing a battery, a resistor, and a capacitor.

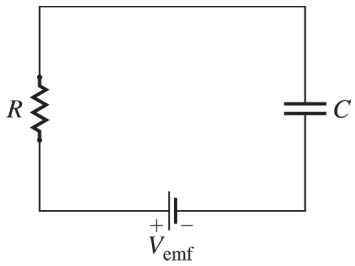

FIGURE 26.30 Series circuit containing a battery, a resistor, and a capacitor.

RESEARCH

The charge on the capacitor as a function of time is given by equation 26.5:

$$q(t) = CV_{\text{emf}}\left(1 - e^{-t/RC}\right).$$

The energy stored in a capacitor that has charge q is given by (see Chapter 24)

$$U = \frac{1}{2}\frac{q^2}{C}. \tag{i}$$

The time derivative of the energy stored in the capacitor is then

$$\frac{dU}{dt} = \frac{d}{dt}\left(\tfrac{1}{2}\frac{q^2(t)}{C}\right) = \frac{q(t)}{C}\frac{dq(t)}{dt}. \tag{ii}$$

The time derivative of the charge is the current, i. Thus, we can replace dq/dt with the expression given by equation 26.6:

$$i(t) = \frac{dq(t)}{dt} = \left(\frac{V_{\text{emf}}}{R}\right)e^{-t/RC}. \tag{iii}$$

SIMPLIFY

We can express the rate of change of the energy stored in the capacitor by combining equations (i) through (iii):

$$\frac{dU}{dt} = \frac{q(t)}{C} i(t) = \frac{CV_{\text{emf}}\left(1 - e^{-t/RC}\right)}{C}\left(\frac{V_{\text{emf}}}{R}\right)e^{-t/RC} = \frac{V_{\text{emf}}^2}{R}e^{-t/RC}\left(1 - e^{-t/RC}\right).$$

CALCULATE

We first calculate the value of the time constant, $\tau = RC$:

$$RC = \left(2.50 \cdot 10^6 \Omega\right)\left(1.25 \cdot 10^{-6}\ \text{F}\right) = 3.125\ \text{s}.$$

We can then calculate the rate of change of the energy stored in the capacitor:

$$\frac{dU}{dt} = \frac{(12.0\ \text{V})^2}{2.50 \cdot 10^6 \Omega} e^{-(2.50\ \text{s})/(3.125\ \text{s})}\left(1 - e^{-(2.50\ \text{s})/(3.125\ \text{s})}\right) = 1.42521 \cdot 10^{-5}\ \text{W}.$$

ROUND

We report our result to three significant figures:

$$\frac{dU}{dt} = 1.43 \cdot 10^{-5}\ \text{W}.$$

DOUBLE-CHECK

The current at $t = 2.50$ s is

$$i(2.50\ \text{s}) = \left(\frac{12.0\ \text{V}}{2.50\ \text{M}\Omega}\right)e^{-(2.50\ \text{s})/(3.125\ \text{s})} = 2.16 \cdot 10^{-6}\ \text{A}.$$

The rate of energy dissipation in the resistor at this time is

$$P = \frac{dU}{dt} = i^2 R = \left(2.16 \cdot 10^{-6}\ \text{A}\right)^2\left(2.50 \cdot 10^6\ \Omega\right) = 1.16 \cdot 10^{-5}\ \text{W}.$$

The rate at which the battery delivers energy to the circuit at this time is given by

$$P = \frac{dU}{dt} = iV_{\text{emf}} = (2.16 \cdot 10^{-6}\ \text{A})(12.0\ \text{V}) = 2.59 \cdot 10^{-5}\ \text{W}.$$

Energy conservation dictates that at any time the energy supplied by the battery is either dissipated as heat in the resistor or stored in the capacitor. In this case, the power supplied by the battery, $2.59 \cdot 10^{-5}$ W, is equal to the power dissipated as heat in the resistor, $1.16 \cdot 10^{-5}$ W, plus the rate at which energy is stored in the capacitor, $1.43 \cdot 10^{-5}$ W. Thus, our answer is consistent.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- Kirchhoff's rules for analyzing circuits are as follows:
  - Kirchhoff's Junction Rule: The sum of the currents entering a junction must equal the sum of the currents leaving a junction.
  - Kirchhoff's Loop Rule: The potential difference around a complete loop must sum to zero.
- In applying Kirchhoff's Loop Rule, the sign of the potential change for each circuit element is determined by the direction of the current and the direction of analysis. The conventions are
  - Sources of emf in the same direction as the direction of analysis provide potential gains, while sources opposite to the analysis direction give potential drops.
  - For resistors, the magnitude of the potential change is $|iR|$, where i is the assumed current and R is the resistance. The sign of the potential change depends on the (known or assumed) direction of the current as well as the direction of analysis. If these directions are the same, the resistor produces a potential drop. If the directions are opposite, the resistor produces a potential gain.
- An RC circuit contains a resistor of resistance R and a capacitor of capacitance C. The time constant, τ, is given by $\tau = RC$.
- In an RC circuit, the charge, q, as a function of time for a charging capacitor with capacitance C is given by $q(t) = CV_{\text{emf}}\left(1 - e^{-t/RC}\right)$, where V_{emf} is the voltage supplied by the source of emf and R is the resistance of the resistor.
- In an RC circuit, the charge, q, as a function of time for a discharging capacitor with capacitance C is given by $q(t) = q_{\max}e^{-t/RC}$, where $q_{\max}$ is the size of the charge on the capacitor plates at $t = 0$ and R is the resistance of the resistor.

ANSWERS TO SELF-TEST OPPORTUNITIES

26.1 The resistors R_1 and R_u are in series and have an equivalent resistance of $R_{1\,u} = R_1 + R_u$. The resistors R_3 and R_v are in series and have an equivalent resistance of $R_{3v} = R_3 + R_v$. The equivalent resistances R_{1u} and R_{3v} are in parallel. Thus, we can write

$$\frac{1}{R_{eq}} = \frac{1}{R_{1u}} + \frac{1}{R_{3v}},$$

or

$$R_{eq} = \frac{R_{1u}R_{3v}}{R_{1u} + R_{3v}} = \frac{(R_1 + R_u)(R_3 + R_v)}{R_1 + R_u + R_3 + R_v}.$$

26.2 When the headlights are on, the battery is supplying a modest amount of current to the lights, and the potential drop across the internal resistance of the battery is small. The starter motor is wired in parallel with the lights. When the starter motor engages, it draws a large current, producing a noticeable drop in potential across the internal resistance of the battery and causing less current to flow to the headlights.

26.3 $q = q_{max}e^{-t/RC}$

$$\frac{q}{q_{max}} = 0.01 = e^{-t/RC} \Rightarrow \ln\, 0.01 = -\frac{t}{RC}$$

$$t = -RC \ln\, 0.01 = -(100\ \Omega)(1.00 \cdot 10^{-3}\ \text{F})(\ln\, 0.01) = 0.461\ \text{s}.$$

Page 821

PROBLEM-SOLVING GUIDELINES

1. It is always helpful to label everything in a circuit diagram, including all the given information and all the unknowns, as well as pertinent currents, branches, and junctions. Redraw the diagram at a larger scale if you need more space for clarity.

2. Remember that the directions you choose for currents and for the path around a circuit loop are arbitrary. If your choice turns out to be incorrect, a negative value for the current will result.

3. Review the signs for potential changes given in Table 26.1. Moving through a circuit loop in the same direction as the assumed current means that an emf device produces a positive potential change in the direction from negative to positive within the device and that the potential change across a resistor is negative. Sign errors are common, and it pays to stick to the conventions to avoid such errors.

4. Sources of emf or resistors may be parts of two separate loops. Count each circuit component as a part of each loop it is in, according to the sign conventions you've adopted for that loop. A resistor may yield a potential drop in one loop and a potential gain in the other loop.

5. It is always possible to use Kirchhoff's rules to write more equations than you need to solve for unknown currents in a circuit's branches. Write as many equations as possible for junctions, and then augment them with equations representing loops. But not all loops are created equal; you need to select them carefully. As a rule of thumb, choose loops with fewer circuit elements.

MULTIPLE-CHOICE QUESTIONS

26.1 A resistor and a capacitor are connected in series. If a second identical capacitor is connected in series in the same circuit, the time constant for the circuit will

a) decrease.

b) increase.

c) stay the same.

26.2 A resistor and a capacitor are connected in series. If a second identical resistor is connected in series in the same circuit, the time constant for the circuit will

a) decrease.

b) increase.

c) stay the same.

26.3 A circuit consists of a source of emf, a resistor, and a capacitor, all connected in series. The capacitor is fully charged. How much current is flowing through it?

a) $i = V/R$

b) zero

c) neither (a) nor (b)

26.4 Which of the following will reduce the time constant in an RC circuit?

a) increasing the dielectric constant of the capacitor

b) adding an additional 20 m of wire between the capacitor and the resistor

c) increasing the voltage of the battery

d) adding an additional resistor in parallel with the first resistor

e) none of the above

26.5 Kirchhoff's Junction Rule states that

a) the algebraic sum of the currents at any junction in a circuit must be zero.

b) the algebraic sum of the potential changes around any closed loop in a circuit must be zero.

c) the current in a circuit with a resistor and a capacitor varies exponentially with time.

d) the current at a junction is given by the product of the resistance and the capacitance.

e) the time for the current development at a junction is given by the product of the resistance and the capacitance.

26.6 How long will it take, as a multiple of the time constant, τ, for the capacitor in an RC circuit to be 98% charged?

a) 9τ

b) 0.9τ

c) 90τ

d) 4τ

e) 0.98τ

26.7 A capacitor C is initially uncharged. At time $t = 0$, the capacitor is attached through a resistor R to a battery. The energy stored in the capacitor increases, eventually reaching a value U as $t \to \infty$. After a time equal to the time constant $\tau = RC$, the energy stored in the capacitor is given by

a) U/e.

b) U/e^2.

c) $U(1 - 1/e)^2$.

d) $U(1 - 1/e)$.

26.8 Which of the following has the same unit as the electromotive force (emf)?

a) current

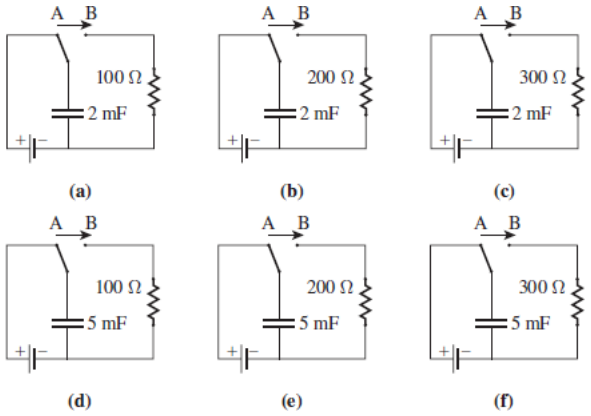
b) electric potential

c) electric field

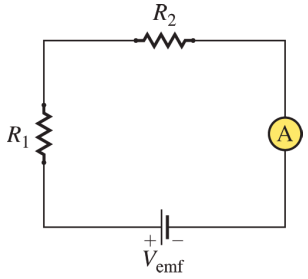
d) electric power

e) none of the above

26.9 The capacitor in each circuit in the figure is first charged by a 10-V battery with no internal resistance. Then, the switch is flipped from position A to position B, and the capacitor is discharged through various resistors. For which circuit is the total energy dissipated by the resistor the largest?



26.10 Two resistors, $R_1 = 3.00\ \Omega$ and $R_2 = 5.00\ \Omega$, are connected in series with a battery and an ammeter, as shown in the figure. The battery supplies $V_{\text{emf}} = 8.00\ \text{V}$, and the ammeter has the resistance $R_{\text{A}} = 1.00\ \Omega$. What is the current measured by the ammeter?



a) 0.500 A

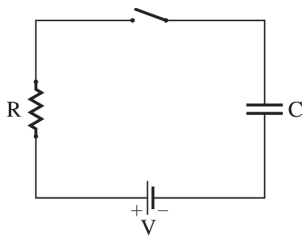
b) 0.750 A

c) 0.889 A

d) 1.00 A

e) 1.50 A

26.11 An uncharged capacitor ($C = 14.9\ \mu\text{F}$), a resistor ($R = 24.3\ \text{k}\Omega$), and a battery ($V = 25.7\ \text{V}$) are connected in series, as shown in the figure. What is the charge on the capacitor at $t = 0.3621$ s after the switch is closed?



a) $5.48 \cdot 10^{-5}$ C

b) $7.94 \cdot 10^{-5}$ C

c) $1.15 \cdot 10^{-5}$ C

d) $1.66 \cdot 10^{-4}$ C

e) $2.42 \cdot 10^{-4}$ C

26.12 Kirchhoff's Loop Rule states that

a) the algebraic sum of the currents around a complete circuit loop must be zero.

b) the resistances around a complete circuit loop must sum to zero.

c) the sources of emf around a complete circuit loop must sum to zero.

d) the sum of the potential differences around a complete circuit loop must be greater than zero.

e) the potential differences around a complete circuit loop must sum to zero.

26.13 Which of the following statements are true?

1. An ideal ammeter should have infinite resistance.
2. An ideal ammeter should have zero resistance.
3. An ideal voltmeter should have infinite resistance.
4. An ideal voltmeter should have zero resistance.

a) 1 and 3

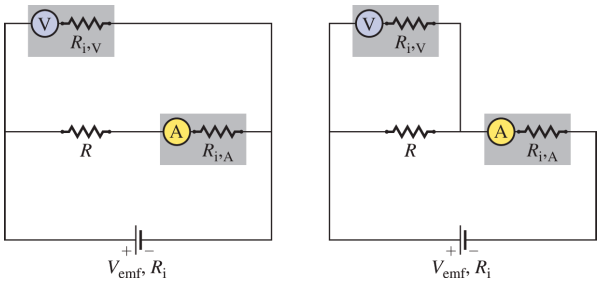
b) 2 and 4

c) 2 and 3

d) 1 and 4

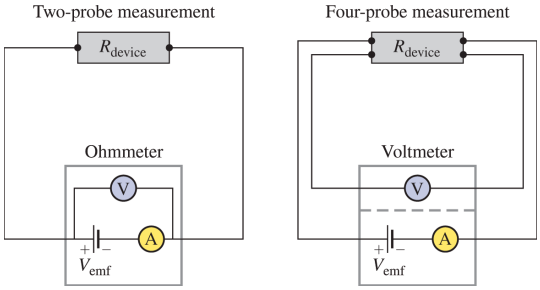
CONCEPTUAL QUESTIONS

26.14 You want to measure simultaneously the potential difference across and the current through a resistor, R. As the circuit diagrams show, there are two ways to connect the two instruments—ammeter and voltmeter—in the circuit. Comment on the result of the measurement using each configuration.



26.15 If the capacitor in an RC circuit is replaced with two identical capacitors connected in series, what happens to the time constant for the circuit?

26.16 You want to accurately measure the resistance, R_{device}, of a new device. The figure shows two ways to accomplish this task. On the left, an ohmmeter produces a current through the device and measures that current, i, and the potential difference, ΔV, across the device. This potential difference includes the potential drops across the wires leading to and from the device and across the contacts that connect the wires to the device. These extra resistances cannot always be neglected, especially if the device has low resistance. This technique is called *two-probe measurement* since two probe wires are connected to the device. The resulting current, i, is measured with an ammeter. The total resistance is then determined by dividing ΔV by i. For this configuration, what is the resistance that the ohmmeter measures? In the alternative configuration, shown on the right, a similar current source is used to produce and measure the current through the device, but the potential difference, ΔV, is measured directly across the device with a nearly ideal voltmeter with extremely large internal resistance. This technique is called a *four-probe measurement* since four probe wires are connected to the device. What resistance is being measured in this four-probe configuration? Is it different from that being assessed by the two-probe measurement? Why or why not? (*Hint:* Four-probe measurements are used extensively by scientists and engineers and are especially useful for accurate measurements of the resistance of materials or devices with low resistance.)



26.17 Explain why the time constant for an RC circuit increases with R and with C. (The answer "That's what the formula says" is not sufficient.)

26.18 A battery, a resistor, and a capacitor are connected in series in an RC circuit. What happens to the current through a resistor after a long time? Explain using Kirchhoff's rules.

26.19 How can you light a 1.0-W, 1.5-V bulb with your 12.0-V car battery?

26.20 A multiloop circuit contains a number of resistors and batteries. If the emf values of all the batteries are doubled, what happens to the currents in all the components of the circuit?

26.21 A multiloop circuit of resistors, capacitors, and batteries is switched on at $t = 0$, at which time all the capacitors are uncharged. The initial distribution of currents and potential differences in

the circuit can be analyzed by treating the capacitors as if they were connecting wires or closed switches. The final distribution of currents and potential differences, which occurs after a long time has passed, can be analyzed by treating the capacitors as open segments or open switches. Explain why these tricks work.

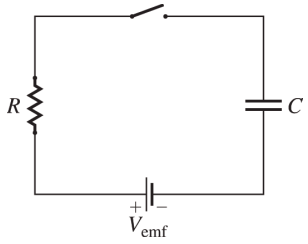
26.22 Voltmeters are always connected in parallel with a circuit component, and ammeters are always connected in series. Explain why.

26.23 You wish to measure both the current through and the potential difference across some component of a circuit. It is not possible to do this simultaneously and accurately with ordinary voltmeters and ammeters. Explain why not.

26.24 Two light bulbs for use at 110 V are rated at 60 W and 100 W, respectively. Which has the filament with lower resistance?

26.25 Two capacitors in series are charged through a resistor. Identical capacitors are instead connected in parallel and charged through the same resistor. How do the times required to fully charge the two sets of capacitors compare?

26.26 The figure shows a circuit consisting of a battery connected to a resistor and a capacitor, which is fully discharged initially, in series with a switch.



a) What is the current in the circuit at any time *t?*

b) Calculate the total energy provided by the battery from $t = 0$ to $t = \infty$.

c) Calculate the total energy dissipated from the resistor over the same time period.

d) Is energy conserved in this circuit?

EXERCISES

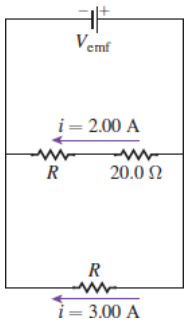
A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Sections 26.1 through 26.3

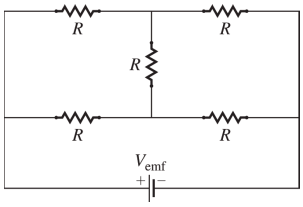
26.27 Two resistors, R_1 and R_2, are connected in series across a potential difference, ΔV_0. Express the potential drop across each resistor individually, in terms of these quantities. What is the significance of this arrangement?

26.28 A battery has $V_{\text{emf}} = 12.0$ V and internal resistance $r = 1.00\ \Omega$. What resistance, R, can be put across the battery to extract 10.0 W of power from it?

26.29 Three resistors are connected across a battery as shown in the figure. What values of R and V_{emf} will produce the indicated currents?



•**26.30** Find the equivalent resistance for the circuit in the figure.

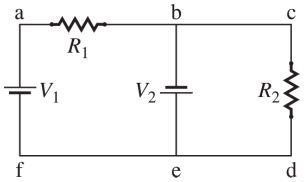


•**26.31** The dead battery of your car provides a potential difference of 9.950 V and has an internal resistance of 1.100 Ω. You charge it by connecting it with jumper cables to the live battery of another car. The live battery provides a potential difference of 12.00 V and has an internal resistance of 0.01000 Ω, and the starter resistance is 0.07000 Ω.

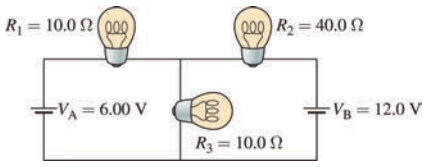
a) Draw the circuit diagram for the connected batteries.

b) Determine the current in the live battery, in the dead battery, and in the starter immediately after you closed the circuit.

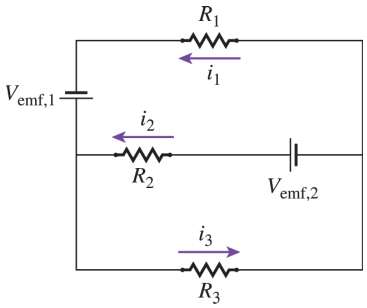
•**26.32** In the circuit shown in the figure, $V_1 = 1.50$ V, $V_2 = 2.50$ V, $R_1 = 4.00\ \Omega$, and $R_2 = 5.00\ \Omega$. What is the magnitude of the current, i_1, flowing through resistor R_1?



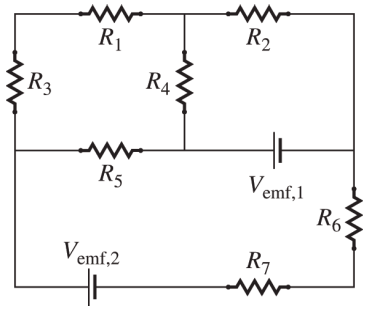
•**26.33** The circuit shown in the figure consists of two batteries supplying voltages V_A and V_B and three light bulbs with resistances R_1, R_2, and R_3. Calculate the magnitudes of the currents i_1, i_2, and i_3 flowing through the bulbs. Indicate the correct directions of current flow on the diagram. Calculate the power, P_A and P_B, supplied by battery A and by battery B.



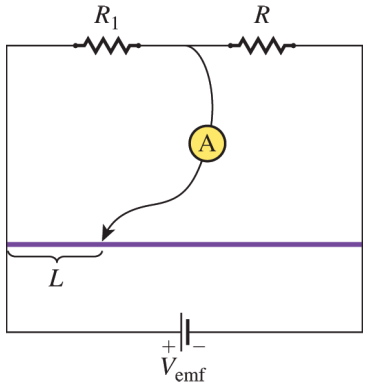
•26.34 In the circuit shown in the figure, $R_1 = 5.00\ \Omega, R_2 = 10.0\ \Omega, R_3 = 15.0\ \Omega, V_{\text{emf},1} = 10.0\ \text{V}$, and $V_{\text{emf},2} = 15.0\ \text{V}$. Using Kirchhoff's Loop and Junction Rules, determine the currents i_1, i_2, and i_3 flowing through R_1, R_2, and R_3, respectively, in the direction indicated in the figure.



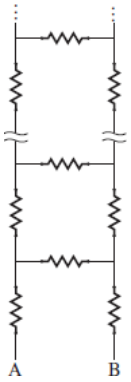
•26.35 For the circuit shown in the figure, find the magnitude and the direction of the current through each resistor and the power supplied by each battery, using the following values: $R_1 = 4.00\ \Omega, R_2 = 6.00\ \Omega, R_3 = 8.00\ \Omega, R_4 = 6.00\ \Omega, R_5 = 5.00\ \Omega, R_6 = 10.0\ \Omega, R_7 = 3.00\ \Omega, V_{\text{e}}$ and $V_{\text{emf},2} = 12.0\ \text{V}$.



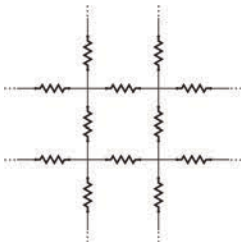
•26.36 A Wheatstone bridge is constructed using a 1.00-m-long Nichrome wire (the purple line in the figure) with a conducting contact that can slide along the wire. A resistor, $R_1 = 100.\Omega$, is placed on one side of the bridge, and another resistor, *R,* of unknown resistance, is placed on the other side. The contact is moved along the Nichrome wire, and it is found that the ammeter reading is zero for $L = 25.0\ \text{cm}$. Knowing that the wire has a uniform cross section throughout its length, determine the unknown resistance.



•• 26.37 A "resistive ladder" is constructed with identical resistors, *R,* making up its legs and rungs, as shown in the figure. The ladder has "infinite" height; that is, it extends very far in one direction. Find the equivalent resistance of the ladder, measured between its "feet" (points A and B), in terms of *R*.

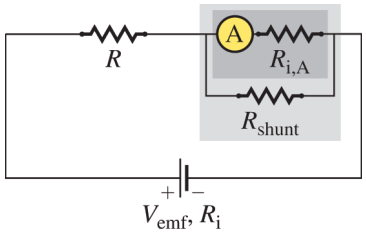


•• **26.38** Consider an "infinite," that is, very large, two-dimensional square grid of identical resistors, *R*, as shown in the figure. Find the equivalent resistance of the grid, as measured across any individual resistor. (*Hint:* Symmetry and superposition are very helpful in solving this problem.)

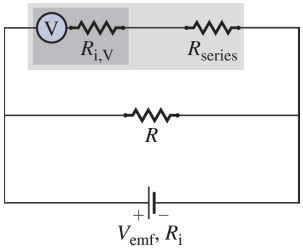


Section 26.4

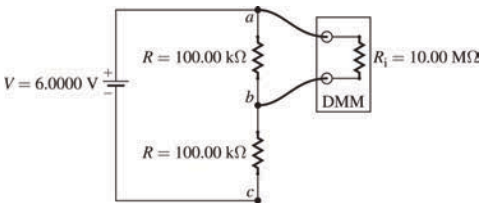
26.39 To extend the useful range of an ammeter, a shunt resistor, R_{shunt}, is placed in parallel with the ammeter as shown in the figure. If the internal resistance of the ammeter is $R_{\text{i,A}}$, determine the resistance that the shunt resistor has to have to extend the useful range of the ammeter by a factor *N*. Then, calculate the resistance the shunt resistor has to have to allow an ammeter with an internal resistance of 1.00 Ω and a maximum range of 1.00 A to measure currents up to 100. A. What fraction of the total 100.-A current flows through the ammeter, and what fraction flows through the shunt resistor?



26.40 To extend the useful range of a voltmeter, an additional resistor, R_{series}, is placed in series with the voltmeter as shown in the figure. If the internal resistance of the voltmeter is $R_{\text{i,V}}$, determine the resistance that the added series resistor has to have to extend the useful range of the voltmeter by a factor *N*. Then, calculate the resistance the series resistor has to have to allow a voltmeter with an internal resistance of 1.00 $\text{M}\Omega\left(10^6\,\Omega\right)$ and a maximum range of 1.00 V to measure potential differences up to 100. V. What fraction of the total 100.-V potential drop occurs across the voltmeter, and what fraction of that drop occurs across the added series resistor?



26.41 As shown in the figure, a 6.0000-V battery is used to produce a current through two identical resistors, *R*, each having a resistance of 100.00 kΩ. A digital multimeter (DMM) is used to measure the potential difference across the first resistor. DMMs typically have an internal resistance of 10.00 MΩ. Determine the potential differences V_{ab} (the potential difference between points *a* and *b*, which is the difference the DMM measures) and V_{bc} (the potential difference between points *b* and *c*, which is the difference across the second resistor). Nominally, $V_{ab} = V_{bc}$, but this may not be the case here. How can this measurement error be reduced?



26.42 You want to make an ohmmeter to measure the resistance of unknown resistors. You have a battery with voltage $V_{\text{emf}} = 9.00$ V, a variable resistor, *R*, and an ammeter that measures current on a linear scale from 0 to 10.0 mA.

a) What resistance should the variable resistor have so that the ammeter gives its full-scale (maximum) reading when the ohmmeter is shorted?

b) Using the resistance from part (a), what is the unknown resistance if the ammeter reads $\frac{1}{4}$ of its full scale?

•26.43 A circuit consists of two 1.00-kΩ resistors in series with an ideal 12.0-V battery.

a) Calculate the current flowing through each resistor.

b) A student trying to measure the current flowing through one of the resistors inadvertently connects an ammeter in parallel with that resistor rather than in series with it. How much current will flow through the ammeter, assuming that it has an internal resistance of 1.00 Ω?

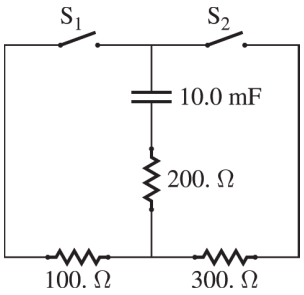
•26.44 A circuit consists of two 100.-kΩ resistors in series with an ideal 12.0-V battery.

a) Calculate the potential drop across one of the resistors.

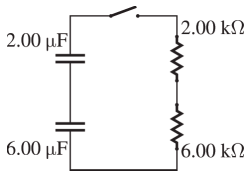
b) A voltmeter with internal resistance 10.0 MΩ is connected in parallel with one of the two resistors in order to measure the potential drop across the resistor. By what percentage will the voltmeter reading deviate from the value you determined in part (a)? (*Hint:* The difference is rather small so it is helpful to solve algebraically first to avoid a rounding error.)

Section 26.5

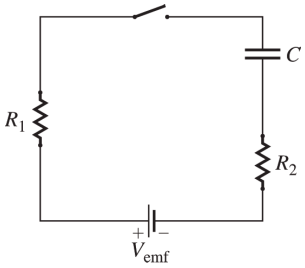
26.45 Initially, switches S_1 and S_2 in the circuit shown in the figure are open and the capacitor has a charge of 100. mC. About how long will it take after switch S_1 is closed for the charge on the capacitor to drop to 5.00 mC?



26.46 What is the time constant for the discharging of the capacitors in the circuit shown in the figure? If the 2.00-μF capacitor initially has a potential difference of 10.0 V across its plates, how much charge is left on it after the switch has been closed for a time equal to half of the time constant?



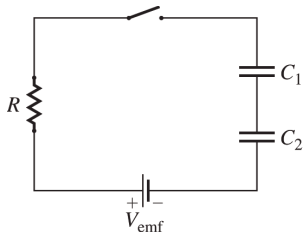
26.47 The circuit shown in the figure has a switch, S, two resistors, $R_1 = 1.00\ \Omega$ and $R_2 = 2.00\ \Omega$, a 12.0-V battery, and a capacitor with $C = 20.0\ \mu\text{F}$. After the switch is closed, what will the maximum charge on the capacitor be? How long after the switch has been closed will the capacitor have 50.0% of this maximum charge?



26.48 In the movie *Back to the Future,* time travel is made possible by a flux capacitor, which generates 1.21 GW of power. Assuming that a 1.00-F capacitor is charged to its maximum capacity with a 12.0-V car battery and is discharged through a resistor, what resistance is necessary to produce a peak power output of 1.21 GW in the resistor? How long would it take for a 12.0-V car battery to charge the capacitor to 90.0% of its maximum capacity through this resistor?

26.49 During a physics demonstration, a fully charged 90.0-μF capacitor is discharged through a 60.0-Ω resistor. How long will it take for the capacitor to lose 80.0% of its initial energy?

•**26.50** Two parallel plate capacitors, C_1 and C_2, are connected in series with a 60.0-V battery and a 300.-kΩ resistor, as shown in the figure. Both capacitors have plates with an area of 2.00 cm^2 and a separation of 0.100 mm. Capacitor C_1 has air between its plates, and capacitor C_2 has the gap filled with a certain porcelain (dielectric constant of 7.00 and dielectric strength of 5.70 kV/mm). The switch is closed, and a long time passes.



a) What is the charge on capacitor C_1?

b) What is the charge on capacitor C_2?

c) What is the total energy stored in the two capacitors?

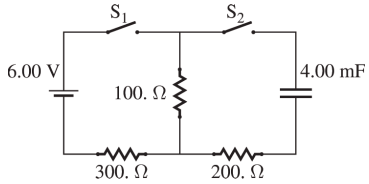
d) What is the electric field inside capacitor C_2?

•26.51 A parallel plate capacitor with $C = 0.0500\ \mu\text{F}$ has a separation between its plates of $d = 50.0\ \mu\text{m}$. The dielectric that fills the space between the plates has dielectric constant $\kappa = 2.50$ and resistivity $\rho = 4.00 \cdot 10^{12}\ \Omega\text{m}$. What is the time constant for this capacitor? (*Hint:* First calculate the area of the plates for the given C and κ, and then determine the resistance of the dielectric between the plates.)

•26.52 A 12.0-V battery is attached to a 2.00-mF capacitor and a 100.-Ω resistor. Once the capacitor is fully charged, what is the energy stored in it? What is the energy dissipated as heat by the resistor as the capacitor is charging?

•26.53 A capacitor bank is designed to discharge 5.00 J of energy through a 10.0-kΩ resistor array in under 2.00 ms. To what potential difference must the bank be charged, and what must the capacitance of the bank be?

•26.54 The circuit in the figure has a capacitor connected to a battery, two switches, and three resistors. Initially, the capacitor is uncharged and both of the switches are open.



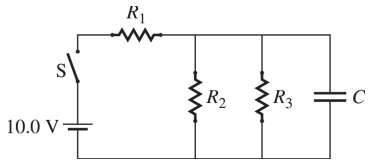
a) Switch S_1 is closed. What is the current flowing out of the battery immediately after switch S_1 is closed?

b) After about 10.0 min, switch S_2 is closed. What is the current flowing out of the battery immediately after switch S_2 is closed?

c) What is the current flowing out of the battery about 10.0 min after switch S_2 has been closed?

d) After another 10.0 min, switch S_1 is opened. How long will it take until the current in the 200.-Ω resistor is below 1.00 mA?

•26.55 In the circuit shown in the figure, $R_1 = 10.0\ \Omega$, $R_2 = 4.00\ \Omega$, and $R_3 = 10.0\ \Omega$, and the capacitor has capacitance $C = 2.00\ \Omega\text{F}$.

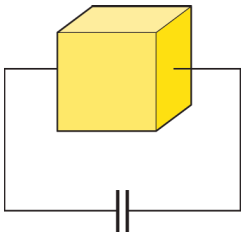


a) Determine the potential difference, ΔV_C, across the capacitor after switch S has been closed for a long time.

b) Determine the energy stored in the capacitor when switch S has been closed for a long time.

c) After switch S is opened, how much energy is dissipated through R_3?

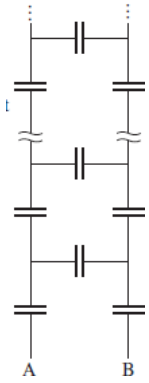
•• **26.56** A cube of gold that is 2.50 mm on a side is connected across the terminals of a 15.0-μF capacitor that initially has a potential difference of 100.0 V between its plates.



a) What time is required to fully discharge the capacitor?

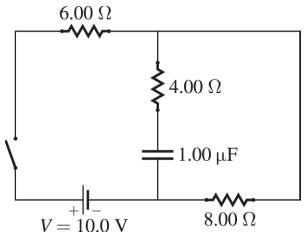
b) When the capacitor is fully discharged, what is the temperature of the gold cube?

•• **26.57** A "capacitive ladder" is constructed with identical capacitors, *C,* making up its legs and rungs, as shown in the figure. The ladder has "infinite" height; that is, it extends very far in one direction. Calculate the equivalent capacitance of the ladder, measured between its "feet" (points A and B), in terms of *C*.



Additional Exercises

26.58 In the circuit in the figure, the capacitors are completely uncharged. The switch is then closed for a long time.



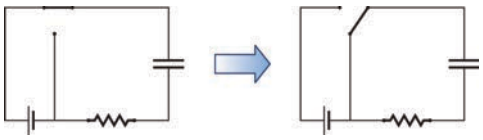
a) Calculate the current through the 4.00-Ω resistor.

b) Find the potential difference across the 4.00-Ω, 6.00-Ω, and 8.00-Ω resistors.

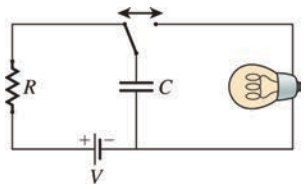
c) Find the potential difference across the 1.00-μF capacitor.

26.59 The ammeter your physics instructor uses for in-class demonstrations has internal resistance $R_1 = 75.0\Omega$ and measures a maximum current of 1.50 mA. The same ammeter can be used to measure currents of much greater magnitudes by wiring a shunt resistor of relatively small resistance, R_{shunt}, in parallel with the ammeter. (a) Sketch the circuit diagram, and explain why the shunt resistor connected in parallel with the ammeter allows it to measure larger currents. (b) Calculate the resistance the shunt resistor has to have to allow the ammeter to measure a maximum current of 15.0 A.

26.60 Many electronics devices can be dangerous even after they are shut off. Consider an RC circuit with a 150.-ΩF capacitor and a 1.00-MΩ resistor connected to a 200.-V power source for a long time and then disconnected and shorted, as shown in the figure. How long will it be until the potential difference across the capacitor drops to below 50.0 V?

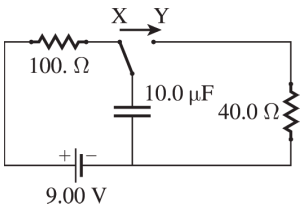


26.61 Design a circuit like that shown in the figure to operate a strobe light. The capacitor discharges power through the light bulb filament (resistance of 2.50 kΩ) in 0.200 ms and charges through a resistor *R*, with a repeat cycle of 1.00 kHz. What capacitor and resistor should be used?



26.62 An ammeter with an internal resistance of 53.0 Ω measures a current of 5.25 mA in a circuit containing a battery and a total resistance of 1130 Ω. The insertion of the ammeter alters the resistance of the circuit, and thus the measurement does not give the actual value of the current in the circuit without the ammeter. Determine the actual value of the current.

•26.63 In the circuit shown in the figure, a 10.0-μF capacitor is charged by a 9.00-V battery with the two-way switch kept in position X for a long time. Then the switch is suddenly flicked to position Y. What current flows through the 40.0-Ω resistor



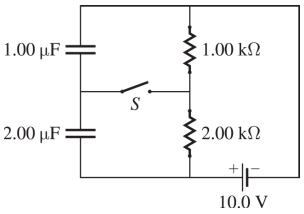
a) immediately after the switch moves to position Y?

b) 1.00 ms after the switch moves to position Y?

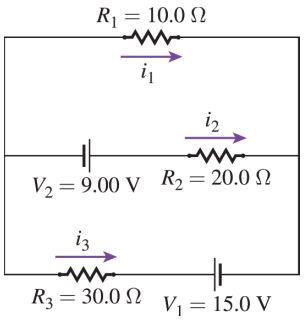
•26.64 How long will it take for the current in a circuit to drop from its initial value to 1.50 mA if the circuit contains two 3.80-μF capacitors that are initially uncharged, two 2.20-kΩ resistors, and a 12.0-V battery all connected in series?

26.65 An RC circuit has a time constant of 3.10 s. At $t = 0$, the process of charging the capacitor begins. At what time will the energy stored in the capacitor reach half of its maximum value?

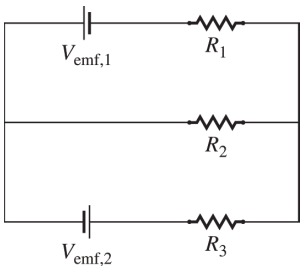
•26.66 For the circuit shown in the figure, determine the charge on each capacitor when (a) switch S has been closed for a long time and (b) switch S has been open for a long time.



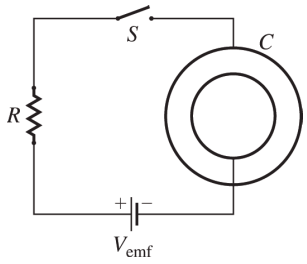
•26.67 Three resistors, $R_1 = 10.0\ \Omega$, $R_2 = 20.0\ \Omega$, and $R_3 = 30.0\ \Omega$, are connected in a multiloop circuit, as shown in the figure. Determine the amount of power dissipated in the three resistors.



•26.68 The figure shows a circuit containing two batteries and three resistors. The batteries provide $V_{\text{emf},1} = 12.0$ V and $V_{\text{emf},2} = 16.0$ V and have no internal resistance. The resistors have resistances of $R_1 = 30.0\ \Omega$, $R_2 = 40.0\ \Omega$, and $R_3 = 20.0\ \Omega$, Find the magnitude of the potential drop across R_2.



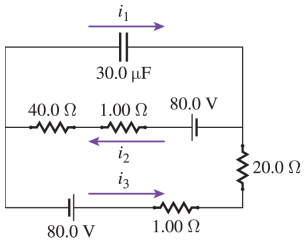
26.69 The figure shows a spherical capacitor. The inner sphere has radius $a = 1.00$ cm, and the outer sphere has radius $b = 1.10$ cm. The battery supplies $V_{\text{emf}} = 10.0$ V and the resistor has a value of $R = 10.0$ MΩ.



a) Determine the time constant of the RC circuit.

b) Determine how much charge has accumulated on the capacitor after switch S has been closed for 0.1 ms.

•**26.70** Write the set of equations that determines the three currents in the circuit shown in the figure. (Assume that the capacitor is initially uncharged.)



•**26.71** Consider a series RC circuit with $R = 10.0\ \Omega$, $C = 10.0$ μF and $V = 10.0$ V.

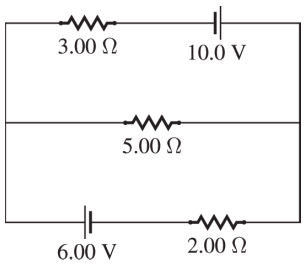
a) How much time, expressed as a multiple of the time constant, does it take for the capacitor to be charged to half of its maximum value?

b) At this instant, what is the ratio of the energy stored in the capacitor to its maximum possible value?

c) Now suppose the capacitor is fully charged. At time $t = 0$, the original circuit is opened and the capacitor is allowed to discharge across another resistor, $R' = 1.00\ \Omega$, that is connected across the capacitor. What is the time constant for the discharging of the capacitor?

d) How many seconds does it take for the capacitor to discharge half of its maximum stored charge, Q?

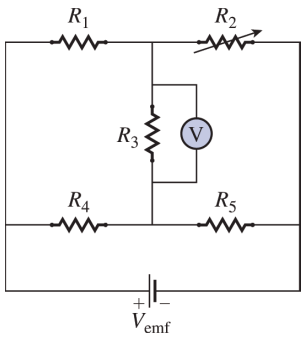
•**26.72**



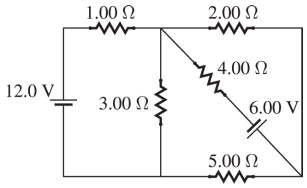
a) What is the current in the 5.00-Ω resistor in the circuit shown in the figure?

b) What is the power dissipated in the 5.00-Ω resistor?

•**26.73** In the Wheatstone bridge shown in the figure, the known resistances are $R_1 = 8.00\ \Omega$, $R_4 = 2.00\ \Omega$, and $R_5 = 6.00\ \Omega$, and the battery supplies $V_{\text{emf}} = 15.0$ V. The variable resistance R_2 is adjusted until the potential difference across R_3 is zero ($V = 0$), Find i_2 (the current through resistor R_2) at this time.



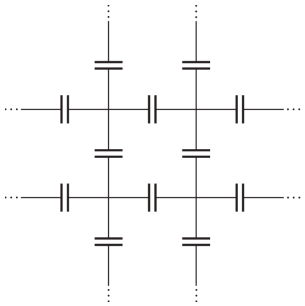
•• **26.74** Consider the circuit with five resistors and two batteries (with no internal resistance) shown in the figure.



a) Write a set of equations that will allow you to solve for the current in each of the resistors.

b) Solve the equations from part (a) for the current in the 4.00-Ω resistor.

•• **26.75** Consider an "infinite," that is, very large, two-dimensional square grid of identical capacitors, *C,* shown in the figure. Find the effective capacitance of the grid, as measured across any individual capacitor.



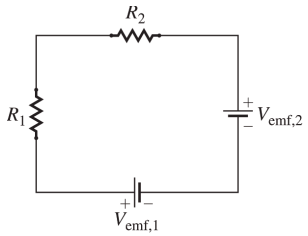
MULTI-VERSION EXERCISES

26.76 A 11.45-V battery with internal resistance $R_\text{i} = 0.1373\ \Omega$ is to be charged by a battery charger that is capable of delivering a current $i = 9.759$ A. What is the minimum emf the battery charger must be able to supply in order to charge the battery?

26.77 A battery with internal resistance $R_\text{i} = 0.1415\ \Omega$ is being charged by a battery charger that delivers a current $i = 5.399$ A. The battery charger supplies an emf of 14.51 V. What is the potential difference across the terminals of the battery?

26.78 A 16.05-V battery with internal resistance R_i is being charged by a battery charger that is capable of delivering a current $i = 6.041$ A. The battery charger supplies an emf of 16.93 V. What is the internal resistance, R_i, of the battery?

26.79 The single-loop circuit shown in the figure has $V_{\text{emf},1} = 21.01$ V, $V_{\text{emf},2} = 10.75$ V, $R_1 = 23.37\ \Omega$, and $R_2 = 11.61\,\Omega$. What is the current flowing in the circuit?



26.80 The single-loop circuit shown in the figure has $V_{\text{emf},1} = 16.37$ V, $V_{\text{emf},2} = 10.81$ V, and $R_1 = 24.65\ \Omega$. The current flowing in the circuit is 0.1600 A. What is the resistance R_2?

26.81 The single-loop circuit shown in the figure has $V_{\text{emf},1} = 17.75$ V, $R_1 = 25.95\ \Omega$, and $R_2 = 13.59\ \Omega$. The current flowing in the circuit is 0.1740 A. What is $V_{\text{emf},2}$?

26.82 A 15.19-mF capacitor is fully charged using a battery that supplies $V_\text{emf} = 131.1$ V. The battery is disconnected, and a 616.5-Ω resistor is connected across the capacitor. What current will be flowing through the resistor after 3.871 s?

26.83 A capacitor is fully charged using a battery that supplies $V_\text{emf} = 131.1$ V. The battery is disconnected, and a 655.1-Ω resistor is connected across the capacitor. The current flowing through the resistor after 1.743 s is 0.1745 A. What is the capacitance of the capacitor?

26.84 A 19.79-mF capacitor is fully charged using a battery. The battery is disconnected, and a 693.5-Ω resistor is connected across the capacitor. The current flowing through the resistor after 6.615 s is 0.1203 A. What is the emf supplied by the battery?

While much of our knowledge of magnetism has been known for two centuries and some of it since ancient times, new and exciting technical applications of this phenomenon continue to be developed today. Many of the devices we use every day make use of magnetism. Cars, computers, power generators, almost anything that uses an electric motor, and almost any information storage technology are just a few examples. One particularly impressive example is Shanghai's Maglev Train, shown in Figure 27.1, which floats on artificially generated magnetic fields and is thus able to reach very high speeds. In order to appreciate these innovations, however, we need to start with the basics of magnetism.

FIGURE 27.1 The Shanghai Maglev Train in the Pudong Airport station. The inset is a display inside the train showing the maximum speed of 430 km/h (267 mph) attained during the 7-minute 20-second trip from the airport to downtown Shanghai.

W. Bauer and G. D. Westfall

This chapter is the first to consider magnetism, describing magnetic fields and magnetic forces and their effects on charged particles and currents. We'll continue to study magnetism in the next few chapters, describing the causes of magnetic fields and their connection to electric fields. You will see that electricity and magnetism are really parts of the same universal force, called the *electromagnetic force*; their connection is one of the most spectacular successes in physical theory.

WHAT WE WILL LEARN

- Permanent magnets exist in nature. A magnet always has a north pole and a south pole. A single magnetic north pole or south pole cannot be isolated—magnetic poles always come in pairs.
- Opposite magnetic poles attract, and like poles repel.
- Breaking a bar magnet in half results in two new magnets, each with a north and a south pole.
- A magnetic field exerts a force on a moving charged particle.
- The force exerted on a charged particle moving in a magnetic field is perpendicular to both the magnetic field and the velocity of the particle.
- The torque on a current-carrying loop can be expressed in terms of the vector product of the magnetic dipole moment of the loop and the magnetic field.
- The Hall effect can be used to measure magnetic fields.

27.1 Permanent Magnets

In the region of Magnesia (in central Greece), the ancient Greeks found several types of naturally occurring minerals that attract and repel each other and attract certain kinds of metal, such as iron. They also, if floating freely, line up with the North and South Poles of the Earth. These minerals are various forms of iron oxide and are called **permanent magnets.** Other examples of permanent magnets include refrigerator magnets and magnetic door latches, which are made of compounds of iron, nickel, or cobalt. If you touch an iron bar to a piece of the mineral lodestone (magnetic magnetite), the iron bar will be magnetized. If you float this iron bar in water, it will align with the Earth's magnetic poles. The end of the magnet that points north is called the **north magnetic pole,** and the other end is called the **south magnetic pole.**

If two permanent magnets are brought close together with the two north poles or two south poles almost touching, the magnets repel each other (Figure 27.2a). If a north pole and a south pole are brought close together, the magnets attract each other (Figure 27.2b). What is called the North Pole of Earth is actually a magnetic south pole, which is why it attracts the north pole of permanent magnets.

FIGURE 27.2 (a) Like magnetic poles repel; (b) unlike magnetic poles attract.

Breaking a permanent magnet in half does not yield one north pole and one south pole. Instead, two new magnets, each with its own north and south pole result (Figure 27.3). Unlike electric charge, which exists as separate positive (proton) and negative (electron) charges, no separate magnetic monopoles (isolated north and south poles) exist. Scientists have carried out extensive searches for magnetic monopoles, and none has been found. The discussion of the source of magnetism in this chapter will help you understand why there are no magnetic monopoles.

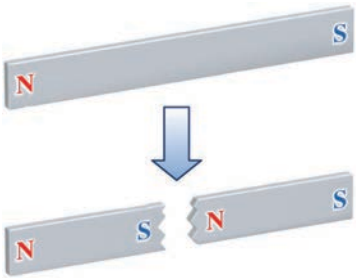

FIGURE 27.3 Breaking a bar magnet in half yields two magnets, each with its own north and south pole.

Magnetic Field Lines

Permanent magnets interact with each other at some distance, without touching. In analogy with the gravitational field and the electric field, the concept of a **magnetic field** is used to describe the magnetic force. The vector $\vec{B}\left(\vec{r}\right)$ denotes the magnetic field vector at any given point in space.

Like an electric field, a magnetic field is represented using field lines. The magnetic field vector is always tangent to the **magnetic field lines.** The magnetic field lines from a permanent bar magnet are shown in Figure 27.4a. As with electric field lines, closer spacing between lines indicates higher field strength. In an electric field, the electric force on a positive test charge points in the same direction as the electric field vector. However, because no magnetic monopole exists, the magnetic force cannot be described in an analogous way.

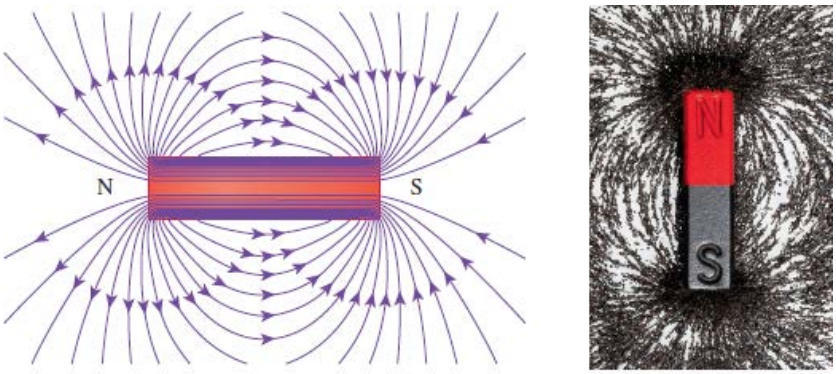

FIGURE 27.4 (a) Computer-generated magnetic field lines from a permanent bar magnet. (b) Iron filings align themselves with the magnetic field lines and make them visible.

b: Alchemy/Alamy Stock Photo

The direction of the magnetic field is established in terms of the direction in which a compass needle points. A compass needle, with a north pole and a south pole, will orient itself so that its north pole points in the direction of the magnetic field. Thus, the direction of the field can be determined at any point by noting the direction in which a compass needle placed at that point points, as illustrated in Figure 27.5 for a bar magnet.

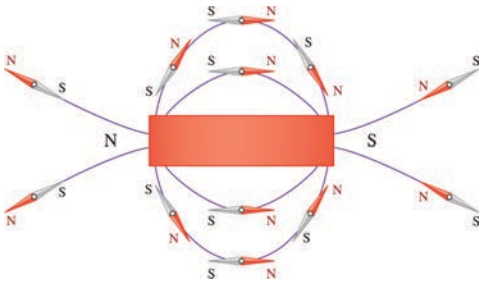

FIGURE 27.5 Using a compass needle to determine the direction of the magnetic field from a bar magnet.

Externally, magnetic field lines appear to originate on north poles and terminate on south poles, but these field lines are actually closed loops that penetrate the magnet itself. This formation of loops is an important difference between electric and magnetic field lines (for static fields—this statement does not apply to time-dependent fields, as we'll see in subsequent chapters). Recall that electric field lines start at positive charges and end on negative charges. However, because no magnetic monopoles exist, magnetic field lines cannot start or stop at particular points. Instead, they form closed loops that do not start or stop anywhere. We'll see later that this difference is important in describing the interaction of electric and magnetic fields. If you see a field pattern and don't know at first if it is an electric field or a magnetic field, check for closed loops. If you find some, it is a magnetic field; if the field lines do not form loops, it is an electric field.

Earth's Magnetic Field

Earth itself is a magnet, with a magnetic field similar to the magnetic field of a bar magnet (Figure 27.4). This magnetic field is important because it protects us from high-energy radiation from space called *cosmic rays*. These cosmic rays consist mostly of charged particles that are deflected away from Earth's surface by its magnetic field. The poles of Earth's magnetic field do not coincide with the geographic poles, defined as the points where Earth's rotation axis intersects its surface.

Figure 27.6 shows a cross section of Earth's magnetic field lines. The field lines are close together, forming a surface that wraps around Earth like a doughnut. Earth's magnetic field is distorted by the solar wind, a flow of ionized particles, mainly protons, emitted by the Sun and moving outward from the Sun at approximately 400 km/s. Two bands of charged particles captured from the solar wind circle the Earth. These are called the **Van Allen radiation belts** (Figure 27.6), after James A. Van Allen (1914–2006), who discovered them in the early days of space flight by putting radiation counters on satellites. The Van Allen radiation belts come closest to Earth near the north and south magnetic poles, where the charged particles trapped within the belts often collide with atoms in the atmosphere, exciting them. These excited atoms emit light of different colors as they collide and lose energy; the results are the fabulous **aurora borealis** (northern lights) in the northern latitudes (see Figure 27.7) and the **aurora australis** (southern lights) in the southern latitudes. Aurorae are not unique to Earth; they have been seen on other planets with strong magnetic fields, such as Jupiter and Saturn (shown in Figure 27.8).

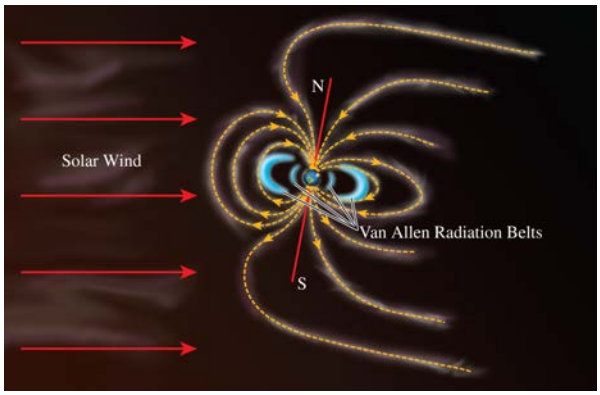

FIGURE 27.6 Cross section through Earth's magnetic field. The dashed lines represent the magnetic field lines. The axis defined by the north and south magnetic poles (red line) currently forms an angle of approximately 11° with the rotation axis.

FIGURE 27.7 Aurora borealis over Finland, photographed from the International Space Station.

NASA

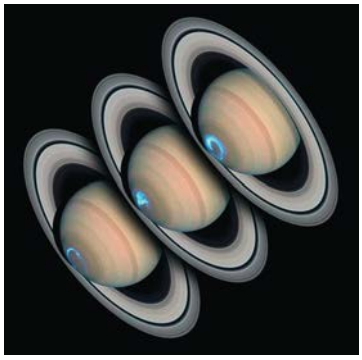

FIGURE 27.8 Aurora on Saturn, photographed by the Hubble Space Telescope.

NASA/Hubble/Z. Levay and J. Clarke

Earth's magnetic poles move at a current rate of up to 40 km in a single year. Right now, the magnetic north pole is located approximately 2800 km away from the geographic South Pole, at the edge of Antarctica, and is moving toward Australia. The magnetic south pole is located in the Canadian Arctic and, if its present rate of motion continues, will reach Siberia in 2050. Earth's magnetic field has decreased steadily at a rate of about 7% per century since it was first measured accurately around 1840. At that rate, Earth's magnetic field will disappear in a few thousand years. However, some geological evidence indicates that the magnetic field of Earth has reversed itself approximately 170 times in the past 100 million years. The last reversal occurred about 770,000 years ago. Thus, rather than disappear, Earth's magnetic field may reverse its direction. What is the cause of Earth's magnetic field? Surprisingly, the answer to this question is not known exactly and is under intense current research. Most likely, it is caused by strong electrical currents inside the Earth, caused by the spinning liquid iron-nickel core. This spinning is often referred to as the *dynamo effect*. (We'll see how currents create magnetic fields in Chapter 28.)

Because the geographic North Pole and the magnetic north pole are not in the same location, a compass needle generally does not point exactly to the geographic North Pole. This difference is called the **magnetic declination.** The magnetic declination is taken to be positive when magnetic north is east of true north and negative when magnetic north is west of true north. The magnetic north pole currently lies on a line that passes through southeastern Missouri, western Illinois, eastern Iowa, and western Wisconsin. Along this line, the magnetic declination is zero. West of this line, the magnetic declination is positive and reaches 18° in Seattle. East of this line, the declination is negative, up to −18° in Maine. A map showing the magnetic declinations in the United States as of 2004 is presented in Figure 27.9.

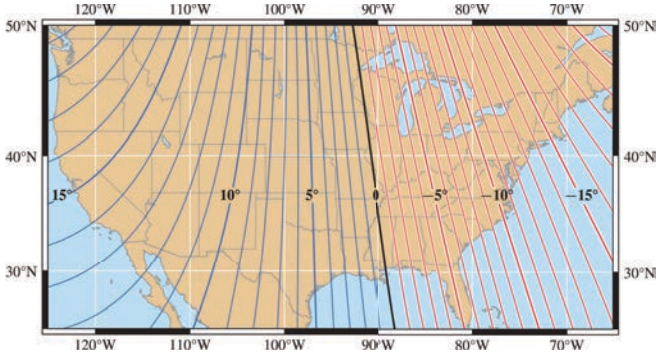

FIGURE 27.9 Magnetic declinations in the United States in 2004. Red lines represent negative magnetic declinations, and blue lines signify positive magnetic declinations. Lines of magnetic declination are separated by 1 degree.

Because the positions of Earth's magnetic poles move with time, the magnetic declinations for all locations on Earth's surface also change with time. For example, Figure 27.10 shows the estimated magnetic declination for Lansing, Michigan, for the period 1900–2025. A similar graph can be drawn for any location on Earth.

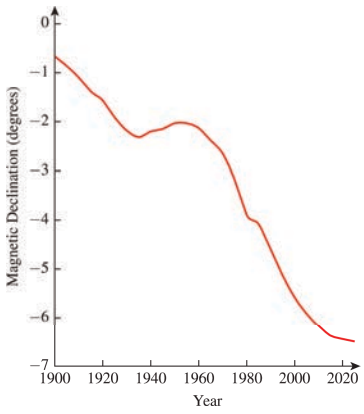

FIGURE 27.10 The magnetic declination at Lansing, Michigan, from 1900 to 2025.

Superposition of Magnetic Fields

If several sources of magnetic field, such as several permanent magnets, are close together, the magnetic field at any given point in space is given by the superposition of the magnetic fields from all the sources. This superposition of fields follows directly from the superposition of forces introduced in Chapter 4. The superposition principle for the total magnetic field, $\overrightarrow{B}_{\text{total}}\left(\overrightarrow{r}\right)$, due to *n* magnetic field sources can be stated as

$$\overrightarrow{B}_{\text{total}}\left(\overrightarrow{r}\right) = \overrightarrow{B}_1\left(\overrightarrow{r}\right) + \overrightarrow{B}_2\left(\overrightarrow{r}\right) + \cdots \overrightarrow{B}_n\left(\overrightarrow{r}\right). \qquad \textbf{(27.1)}$$

This superposition principle for magnetic fields is exactly analogous to the superposition principle for electric fields, presented in Chapter 22.

27.2 Magnetic Force

The qualitative discussion in the preceding section pointed out that a magnetic field has a direction, along the magnetic field lines. The magnitude of a magnetic field is determined by examining its effect on a moving charged particle. We'll start with a constant magnetic field and study its effect on a single charge. As a reminder, we saw in Chapter 22 that the electric field exerts a force on a charge given by $\vec{F}_E = q\vec{E}$. Experiments such as the one shown in Figure 27.11 show that a magnetic field does not exert a force on a charge at rest but only on a *moving* charge.

FIGURE 27.11 A beam of electrons (bluish green), made visible by a small amount of gas in an evacuated tube, is bent by a magnet (at the right edge of picture).

W. Bauer and G. D. Westfall

A magnetic field is defined in terms of the force exerted by the field on a moving charged particle. The magnetic force exerted by a magnetic field on a moving charged particle with charge q moving with velocity $\vec{v}$ is given by

$$\vec{F}_B = q\vec{v} \times \vec{B}. \tag{27.2}$$

The direction of the force is perpendicular to both the velocity of the moving charged particle and the magnetic field (Figure 27.12). This statement is right-hand rule 1. The right-hand rule gives the force direction on a positive charge given the known velocity and field directions. However, for a negative charge the force will be in the opposite direction.

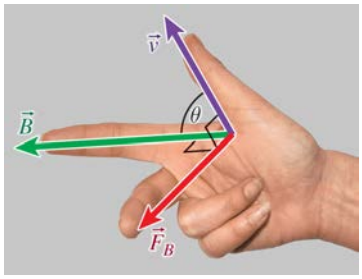

FIGURE 27.12 Right-hand rule 1 for the force exerted by a magnetic field, $\vec{B}$, on a particle with charge q moving with velocity $\vec{v}$. To find the direction of the magnetic force, point your thumb in the direction of the velocity of the moving charged particle and your index finger in the direction of the magnetic field, and your middle finger then gives you the direction of the magnetic force.

Mark Dierker/McGraw Hill

The magnitude of the magnetic force on a moving charged particle is

$$F_B = |q|vB\sin\theta, \tag{27.3}$$

where θ is the angle between the velocity of the charged particle and the magnetic field. (The angle θ is always between 0° and 180°, and therefore, $\sin\theta \geq 0$.) You can see that no magnetic force acts on a charged particle moving parallel to a magnetic field because in that case $\theta = 0^\circ$. If a charged particle is moving perpendicularly to the magnetic field, $\theta = 90^\circ$ and (for fixed values of v and B) the magnitude of the magnetic force has its maximum value of

$$F_B = |q|vB \qquad \left(\text{for } \vec{v} \perp \vec{B}\right). \tag{27.4}$$

Magnetic Force and Work

Equation 27.2 established that the magnetic force is the vector product of the velocity vector and magnetic field vector and thus is perpendicular to both vectors. This implies that $\vec{F}_B \bullet \vec{v} = 0$ and, since the force is the product of mass and acceleration, also that $\vec{a} \bullet \vec{v} = 0$. In Chapter 9 on circular motion, we saw that this condition means that the direction of the velocity vector can change but the magnitude of the velocity vector, the speed, remains the same. Therefore, the kinetic energy, $\frac{1}{2}mv^2$, remains constant for a particle subjected to a magnetic force, and the magnetic force *does no work* on the moving particle.

This is a profound result: A constant magnetic field cannot be used to do work on a particle. The kinetic energy of a particle moving in a constant magnetic field remains constant, even though the direction of the particle's velocity vector can change as a function of time while the particle is moving through the magnetic field. An electric field, on the other hand, can easily be used to do work on a particle.

Units of Magnetic Field Strength

To discuss the motion of charges in magnetic fields, we need to know what units are used to measure the magnetic field strength. Solving equation 27.4 for the field strength and inserting the units of the other quantities gives

$$[F_B] = [q][v][B] \Rightarrow [B] = \frac{[F_B]}{[q]\,[v]} = \frac{\text{N s}}{\text{C m}}.$$

Because the ampere (A) is defined as $1\ \text{C/s}$, $(\text{N s})/(\text{C m}) = \text{N}/(\text{A m})$. The unit of magnetic field strength has been named the **tesla** (T), in honor of Croatian-born American physicist and inventor Nikola Tesla (1856–1943):

$$1\ \text{T} = 1\frac{\text{N s}}{\text{C m}} = 1\frac{\text{N}}{\text{A m}}.$$

A tesla is a rather large amount of magnetic field strength. Sometimes magnetic field strength is given in gauss (G), which is not an SI unit:

$$1\ \text{G} = 10^{-4}\ \text{T}.$$

For example, the strength of Earth's magnetic field at Earth's surface is on the order of $0.5\ \text{G}\left(5 \cdot 10^{-5}\ \text{T}\right)$. It varies with location from 0.2 G to 0.6 G, as illustrated in Figure 27.13.

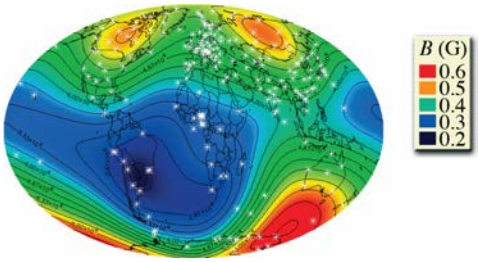

FIGURE 27.13 Global map of the strength of Earth's magnetic field.

SOLVED PROBLEM 27.1 Cathode Ray Tube

PROBLEM

Consider a cathode ray tube similar to the one shown in Figure 27.11. In this tube, a potential difference of $\Delta V = 111$ V accelerates electrons horizontally (starting essentially from rest) in an electron gun, as shown in Figure 27.14a. The electron gun has a specially coated filament that emits electrons when heated. A negatively charged cathode controls the number of electrons emitted. Positively charged anodes focus and accelerate the electrons into a beam. Downstream from the anodes are horizontal and vertical deflecting plates. Beyond the electron gun is a constant magnetic field with magnitude $B = 3.40 \cdot 10^{-4}$ T. The direction of the magnetic field is upward, perpendicular to the initial velocity of the electrons. What is the magnitude of the acceleration of the electrons due to the magnetic field? (The mass of an electron is $9.11 \cdot 10^{-31}$ kg.)

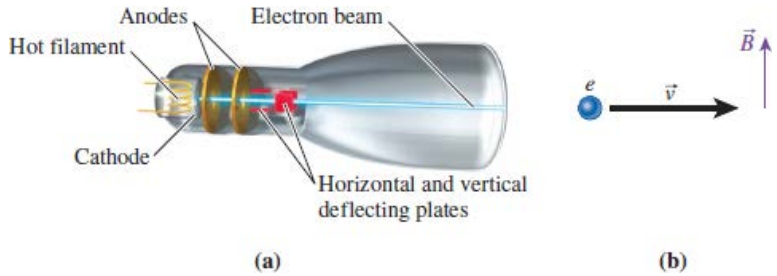

FIGURE 27.14 (a) A cathode ray tube. (b) Electrons moving with velocity $\vec{v}$ enter a constant magnetic field.

SOLUTION

THINK

The electrons gain kinetic energy in the electron gun of the cathode ray tube. The gain in kinetic energy of each electron is equal to the charge of the electron times the potential difference. The speed of the electrons can be found from the definition of kinetic energy. The magnetic force on an electron can be found from the electron charge, the electron velocity, and the strength of the magnetic field, and it is equal to the mass of the electron times its acceleration.

SKETCH

Figure 27.14b shows an electron, moving with velocity $\vec{v}$, entering a constant magnetic field that is perpendicular to the electron path.

RESEARCH

The change in kinetic energy, ΔK, of the electrons plus the change in potential energy of the electrons is equal to zero:

$$\Delta K + \Delta U = \frac{1}{2}mv^2 + q\Delta V = 0.$$

Since, in this case, $q = -e$, we see that

$$e\Delta V = \frac{1}{2}mv^2, \qquad \text{(i)}$$

where ΔV is the magnitude of the potential difference across which the electrons were accelerated and m is the mass of an electron. We can solve equation (i) for the speed of the electrons:

$$v = \sqrt{\frac{2e\Delta V}{m}}. \qquad \text{(ii)}$$

The magnitude of the force exerted by the magnetic field on the electrons is given by equation 27.3:

$$F_B = evB\sin 90^\circ = evB,$$

where $-e$ is the charge of an electron and B is the magnitude of the magnetic field. According to Newton's Second Law, $F_{\text{net}} = ma$. Since the only force present is the magnetic one, we have

$$F_B = ma = evB, \qquad \text{(iii)}$$

where a is the acceleration of the electrons.

SIMPLIFY

We can rearrange equation (iii) and substitute the expression for the speed of the electrons from equation (ii) to obtain the acceleration of the electrons:

$$a = \frac{evB}{m} = \frac{eB\sqrt{\frac{2e\Delta V}{m}}}{m} = B\sqrt{2\Delta V\frac{e^3}{m^3}}.$$

CALCULATE

Putting in the numerical values gives us

$$a = \left(3.40 \cdot 10^{-4}\ \mathrm{T}\right)\sqrt{2(111\ \mathrm{V})\frac{\left(1.602 \cdot 10^{-19}\ \mathrm{C}\right)^3}{\left(9.11 \cdot 10^{-31}\ \mathrm{kg}\right)^3}} = 3.7357 \cdot 10^{14}\ \mathrm{m/s^2}.$$

ROUND

We report our result to three significant figures:

$$a = 3.74 \cdot 10^{14}\ \mathrm{m/s^2}.$$

DOUBLE-CHECK

The calculated acceleration is tremendously large, almost 40 trillion times the Earth's gravitational acceleration. So we certainly want to double-check. We first calculate the speed of the electrons:

$$v = \sqrt{\frac{2e\Delta V}{m}} = \sqrt{\frac{2\left(1.602 \cdot 10^{-19}\ \mathrm{C}\right)(111\ \mathrm{V})}{9.11 \cdot 10^{-31}\ \mathrm{kg}}} = 6.25 \cdot 10^{6}\mathrm{m/s}.$$

A speed of 6250 km/s may seem large, but it is reasonable for electrons because it is only 2% of the speed of light. The magnetic force on each electron is then

$$F_B = evB = \left(1.602 \cdot 10^{-19}\ \mathrm{C}\right)\left(6.25 \cdot 10^{6}\ \mathrm{m/s}\right)\left(3.40 \cdot 10^{-4}\ \mathrm{T}\right) = 3.40 \cdot 1($$

The acceleration is very large because the mass of an electron is very small.

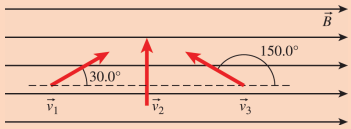
Concept Check 27.1

In what direction will the electron in Figure 27.14b be deflected as it enters the constant magnetic field?

a) into the page
b) out of the page
c) upward
d) downward
e) no deflection

Self-Test Opportunity 27.1

Three particles, each with charge $q = 6.15\,\mu\text{C}$ and speed $v = 465\,\text{m/s}$, enter a uniform magnetic field with magnitude $B = 0.165\,\text{T}$ (see the figure). What is the magnitude of the magnetic force on each of the particles?



27.3 Motion of Charged Particles in a Magnetic Field

The fact that the force due to a magnetic field acting on a moving charged particle is perpendicular to both the field and the particle's velocity makes this force different from any we've considered so far. However, the tools we use to analyze this force—Newton's laws and the laws of conservation of energy, momentum, and angular momentum—are the same.

Paths of Moving Charged Particles in a Constant Magnetic Field

Suppose you drive your car at constant speed around a circular track. The friction between the tires and the road provides the centripetal force that keeps the car moving in a circle. This force always points toward the center of the circle and creates a centripetal acceleration (discussed in Chapter 9). A similar physical situation occurs when a particle with charge q and mass m moves with velocity $\vec{v}$, perpendicular to a uniform magnetic field, $\vec{B}$, as illustrated in Figure 27.15.

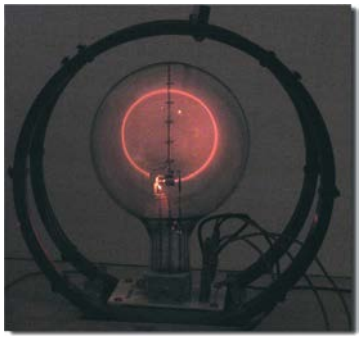


FIGURE 27.15 Electron beam bent into a circular path by the magnetic field generated by two coils.

W. Bauer and G. D. Westfall

In this situation, the particle moves in a circle with constant speed v and the magnetic force of magnitude $F_B = |q|vB$ supplies the centripetal force that keeps the particle moving in a circle. Particles with opposite charges and the same mass will orbit in opposite directions at the same orbital radius. For example, electrons and positrons are elementary particles with the same mass; the electron has a negative charge, and the positron has a positive charge. Figure 27.16 is a bubble chamber photograph showing two electron-positron pairs. A bubble chamber is a device that can track charged particles moving in a constant magnetic field. (The pairs of electrons and positrons were created by interactions of elementary particles, which will be covered in detail in Chapter 39.) Pair 1 has an electron and a positron that have the same relatively low speed. The particles initially travel in a circle. However, as they move through the bubble chamber, they slow down. (This slowdown is not due to the magnetic force but to collisions of the particles with the molecules of the gas in the bubble chamber.) Thus, the radius of the circle gets smaller and smaller, creating a spiral. The electron and positron in pair 2 have a much higher speed. Their tracks are curved but do not form a complete circle before the particles exit the bubble chamber.

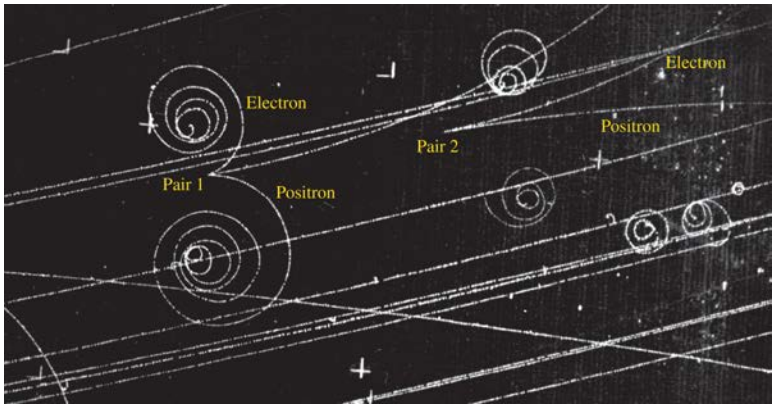

FIGURE 27.16 Bubble chamber photograph showing two electron-positron pairs. The bubble chamber is located in a constant magnetic field pointing directly out of the page.

Lawrence Berkeley National Lab

If the velocity of a charged particle is parallel (or antiparallel) to the magnetic field, the particle experiences no magnetic force and continues to travel in a straight line.

For motion perpendicular to a magnetic field, as in Figure 27.15, the force required to keep a particle moving with speed v in a circle with radius r is the centripetal force:

$$F = \frac{mv^2}{r}.$$

Setting this expression for the centripetal force equal to that for the magnetic force, we obtain

$$vB\,|q| = \frac{mv^2}{r}.$$

Rearranging gives an expression for the radius of the circle in which the particle is traveling:

$$r = \frac{mv}{|q|B}. \tag{27.5}$$

A common way to express this relationship is in terms of the magnitude of the momentum of the particle:

$$Br = \frac{p}{|q|}. \tag{27.6}$$

If the velocity $\overrightarrow{v}$ is not perpendicular to $\overrightarrow{B}$, then the velocity component perpendicular to $\overrightarrow{B}$ causes circular motion while the parallel velocity component is unaffected by $\overrightarrow{B}$ and drags this orbit into a helical shape.

Time Projection Chamber

Particle physicists create new elementary particles by colliding larger particles at the highest energies. In these collisions, many particles stream away from the interaction point at high speeds. A simple particle detector is not sufficient to identify these particles. A device that can help physicists study these collisions is a time projection chamber (TPC). The STAR TPC was described in Example 22.4.

Figure 27.17 shows collisions of two protons and two gold nuclei that occurred in the center of the STAR TPC. The proton-proton collision creates dozens of particles; the gold-gold collision creates thousands of particles. Each charged particle leaves a track in the TPC. The color assigned by a computer to the track represents the ionization density of the track as particles pass through the gas of the TPC. As they pass through the gas, the particles ionize the atoms of the gas, releasing free electrons. The gas allows the free electrons to drift without recombining with positive ions. Electric fields applied between the center of the TPC and the end caps of the cylinder exert an electric force on the free electrons, making them drift toward the end caps, where they are recorded electronically. Using the drift time and the recording positions, computer software reconstructs the trajectories that the particles took through the TPC. The particles produced in the collisions have a velocity component that is perpendicular to the TPC's magnetic field and thus have circular trajectories.

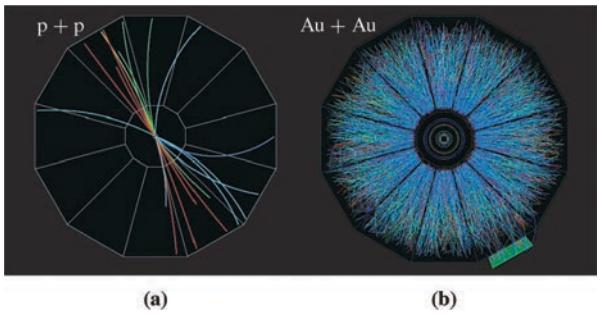

FIGURE 27.17 Curved tracks left by the motion of charged particles produced in collisions of (a) two protons, each with kinetic energy of 100 GeV, and (b) two gold nuclei, each with kinetic energy of 100 GeV.

EXAMPLE 27.1 Transverse Momentum of a Particle in the TPC

One track of a moving charged particle from Figure 27.17a is shown in Figure 27.18. The radius of the circular trajectory this particle is following is $r = 2.300$ m. The magnitude of the magnetic field in the TPC is $B = 0.5000$ T. We can assume that the particle has charge $|q| = 1.602177 \cdot 10^{-19}$ C.

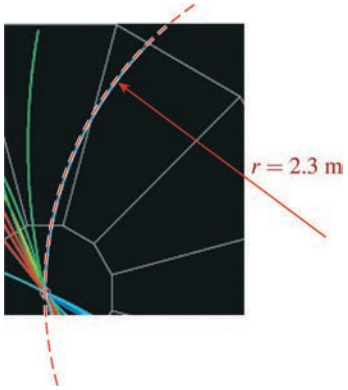

FIGURE 27.18 Circle fitted to the trajectory of one of the charged particles produced from the proton-proton collision in the STAR TPC shown in Figure 27.17a.

Brookhaven National Laboratory

PROBLEM

What is the component of the particle's momentum that is perpendicular to the magnetic field?

SOLUTION

We'll call this component the transverse momentum of the particle, p_t. We use equation 27.6, replacing p with p_t, because the magnetic force depends only on p_t, and not on the component of the momentum that is parallel to $\vec{B}$:

$$Br = \frac{p_{\mathrm{t}}}{|q|}.$$

We can express the magnitude of the transverse momentum of the particle in terms of the magnitude of the TPC's magnetic field and the absolute value of the charge of the particle:

$$p_{\mathrm{t}} = |q|Br = (1.602177 \cdot 10^{-19}\ \mathrm{C})(0.5000\ \mathrm{T})(2.300\ \mathrm{m}) = 1.843 \cdot 10^{-19}\ \mathrm{kg}$$

Instead of these SI units for momentum, particle physicists often use MeV/c (recall Example 7.5). Since $1\ \mathrm{MeV} = 1.602 \cdot 10^{-13}\ \mathrm{J}$, the conversion between $\mathrm{kg\ m/s}$ and MeV/c is

$$1\ \mathrm{MeV}/c = \frac{1.60218 \cdot 10^{-13}\ \mathrm{J}}{2.99792 \cdot 10^{8}\mathrm{m/s}} = 5.3443 \cdot 10^{-22}\ \mathrm{kg\ m/s} \Leftrightarrow 1\mathrm{kg\ m/s} = 1.8$$

Therefore, our result for the transverse momentum is

$$p_t = 344.8\ \mathrm{MeV/c}.$$

The analysis of a particle's transverse momentum carried out here can be done by automated computer algorithms on up to approximately 5000 charged particles created in a single collision of two gold nuclei. This very complex task takes about 30 seconds for a computer (3-GHz processor) to finish. In contrast, the TPC can record up to 10,000 events per second, which corresponds to 0.1 millisecond per event.

EXAMPLE 27.2 The Solar Wind and Earth's Magnetic Field

Section 27.1 discussed the Van Allen radiation belts that trap particles emitted from the Sun. The Sun throws approximately 1 million tons of matter into space every second. This matter is mostly protons traveling at a speed of around 400. km/s.

PROBLEM

If protons from the Sun are incident perpendicular to Earth's magnetic field (which has a magnitude of 50.0 μT at the Equator), what is the radius of the orbit of the protons? The mass of a proton is $1.67 \cdot 10^{-27}$ kg.

SOLUTION

Equation 27.5 relates the magnitude of the magnetic field, B, the radius of a circular orbit, r, and the speed, v, of a particle with mass m and charge q traveling perpendicular to a magnetic field:

$$r = \frac{mv}{|q|B}.$$

Putting in the numerical values, we get

$$r = \frac{\left(1.67 \cdot 10^{-27}\ \text{kg}\right)\left(400. \cdot 10^{3}\ \text{m/s}\right)}{\left(1.602 \cdot 10^{-19}\ \text{C}\right)\left(50.0 \cdot 10^{-6}\ \text{T}\right)} = 83.5\ \text{m}.$$

Thus, the protons of the solar wind orbit around the Earth's magnetic field lines at the Equator in circles of radius 83.5 m. Protons that are incident on the Earth's magnetic field away from the Equator are not traveling perpendicular to the magnetic field, so their orbital radius is larger. However, the magnetic field lines are closer together, meaning that the field is stronger toward the poles. The protons thus spiral along the field lines as they approach the poles. The shape of the Earth's magnetic field forces these protons traveling toward the poles to reverse and travel back toward the Equator, trapping the protons in the Van Allen radiation belts. Thus, the Earth's magnetic field completely blocks the solar wind from reaching the Earth's surface. This is vital, because the blocked cosmic radiation would otherwise make it impossible for higher organisms to live on Earth by ionizing (removing electrons from) atoms and destroying large molecules, for example, DNA.

Cyclotron Frequency

If a particle performs a complete circular orbit inside a uniform magnetic field—for example, like the electrons in the beam shown in Figure 27.15—then the period of revolution, *T,* of the particle is the circumference of the circle divided by the speed:

$$T = \frac{2\pi r}{v} = \frac{2\pi m}{|q|B}. \tag{27.7}$$

The frequency, *f,* of the motion of the charged particle is the inverse of the period:

$$f = \frac{1}{T} = \frac{|q|B}{2\pi m}. \tag{27.8}$$

The angular speed, *ω,* of the motion is

$$\omega = 2\pi f = \frac{|q|B}{m}. \tag{27.9}$$

Thus, the frequency and the angular speed of the particle's motion are independent of the particle's speed and thus independent of the particle's kinetic energy. This fact is used in cyclotrons, which is why ω as given by equation 27.9 is referred to as the **cyclotron frequency.** In a cyclotron, particles are accelerated to higher and higher kinetic energies, and the fact that the cyclotron frequency is independent of the kinetic energy makes designing a cyclotron much easier.

EXAMPLE 27.3 Energy of a Cyclotron

A cyclotron is a particle accelerator (Figure 27.19). The golden horn-shaped pieces of metal shown in the figure (historically called *dees*) have alternating electric potentials applied to them, so a positively charged particle always has a negatively charged dee ahead when it emerges from under any dee, which is now positively charged. The resulting electric field accelerates the particle. Because the cyclotron sits in a strong magnetic field, the particle's trajectory is curved. The radius of the trajectory is proportional to the magnitude of the particle's momentum, according to equation 27.6, so the accelerated particle spirals outward until it reaches the edge of the magnetic field (where its path is no longer bent by the field) and is extracted. According to equation 27.9, the angular frequency is independent of the particle's momentum or energy, so the frequency with which the polarity of the dees is changed does not have to be adjusted as the particle is accelerated. (This holds true only as long as the speed of the accelerated particles does not approach a sizable fraction of the speed of light, as we'll see in Chapter 35 on relativity. To compensate for relativistic effects, the magnetic field of a cyclotron increases with the orbital radius of the accelerated particles.)

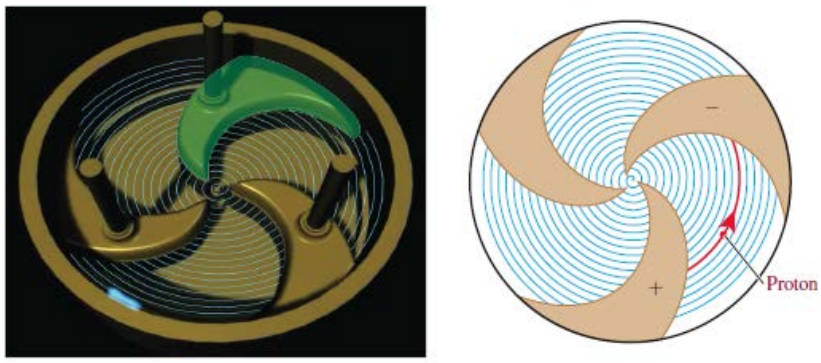

FIGURE 27.19 (a) Computer-generated drawing of the central section of the K500 superconducting cyclotron at the National Superconducting Cyclotron Laboratory at Michigan State University, with the spiral trajectory of an accelerated particle superimposed. One of the three dees of the cyclotron is highlighted in green. (b) Top view of the K500, showing a proton being accelerated between two dees.

a: Michigan State University, National Superconducting Cyclotron Lab

PROBLEM

What is the kinetic energy, in mega-electron-volts (MeV), of a proton extracted from a cyclotron with radius $r = 1.81$ m, if the magnetic field of the cyclotron is uniform and has magnitude $B = 0.851$ T? The mass of a proton is $1.67 \cdot 10^{-27}$ kg.

SOLUTION

We can solve equation 27.5 for the speed, v, of the proton:

$$v = \frac{r\,|q|B}{m}.$$

We substitute this expression for v into the equation for kinetic energy:

$$K = \frac{1}{2}mv^2 = \frac{1}{2}m\left(\frac{r\,|q|B}{m}\right)^2 = \frac{r^2q^2B^2}{2m}.$$

Putting in the given numbers, we get the kinetic energy in joules:

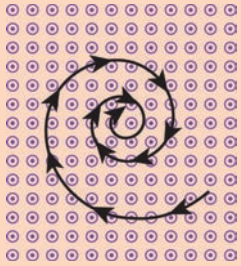
$$K = \frac{(1.81\text{ m})^2(1.602 \cdot 10^{-19}\text{ C})^2(0.851\text{ T})^2}{2(1.67 \cdot 10^{-27}\text{ kg})} = 1.82 \cdot 10^{-11}\text{ J}.$$

Since $1\text{ eV} = 1.602 \cdot 10^{-19}$ J and $1\text{ MeV} = 10^6$ eV, we have

$$K = 1.82 \cdot 10^{-11}\text{ J}\left(\frac{1\text{ eV}}{1.602 \cdot 10^{-19}\text{ J}}\right)\left(\frac{1\text{ MeV}}{10^6\text{ eV}}\right) = 114\text{ MeV}.$$

Self-Test Opportunity 27.2

A uniform magnetic field is directed out of the page (the standard notation of a dot within a circle represents the tip of the arrowhead of a field line). A charged particle is traveling in the plane of the page, as shown by the arrows in the figure.



a) Is the charge of the particle positive or negative?

b) Is the particle slowing down, speeding up, or moving at constant speed?

c) Is the magnetic field doing work on the particle?

Mass Spectrometer

One application of the motion of charged particles in a magnetic field is a **mass spectrometer,** which allows precise determination of atomic and molecular masses and can be useful for carbon dating and the analysis of unknown chemical compounds. A mass spectrometer operates by ionizing the atoms or molecules to be studied and accelerating them through an electric potential. The ions are then passed through a velocity selector (described further in Solved Problem 27.2), which allows only ions with a given velocity to pass through and blocks the remaining ions. The ions then enter a region of constant magnetic field. In the magnetic field, the radius of curvature of the orbit of each ion is given by equation 27.5: $r = mv/|q|B$. Assuming that all the atoms or molecules are singly ionized (have a charge of $+1$ or -1), the radius of curvature is proportional to the mass of the ion. A schematic diagram of a mass spectrometer is shown in Figure 27.20.

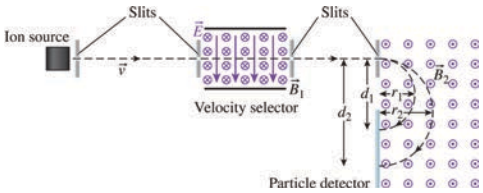


FIGURE 27.20 Schematic diagram of a mass spectrometer showing an ion source, a velocity selector consisting of crossed electric and magnetic fields (see Solved Problem 27.2), a region of constant magnetic field, and a particle detector.

Ions with different masses will have orbits with different radii in the constant magnetic field. For example, in Figure 27.20, ions with orbital radius r_1 have a smaller mass than ions with orbital radius r_2. The particle detector measures the distances from the entrance point, d_1 and d_2, which can be related to the orbital radii and thus the mass of the ions.

Concept Check 27.2

Cosmic rays would continuously bombard Earth's surface if most of them were not deflected by Earth's magnetic field. Given that Earth is approximately a magnetic dipole (see Figure 27.6), the intensity of cosmic rays incident on its surface is greatest at the

a) North and South Poles.

b) Equator.

c) middle latitudes.

SOLVED PROBLEM 27.2 Velocity Selector

Protons are accelerated from rest through an electric potential difference of $\Delta V = 14.0\ \text{kV}$. The protons enter a velocity selector, consisting of a parallel plate capacitor in a constant magnetic field, directed perpendicularly into the plane of the page in Figure 27.21a. The electric field between the plates of the parallel plate capacitor is $\vec{E} = 4.30 \cdot 10^5\ \text{V/m}$, directed along the plane of the page and downward in Figure 27.21a. This arrangement of perpendicular electric and magnetic fields is referred to as *crossed fields*.

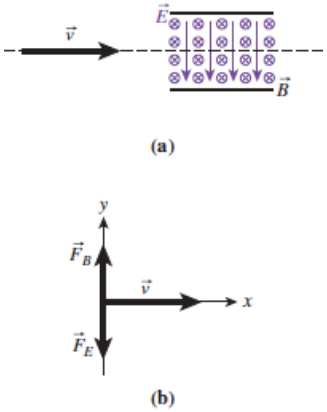

FIGURE 27.21 (a) A proton entering a velocity selector, consisting of crossed electric and magnetic fields. (b) Electric and magnetic forces on a proton passing through the combined fields.

PROBLEM

What magnetic field is required for the protons to move through the velocity selector without being deflected?

SOLUTION

THINK

For a proton to move on a straight line without deflection requires that the net force on the proton be zero. Since the proton has a certain velocity and since the magnetic force depends on the velocity, it is plausible that this condition of zero net force cannot be realized for arbitrary speeds of the proton—hence the name *velocity selector*.

SKETCH

Figure 27.21b shows the electric and magnetic forces on the protons as they pass through the velocity selector. Note that the two forces point in opposite directions.

RESEARCH

The change in kinetic energy of the protons plus the change in electric potential energy is equal to zero, which can be expressed as

$$\Delta K = -\Delta U = \frac{1}{2}mv^2 = e\Delta V,$$

where m is the mass of a proton, v is the speed of the proton after acceleration, e is the charge of the proton, and ΔV is the electric potential difference across which the protons were accelerated. The speed of the protons after acceleration is

$$v = \sqrt{\frac{2e\Delta V}{m}}. \qquad \textbf{(i)}$$

When the protons enter the velocity selector, the direction of the electric force is in the direction of the electric field, which is downward (negative y-direction). The magnitude of the electric force is

$$F_E = eE, \qquad \textbf{(ii)}$$

where E is the magnitude of the electric field in the velocity selector. Right-hand rule 1 gives the direction of the magnetic force: With your thumb in the direction of the velocity of the protons (positive x-direction) and your index finger in the direction of the magnetic field (into the page), your middle finger points up (positive y-direction). Thus, the direction of the magnetic force on the protons is upward. The magnitude of the magnetic force is given by

$$F_B = evB, \qquad \textbf{(iii)}$$

where B is the magnitude of the magnetic field in the velocity selector.

SIMPLIFY

The condition that allows the protons to pass though the velocity selector without being deflected is that the electric force balances the magnetic force, or $F_E = F_B$. Using equations (ii) and (iii), we can express this condition as

$$eE = evB.$$

Solving for the magnetic field, B, and substituting for v from equation (i), we obtain

$$B = \frac{E}{\sqrt{\frac{2e\Delta V}{m}}} = E\sqrt{\frac{m}{2e\Delta V}}.$$

CALCULATE

Putting in the numerical values gives us

$$B = \left(4.30 \cdot 10^5 \text{ V/m}\right)\sqrt{\frac{1.67 \cdot 10^{-27} \text{ kg}}{2\left(1.602 \cdot 10^{-19} \text{ C}\right)\left(14.0 \cdot 10^3 \text{ V}\right)}} = 0.262371 \text{ T}.$$

ROUND

We report our result to three significant figures:

$$B = 0.262 \text{ T}.$$

DOUBLE-CHECK

We verify that the electric force is equal to the magnetic force. The electric force is

$$F_E = eE = \left(1.602 \cdot 10^{-19} \text{ C}\right)\left(4.30 \cdot 10^5 \text{ V/m}\right) = 6.89 \cdot 10^{-14} \text{ N}.$$

To calculate the magnitude of the magnetic force, we need to find the speed of the protons:

$$v = \sqrt{\frac{2e\Delta V}{m}} = \sqrt{\frac{2\left(1.602 \cdot 10^{-19} \text{ C}\right)\left(14.0 \cdot 10^3 \text{ V}\right)}{1.67 \cdot 10^{-27} \text{ kg}}} = 1.64 \cdot 10^6 \text{ m/s}.$$

This speed is 0.55% of the speed of light, which is not totally impossible. The magnitude of the magnetic force is then

$$F_B = evB = (1.602 \cdot 10^{-19} \text{ C})(1.64 \cdot 10^6 \text{ m/s})(0.262 \text{ T}) = 6.88 \cdot 10^{-14} \text{ N}$$

which agrees with the value of the electric force within rounding error. Thus, our result seems reasonable.

Magnetic Levitation

An interesting application of magnetic force is **magnetic levitation,** a situation in which an upward magnetic force on an object balances the downward gravitational force, achieving static equilibrium with no need for direct contact of surfaces. But if you try to balance a magnet over another magnet by orienting the north poles (or south poles) toward each other, you'll see right away that this is not possible. Instead, one of the magnets will simply flip over, and then the opposite poles will point toward each other, and the attractive force between them will cause the two magnets to snap together. As we saw in Chapter 11, a stable equilibrium requires a local minimum of the potential energy, which does not exist for the pure repulsive interaction of two like magnetic poles.

Figure 27.22 shows a toy called the Levitron demonstrating the principle of magnetic levitation. The magnetic top is spun on a plate and then lifted to the proper height and released. The top can remain suspended for several minutes. How does this toy work, considering the requirement for stable equilibrium just mentioned? The answer is that the rapid rotation of the top provides a sufficiently large angular momentum and creates a potential energy barrier that prevents the magnet from flipping over.

FIGURE 27.22 The Levitron, a toy demonstrating the magnetic levitation of a spinning magnet above a base magnet.

W. Bauer and G. D. Westfall

Of course, there are other ways to create stable magnetic levitation systems, all of them involving multiple magnets attached rigidly to each other. Magnetic levitation has real-world applications in magnetic levitation (maglev) trains. These trains have several advantages over trains that run on normal steel rails: There are no moving parts to wear out, there is less vibration, and reduced friction means that high speeds are possible. Several maglev trains are already in service around the world and more are being planned. One example is the Shanghai Maglev Train (Figure 27.1), which operates between the Shanghai Pudong Airport and downtown Shanghai and reaches speeds of up to 430 km/h (267 mph).

The Shanghai Maglev Train operates using magnets attached to the cars (Figure 27.23). These are normal, non-superconducting magnetic coils with electronic feedback to produce stable levitation and guidance. The train cars are

held 15 cm above the guideway to allow clearance of any objects that may be on the guideway. The levitation and guidance magnets are held at a distance of 10 mm from the guideway, which is constructed of a magnetic material. The propulsion of the train is provided by magnetic fields built into the guideway. The train propulsion system operates like an electric motor (see Section 27.5) whose circular loops have been unwrapped to a linear configuration.

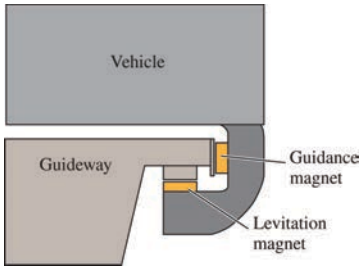

FIGURE 27.23 Cross section of one side of a train car of the Shanghai Maglev Train. The levitation magnets lift the cars 15 cm off the guideway, and the guidance magnets keep the cars centered on the guideway. The magnets are all mounted on the moving vehicle.

Maglev trains that use superconducting magnets have been tested, but some technical problems have yet to be resolved, including the maintenance of the superconducting coils and the exposure of the passengers to high magnetic fields.

27.4 Magnetic Force on a Current-Carrying Wire

Consider a wire carrying a current, i, in a constant magnetic field, $\vec{B}$ (Figure 27.24a). The magnetic field exerts a force on the moving charges in the wire. The charge, q, flowing past a point in the wire in a given time, t, is $q = ti$. During this time, the charge occupies a length, L, of wire given by $L = v_d t$, where v_d is the drift speed (the magnitude of the drift velocity) of the charge carriers in the wire. Thus, we obtain

$$q = ti = \frac{L}{v_d} i. \tag{27.10}$$

The magnitude of the magnetic force is then

$$F_B = qv_\mathrm{d} B \sin\theta = \left(\frac{L}{v_\mathrm{d}} i\right) v_\mathrm{d} B \sin\theta = iLB \sin\theta, \tag{27.11}$$

where θ is the angle between the direction of the current flow and the direction of the magnetic field. The direction of the force is perpendicular to both the current and the magnetic field and is given by a variant of right-hand rule 1, with the current in the direction of the velocity of a charged particle, as illustrated in Figure 27.24b. This variant of right-hand rule 1 takes advantage of the fact that current can be thought of as charges in motion.

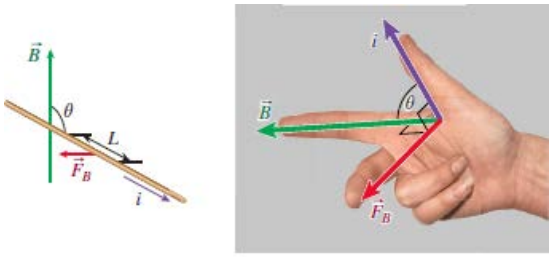

FIGURE 27.24 (a) Magnetic force on a current-carrying wire. (b) A variant of right-hand rule 1 giving the direction of the magnetic force on a current-carrying wire. To determine the direction of the force on a current-carrying wire using your right hand, point your thumb in the direction of the current and your index finger in the direction of the magnetic field; then your middle finger will point in the direction of the force.

Mark Dierker/McGraw Hill

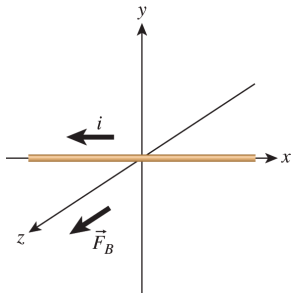
Equation 27.11 can be expressed as a vector product:

$$\vec{F}_B = i\vec{L} \times \vec{B}, \qquad \textbf{(27.12)}$$

where the notation $i\vec{L}$ represents the current in a length of wire. Equation 27.12 is simply a reformulation of equation 27.2 for the case in which the moving charges make up a current flowing in a wire. Since physical situations involving currents are far more common than those involving the motion of an isolated charged particle, equation 27.12 is the most useful form for determining the magnetic force in practical applications.

Concept Check 27.3

The figure shows a wire lying along the *x*-axis with a current, *i*, flowing in the negative *x*-direction. The wire is in a uniform magnetic field. The magnetic force, $\vec{F}_B$, acts on the wire in the positive *z*-direction. The magnetic field is oriented so that the force is maximum. What is the direction of the magnetic field?



a) positive *y*-direction

b) negative *x*-direction

c) negative *y*-direction

d) positive *z*-direction

e) negative *z*-direction

EXAMPLE 27.4 Force on the Voice Coil of a Loudspeaker

A loudspeaker produces sound by exerting a magnetic force on a voice coil in a magnetic field, as shown in Figure 27.25. The movable voice coil is connected to a speaker cone that actually produces the sounds. The magnetic field is produced by the two permanent magnets as shown. The magnitude of the magnetic field is $B = 1.50\ \text{T}$. The voice coil is composed of $n = 100$ turns of wire carrying a current, $i = 1.00\ \text{mA}$. The diameter of the voice coil is $d = 2.50\ \text{cm}$.

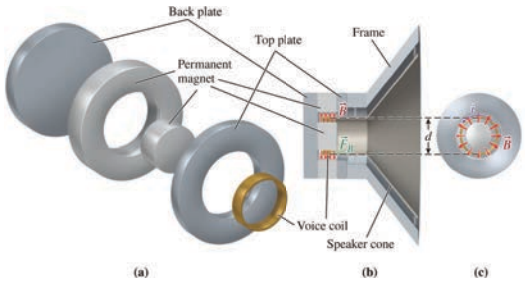


FIGURE 27.25 Schematic diagram of a loudspeaker: (a) an exploded three-dimensional view of the driver end of the loudspeaker; (b) a cross-sectional side view of the loudspeaker; (c) a front view of the driver end of the loudspeaker.

PROBLEM

What is the magnetic force exerted by the magnetic field on the loudspeaker's voice coil?

SOLUTION

The magnitude of the magnetic force on the voice coil is given by equation 27.11:

$$F = iLB\sin\theta,$$

where L is the length of wire carrying current i in the magnetic field with magnitude B. The wire makes an angle θ with the magnetic field. In this case, the wire is always perpendicular to the magnetic field, so $\theta = 90^\circ$. The length of wire in the voice coil is given by the number of turns, n, times the circumference, πd, of each turn

$$L = n\pi d.$$

Thus, the force on the voice coil is

$$F = i(n\pi d)B(\sin 90^\circ) = n\pi idB.$$

Putting in the numerical values, we get

$$F = n\pi idB = (100)(\pi)\left(1.00 \cdot 10^{-3}\ \text{A}\right)\left(2.50 \cdot 10^{-2}\ \text{m}\right)(1.50\ \text{T}) = 0.0118$$

From the right-hand rule 1 illustrated in Figure 27.24b, the direction of the force exerted by the magnetic field on the voice coil is toward the left in Figure 27.25b and perpendicularly into the page in Figure 27.25c.

If the current in the voice coil is reversed, the force will be in the opposite direction. If the current is proportional to the amplitude of a sound wave, sound waves can be reproduced in the cone of the loudspeaker. This basic idea is used in most speakers and headphones.

27.5 Torque on a Current-Carrying Loop

Electric motors rely on the magnetic force exerted on a current-carrying wire. This force is used to create a torque that turns a shaft. Let's consider a simple electric motor, consisting of a single square loop carrying a current, i, in a constant magnetic field, $\vec{B}$. The loop is oriented so that its horizontal sections are parallel to the magnetic field and its vertical sections are perpendicular to the magnetic field, as shown in Figure 27.26. The magnitude of the magnetic force on the two vertical sections of the loop is given by equation 27.11 with $\theta = 90^\circ$:

$$F = iLB.$$

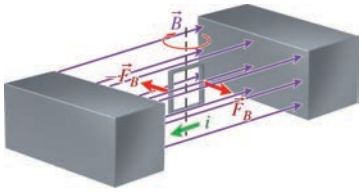

FIGURE 27.26 A primitive element of an electric motor consisting of a current-carrying loop in a magnetic field.

The direction of the magnetic force is given by the variant of right-hand rule 1 illustrated in Figure 27.24b. The two magnetic forces, $\vec{F}_B$ and $-\vec{F}_B$, shown in Figure 27.26 have equal magnitudes and opposite directions. These forces create a torque that tends to rotate the loop around a vertical axis of rotation. These two forces sum to zero. The two horizontal sections of the loop are parallel to the magnetic field and thus experience no magnetic force. Thus, no net force acts on the coil, even though a torque is produced.

Now we consider the case where the loop rotates about its center. As the loop turns in the magnetic field, the forces on the vertical sides of the loop, perpendicular to the direction of the field, do not change. The forces on the square loop, with side length a, are illustrated in Figure 27.27, which shows a bottom view of the coil. In Figure 27.27, θ is the angle between a unit vector, $\hat{n}$, normal to the plane of the coil, and the magnetic field, $\vec{B}$. The unit normal vector is perpendicular to the plane of the wire loop and points in a direction given by right-hand rule 2 (Figure 27.28), based on the current flowing around the loop.

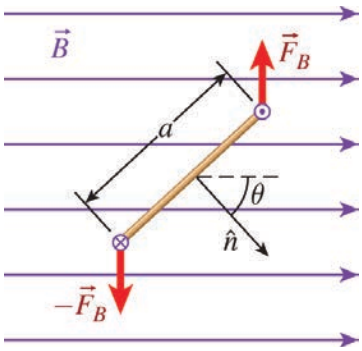

FIGURE 27.27 Bottom view of a current-carrying loop in a magnetic field, showing the forces acting on the loop.

FIGURE 27.28 Right-hand rule 2 gives the direction of the unit normal vector for a current-carrying loop. According to the rule, if you curl the fingers of your right hand in the direction of the current in the loop, your thumb points in the direction of the unit normal vector.

Mark Dierker/McGraw Hill

In Figure 27.27, the current is flowing out of the page in the right side of the loop, indicated by the dot in a circle (representing the tip of an arrowhead) and flowing into the page in the left side of the loop, indicated by the cross in a circle (representing the tail of an arrow). The magnitude of the force on each of these vertical segments is

$$F = iaB.$$

The forces on the two horizontal segments of the loop are parallel or antiparallel to the axis of rotation and do not cause a torque, and these two forces sum to zero. Therefore, there is no net force on the loop.

The sum of the torques on the two vertical segments of the square loop gives the net torque exerted on the loop about its center:

$$\tau_1 = (iaB)\left(\frac{a}{2}\right)\sin\theta + (iaB)\left(\frac{a}{2}\right)\sin\theta = ia^2B\sin\theta = iAB\sin\theta, \quad \textbf{(27.13)}$$

where the index 1 on τ_1 indicates that it is the torque on a single loop and $A = a^2$ is the area of the loop. The reason that the loop continues to rotate and doesn't stop at $\theta = 0^\circ$ is that it is connected to a device called a **commutator,** which causes the current to change directions as the coil rotates. This commutator consists of a split ring, with one end of the loop connected to each half of the loop, as shown in Figure 27.29. The current in the loop switches direction two times for every complete rotation of the loop.

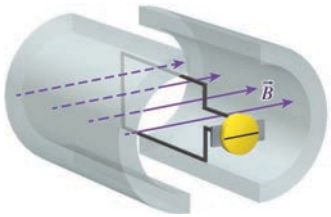

FIGURE 27.29 A wire loop connected to a source of current through a commutator ring.

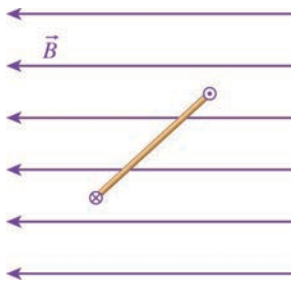
If the single loop is replaced with a coil consisting of many loops wound closely together, the torque on the coil is found by multiplying the torque on a loop, τ_1 from equation 27.13, by the number of windings (loops in the coil), *N:*

$$\tau = N\tau_1 = NiAB\sin\theta. \quad \textbf{(27.14)}$$

Does this expression for the torque hold for other shapes with area *A,* other than squares? The answer is yes, though we will not prove it here.

Concept Check 27.4

The top view of a current-carrying loop in a constant magnetic field is shown in the figure. The torque on the loop will cause it to rotate



a) clockwise.

b) counterclockwise.

c) not at all.

27.6 Magnetic Dipole Moment

A current-carrying coil can be described with one parameter, which contains information about a key characteristic of the coil in a magnetic field. The magnitude of the **magnetic dipole moment,** $\vec{\mu}$, of a current-carrying coil of wire is defined to be

$$\mu = NiA, \tag{27.15}$$

where N is the number of windings, i is the current through the wire, and A is the area of the loops. The direction of the magnetic dipole moment is given by right-hand rule 2 and is the direction of the unit normal vector, $\hat{n}$. Using equation 27.15, we can rewrite equation 27.14 as

$$\tau = (NiA)B\sin\theta = \mu B\sin\theta. \tag{27.16}$$

The torque on a magnetic dipole is given by

$$\vec{\tau} = \vec{\mu} \times \vec{B}. \tag{27.17}$$

That is, the torque on a current-carrying coil is the vector product of the magnetic dipole moment of the coil and the magnetic field.

SOLVED PROBLEM 27.3 Torque on a Rectangular Current-Carrying Loop

A rectangular loop with height $h = 6.50$ cm and width $w = 4.50$ cm is in a uniform magnetic field of magnitude $B = 0.250$ T, which points in the negative y-direction (Figure 27.30a). The loop makes an angle of $\theta = 33.0^\circ$ with the y-axis, as shown in the figure. The loop carries a current of magnitude $i = 9.00$ A in the direction indicated by the arrows.

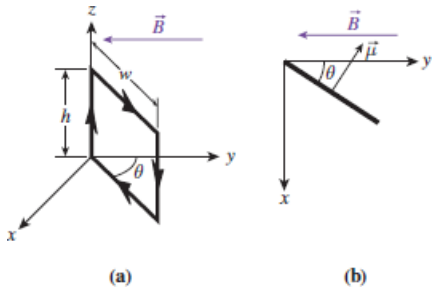


FIGURE 27.30 (a) A rectangular loop carrying a current in a magnetic field. (b) View of the rectangular loop looking down on the *xy*-plane. The magnetic dipole moment is perpendicular to the plane of the loop, with a direction determined by right-hand rule 2.

PROBLEM

What is the magnitude of the torque on the loop around the *z*-axis?

SOLUTION

THINK

The torque on the loop is equal to the vector cross product of the magnetic dipole moment and the magnetic field. The magnetic dipole moment is perpendicular to the plane of the loop, with the direction given by right-hand rule 2.

SKETCH

Figure 27.30b is a view of the loop looking down on the *xy*-plane.

RESEARCH

The magnitude of the magnetic dipole moment of the loop is

$$\mu = NiA = iwh. \tag{i}$$

The magnitude of the torque on the loop is

$$\tau = \mu B \sin\theta_{\mu B}, \tag{ii}$$

where $\theta_{\mu B}$ is the angle between the magnetic dipole moment and the magnetic field. From Figure 27.30b, we can see that

$$\theta_{\mu B} = \theta + 90^\circ. \tag{iii}$$

SIMPLIFY

We can combine equations (i), (ii), and (iii) to obtain

$$\tau = iwhB\sin(\theta + 90^\circ).$$

CALCULATE

Putting in the numerical values, we get

$$\begin{aligned}\tau &= (9.00\text{ A})\left(4.50 \cdot 10^{-2}\text{ m}\right)\left(6.50 \cdot 10^{-2}\text{ m}\right)(0.250\text{ T})\left[\sin(33.0^\circ + 90^\circ)\right] \\ &= 0.0055195\text{ N m}.\end{aligned}$$

ROUND

We report our result to three significant figures:

$$\tau = 5.52 \cdot 10^{-3}\text{ N m}.$$

DOUBLE-CHECK

The magnitude of the force on each of the vertical segments of the loop is

$$F_B = ihB = (9.00\text{ A})\left(6.50 \cdot 10^{-2}\text{ m}\right)(0.250\text{ T}) = 0.146\text{ N}.$$

The magnitude of the torque is then the magnitude of the force on the vertical segment that is not along the z-axis times the moment arm (which is w) times the sine of the angle between the force and the moment arm:

$$\tau = Fw\sin(33.0^\circ + 90^\circ) = 0.146\text{ N}\left(4.50 \cdot 10^{-2}\text{m}\right)\left[\sin(33.0^\circ + 90^\circ)\right] = 5.$$

This is the same as the result calculated above.

A magnetic dipole has potential energy in an external magnetic field. If the dipole moment is aligned with the magnetic field, the dipole has its minimum potential energy. If the dipole moment is oriented in a direction opposite to the external field, the dipole has its maximum potential energy. From Chapter 10, the work done by a torque is

$$W = \int_{\theta_0}^{\theta} \tau(\theta')\, d\theta'. \tag{27.18}$$

Using the work-energy theorem and equation 27.16 and setting $\theta_0 = 90^\circ$, we can express the magnetic potential energy, U, of a magnetic dipole in an external magnetic field, $\vec{B}$ as

$$W = \int_{\theta_0}^{\theta} \tau(\theta')\, d\theta' = \int_{\theta_0}^{\theta} \mu B \sin\theta' d\theta' = -\mu B \cos\theta' \Big|_{\theta_0}^{\theta} = U(\theta) - U(90^\circ),$$

or

$$U(\theta) = -\mu B \cos\theta = -\vec{\mu} \bullet \vec{B}, \tag{27.19}$$

where θ is the angle between the magnetic dipole moment and the external magnetic field.

The lowest value, $-\mu B$, of the potential energy of a magnetic dipole in an external magnetic field is achieved when the dipole's magnetic moment vector is parallel to the external magnetic field vector, and the highest value, $+\mu B$, results when the two vectors are antiparallel (see Figure 27.31). This dependence of potential energy on orientation occurs in diverse physical situations, for which magnetic dipoles in external magnetic fields are a simple model. So far, the only magnetic dipoles we have discussed are current-carrying loops. However, other types of magnetic dipoles exist, including bar magnets and even the Earth. In addition, elementary charged particles such as protons have intrinsic magnetic dipole moments.

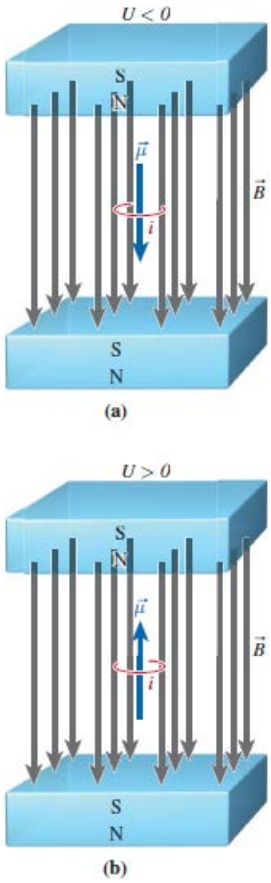

FIGURE 27.31 Magnetic dipole moment vector in an external magnetic field: (a) magnetic dipole and external magnetic field are parallel, resulting in a negative potential energy; (b) magnetic dipole and external magnetic field are antiparallel, resulting in a positive potential energy.

Self-Test Opportunity 27.3

What is the maximum difference in magnetic potential energy between two orientations of a loop with area $0.100\ \mathrm{m}^2$ carrying a current of 2.00 A in a constant magnetic field of magnitude 0.500 T?

27.7 Hall Effect

Consider a conductor carrying a current, *i,* flowing in a direction perpendicular to a magnetic field, $\vec{B}$ (Figure 27.32a). The electrons in the conductor are moving with velocity $\vec{v}_d$ in the direction opposite to the current. The moving electrons experience a force perpendicular to their velocity, causing them to move toward one edge of the conductor. After some time, many electrons have moved to one edge of the conductor, creating a net negative charge on that edge and leaving a net positive charge on the opposite edge of the conductor. This charge distribution creates an electric field, $\vec{E}$, which exerts a force on the electrons in a direction opposite to that exerted by the magnetic field. When the magnitude of the force exerted on the electrons by the electric field is equal to the magnitude of the force exerted on them by the magnetic field, the net number of electrons on the edges of the conductor no longer changes with time. This result is called the **Hall effect.** The potential difference, ΔV_H, between the edges of the conductor when equilibrium is reached is termed the **Hall potential difference,** given by

$$\Delta V_H = Ed, \tag{27.20}$$

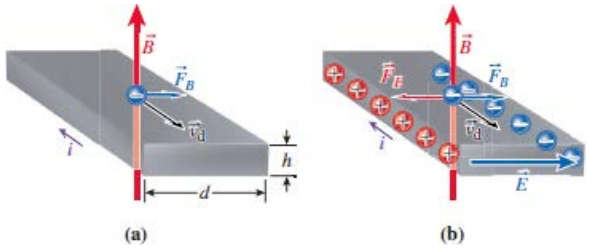

FIGURE 27.32 (a) A conductor carrying a current in a magnetic field. The charge carriers are electrons. (b) The electrons have drifted to one side of the conductor, leaving a net positive charge on the opposite side. This distribution of charges creates an electric field. The potential difference across the conductor is the Hall potential difference.

where d is the width of the conductor and E is the magnitude of the created electric field. (See Chapter 23 for the relationship between the electric potential difference and the constant electric field.)

The Hall effect can be used to demonstrate that the charge carriers in metals are negatively charged. If the charge carriers in a metal were positive and moving in the direction of the current shown in Figure 27.32a, those positive charges would collect on the same edge of the conductor as the electrons in Figure 27.32b, giving an electric field with the opposite sign. Thus, the charge carriers in conductors are negatively charged and must be electrons. The Hall effect also establishes that in some semiconductors the charge carriers are electron holes (missing electrons), which appear to be positively charged carriers.

The Hall effect can also be used to determine a magnetic field by measuring the current flowing through the conductor and the resulting potential difference across the conductor. To obtain the formula for the magnetic field, we start with the equilibrium condition of the Hall effect, that the magnitudes of the magnetic and electric forces are equal:

$$F_E = F_B \Rightarrow eE = v_{\mathrm{d}}Be = \frac{E}{v_{\mathrm{d}}} = \frac{\Delta V_H}{v_{\mathrm{d}}d}, \qquad \textbf{(27.21)}$$

where substitution for *E* from equation 27.20 is used in the last step. In Chapter 25, we saw that the drift speed, v_d, of an electron in a conductor can be related to the magnitude of the current density, *J,* in the conductor:

$$J = \frac{i}{A} = nev_{\mathrm{d}},$$

where *A* is the cross-sectional area of the conductor and *n* is the number of electrons per unit volume in the conductor. As shown in Figure 27.32a, the cross-sectional area is given by $A = dh$, where *d* is the width and *h* is the height of the conductor. Solving $i/A = nev_{\mathrm{d}}$ for the drift speed and substituting *hd* for *A* gives

$$v_{\mathrm{d}} = \frac{i}{Ane} = \frac{i}{hdne}.$$

Substituting this expression for v_d into equation 27.21, we have

$$B = \frac{\Delta V_{\mathrm{H}}}{v_{\mathrm{d}}d} = \frac{\Delta V_{\mathrm{H}}dhne}{id} = \frac{\Delta V_{\mathrm{H}}hne}{i}. \qquad \textbf{(27.22)}$$

Thus, equation 27.22 gives the magnetic field strength (magnitude) from a measured value of the Hall potential difference, ΔV_H, and the known height, *h,* and density of charge carriers, *n,* of the conductor. Equivalently, a rearranged form of equation 27.22 can be used to find the Hall voltage if the magnetic field strength is known:

$$\Delta V_{\mathrm{H}} = \frac{iB}{neh}. \tag{27.23}$$

EXAMPLE 27.5 Hall Effect

Suppose we use a Hall probe to measure the magnitude of a constant magnetic field. The Hall probe is a strip of copper with a height, h, of 2.00 mm. We measure a voltage of 0.250 μV across the probe when we run a current of 1.25 A through it.

PROBLEM

What is the magnitude of the magnetic field?

SOLUTION

The magnetic field is given by equation 27.22:

$$B = \frac{\Delta V_{\mathrm{H}} hne}{i}.$$

We have been given the values of V_H, h, and i, and we know e. The density of the electrons, n, is defined as the number of electrons per unit volume:

$$n = \frac{\text{number of electrons}}{\text{volume}}.$$

The density of copper is $\rho_{\mathrm{Cu}} = 8.96\ \mathrm{g/cm^3} = 8960\ \mathrm{kg/m^3}$, and 1 mole of copper has a mass of 63.5 g and $6.02 \cdot 10^{23}$ atoms. Each copper atom has one conduction electron. Thus, the density of the electrons is

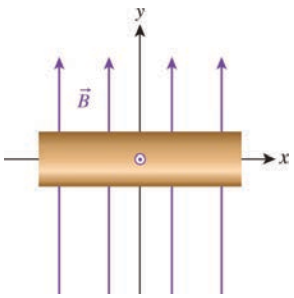
$$n = \left(\frac{1\ \text{electron}}{1\ \text{atom}}\right)\left(\frac{6.02 \cdot 10^{23}\ \text{atoms}}{63.5\ \text{g}}\right)\left(\frac{8.96\ \text{g}}{1\ \text{cm}^3}\right)\left(\frac{1.0 \cdot 10^{6}\ \text{cm}^3}{1\ \text{m}^3}\right) = 8$$

We can now calculate the magnitude of the magnetic field:

$$B = \frac{\left(0.250 \cdot 10^{-6}\ \text{V}\right)\left(0.002\ \text{m}\right)\left(8.49 \cdot 10^{28}\,\frac{\text{electrons}}{\text{m}^3}\right)\left(1.602 \cdot 10^{-19}\ \text{C}\right)}{1.25\ \text{A}}$$

Concept Check 27.5

A conductor is carrying a current in a constant magnetic field, as shown in the figure. The resulting electric field due to the Hall effect is



a) in the positive x-direction.

b) in the negative x-direction.

c) in the positive y-direction.

d) in the negative y-direction.

WHAT WE HAVE LEARNED EXAM STUDY GUIDE

- Magnetic field lines indicate the direction of a magnetic field in space. Magnetic field lines do not end on magnetic poles, but form closed loops instead.
- The magnetic force on a particle with charge q moving with velocity $\vec{v}$ in a magnetic field, $\vec{B}$, is given by $\vec{F} = q\vec{v} \times \vec{B}$. Right-hand rule 1 gives the direction of the force.
- For a particle with charge q moving with speed v perpendicular to a magnetic field of magnitude B, the magnitude of the magnetic force on the moving charged particle is $F = |q|vB$.
- The unit of magnetic field is the tesla, abbreviated T.
- The average magnitude of the Earth's magnetic field at the surface is approximately $0.5 \cdot 10^{-4}$ T.
- A particle with mass m and charge q moving with speed v perpendicular to a magnetic field with magnitude B has a trajectory that is a circle with radius $r = mv/|q|B$.
- The cyclotron frequency, ω, of a particle with charge q and mass m moving in a circular orbit in a constant magnetic field of magnitude B is given by $\omega = |q|B/m$.

- The force exerted by a magnetic field, $\vec{B}$, on a length of wire, $\vec{L}$, carrying a current, i, is given by $\vec{F} = i\vec{L} \times \vec{B}$. The magnitude of this force is $F = iLB \sin\theta$, where θ is the angle between the direction of the current and the direction of the magnetic field.
- The magnitude of the torque on a loop carrying a current, i, in a magnetic field with magnitude B is $\tau = iAB \sin\theta$, where A is the area of the loop and θ is the angle between a unit vector normal to the loop and the direction of the magnetic field. Right-hand rule 2 gives the direction of the unit normal vector to the loop.
- The magnitude of the magnetic dipole moment of a coil carrying a current, i, is given by $\mu = NiA$, where N is the number of loops (windings) and A is the area of a loop. The direction of the dipole moment is given by right-hand rule 2 and is the direction in which the unit normal vector points.
- The Hall effect results when a current, i, flowing through a conductor with height h in a magnetic field of magnitude B produces a potential difference across the conductor (the Hall potential difference), given by

$\Delta V_{\mathrm{H}} = iB/neh$, where n is the number of electrons per unit volume and e is the magnitude of an electron's charge.

ANSWERS TO SELF-TEST OPPORTUNITIES

27.1 Particle 1:
$F_{\mathrm{B}} = qvB\sin\theta = (6.15 \cdot 10^{-6}\ \mathrm{C})(465\ \mathrm{m/s})(0.165\ \mathrm{T})(\sin\ 30.0^\circ) = 2.36 \cdot 10^{-4}\ \mathrm{N}.$

Particle 2:
$F_{\mathrm{B}} = qvB\sin\theta = (6.15 \cdot 10^{-6}\ \mathrm{C})(465\ \mathrm{m/s})(0.165\ \mathrm{T})(\sin\ 90.0^\circ) = 4.72 \cdot 10^{-4}\ \mathrm{N}.$

Particle 3:
$F_{\mathrm{B}} = qvB\sin\theta = (6.15 \cdot 10^{-6}\ \mathrm{C})(465\ \mathrm{m/s})(0.165\ \mathrm{T})(\sin\ 150.0^\circ) = 2.36 \cdot 10^{-4}\ \mathrm{N}.$

27.2 a) positive

b) slowing down

c) no (Therefore, another force must be acting on the particle to slow it down.)

27.3
$\Delta U = U_{\max} - U_{\min} = 2\mu B = 2iAB = 2(2.00\ \mathrm{A})(0.100\ \mathrm{m}^2)(0.500\ \mathrm{T}) = 0.200\ \mathrm{J}.$

PROBLEM-SOLVING GUIDELINES: CIRCULAR MOTION

1. When working with magnetic fields and forces, you need to sketch a clear diagram of the problem situation in three dimensions. Often, a separate sketch of the velocity and magnetic field vectors (or of the length of wire and the field vectors) is useful to visualize the plane in which they lie, since the magnetic force will be perpendicular to that plane.

2. Remember that the right-hand rules apply for positive charges and currents. If a charge or a current is negative, you can use the right-hand rule, but the force will then be in the opposite direction.

3. A particle in both an electric and a magnetic field experiences an electric force, $\vec{F}_E = q\vec{E}$, and a magnetic force, $\vec{F}_B = q\vec{v} \times \vec{B}$. Be sure you take the vector sum of the individual forces.

MULTIPLE-CHOICE QUESTIONS

27.1 A magnetic field is oriented in a certain direction in a horizontal plane. An electron moves in a certain direction in the horizontal plane. For this situation, there

a) is one possible direction for the magnetic force on the electron.

b) are two possible directions for the magnetic force on the electron.

c) are infinite possible directions for the magnetic force on the electron.

27.2 A particle with charge q is at rest when a magnetic field is suddenly turned on. The field points in the z-direction. What is the direction of the net force acting on the charged particle?

a) in the x-direction

b) in the y-direction

c) The net force is zero.

d) in the z-direction

27.3 Which of the following has the largest cyclotron frequency?

a) an electron with speed v in a magnetic field with magnitude B

b) an electron with speed $2v$ in a magnetic field with magnitude B

c) an electron with speed $v/2$ in a magnetic field with magnitude B

d) an electron with speed $2v$ in a magnetic field with magnitude $B/2$

e) an electron with speed $v/2$ in a magnetic field with magnitude $2B$

27.4 In the Hall effect, a potential difference produced across a conductor of finite thickness in a magnetic field by a current flowing through the conductor is given by

a) the product of the density of electrons, the charge of an electron, and the conductor's thickness divided by the product of the magnitudes of the current and the magnetic field.

b) the reciprocal of the expression described in part (a).

c) the product of the charge on an electron and the conductor's thickness divided by the product of the density of electrons and the magnitudes of the current and the magnetic field.

d) the reciprocal of the expression described in (c).

e) none of the above.

27.5 An electron (with charge $-e$ and mass m_e) moving in the positive x-direction enters a velocity selector. The velocity selector consists of crossed electric and magnetic fields: $\vec{E}$ is directed in the positive y-direction, and $\vec{B}$ is directed in the positive z-direction. For a velocity v (in the positive x-direction), the net force on the electron is zero, and the electron moves straight through the velocity selector. With

what velocity will a proton (with charge $+e$ and mass $m_\mathrm{p} = 1836\, m_\mathrm{e}$) move straight through the velocity selector?

a) v

b) $-v$

c) $v/1836$

d) $-v/1836$

27.6 In which direction does a magnetic force act on an electron that is moving in the positive *x*-direction in a magnetic field pointing in the positive *z*-direction?

a) the positive *y*-direction

b) the negative *y*-direction

c) the negative *x*-direction

d) any direction in the *xy*-plane

27.7 A charged particle is moving in a constant magnetic field. Which of the following statements concerning the magnetic force exerted on the particle is (are) true? (Assume that the magnetic field is not parallel or antiparallel to the velocity.)

a) It does no work on the particle.

b) It may increase the speed of the particle.

c) It may change the velocity of the particle.

d) It can act only on the particle while the particle is in motion.

e) It does not change the kinetic energy of the particle.

27.8 An electron moves in a circular trajectory with radius r_i in a constant magnetic field. What is the final radius of the trajectory when the magnetic field is doubled?

a) $\dfrac{r_\mathrm{i}}{4}$

b) $\dfrac{r_\mathrm{i}}{2}$

c) r_i

d) $2r_\mathrm{i}$

e) $4r_\mathrm{i}$

27.9 Protons in the solar wind reach Earth's magnetic field with a speed of 400 km/s. If the magnitude of this field is $5.0 \cdot 10^{-5}$ T and the velocity of the protons is perpendicular to it, what is the cyclotron frequency of the protons after entering the field?

a) 122 Hz

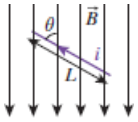
b) 233 Hz

c) 321 Hz

d) 432 Hz

e) 763 Hz

27.10 An isolated segment of wire of length $L = 4.50$ m carries a current of magnitude $i = 35.0$ A at an angle $\theta = 50.3^\circ$ with respect to a constant magnetic field of magnitude $B = 6.70 \cdot 10^{-2}$ T (see the figure). What is the magnitude of the magnetic force on the wire?



a) 2.66 N

b) 3.86 N

c) 5.60 N

d) 8.12 N

e) 11.8 N

27.11 A coil is composed of circular loops of radius $r = 5.13$ cm and has $N = 47$ windings. A current, $i = 1.27$ A, flows through the coil, which is inside a homogeneous magnetic field of magnitude 0.911 T. What is the maximum torque on the coil due to the magnetic field?

a) 0.148 N m

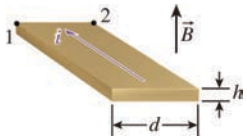
b) 0.211 N m

c) 0.350 N m

d) 0.450 N m

e) 0.622 N m

27.12 A copper conductor has a current, $i = 1.41$ A, flowing through it, perpendicular to a constant magnetic field, $B = 4.94$ T, as shown in the figure. The conductor is $d = 0.100$ m wide and $h = 2.00$ mm high. What is the electric potential difference between points 1 and 2?



a) $2.56 \cdot 10^{-9}$ V

b) $5.12 \cdot 10^{-9}$ V

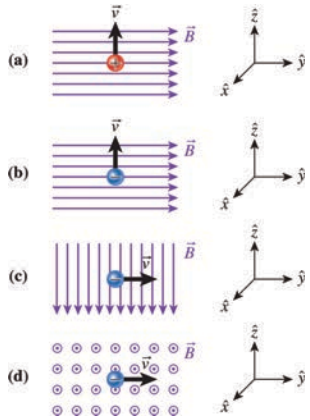
c) $7.50 \cdot 10^{-8}$ V

d) $2.56 \cdot 10^{-7}$ V

e) $9.66 \cdot 10^{-7}$ V

CONCEPTUAL QUESTIONS

27.13 Draw on the *xyz*-coordinate system and specify (in terms of the unit vectors $\hat{x}, \hat{y}$, and $\hat{z}$) the direction of the magnetic force on each of the moving particles shown in the figures. *Note:* The positive *y*-axis is toward the right, the positive *z*-axis is toward the top of the page, and the positive *x*-axis is directed out of the page.



27.14 A particle with mass *m,* charge *q,* and velocity *v* enters a magnetic field of magnitude *B* and with direction perpendicular to the initial velocity of the particle. What is the work done by the magnetic field on the particle? How does this affect the particle's motion?

27.15 An electron is moving with a constant velocity. When it enters an electric field that is perpendicular to its velocity, the electron will follow a _____ trajectory. When the electron enters a magnetic field that is perpendicular to its velocity, it will follow a _____ trajectory.

27.16 A proton, moving in negative *y*-direction in a magnetic field, experiences a force of magnitude *F,* acting in the negative *x*-direction.

a) What is the direction of the magnetic field producing this force?

b) Does your answer change if the word "proton" in the statement is replaced by "electron"?

27.17 It would be mathematically possible, for a region with zero current density, to define a scalar magnetic potential analogous to the electrostatic potential: $V_B(\vec{r}) = -\int_{\vec{r}_0}^{\vec{r}} \vec{B} \cdot d\vec{s}$, or $\vec{B}(\vec{r}) = -\nabla V_B(\vec{r})$. However, this has not been done. Explain why not.

27.18 A current-carrying wire is positioned within a large, uniform magnetic field, $\vec{B}$. However, the wire experiences no force. Explain how this might be possible.

27.19 A charged particle moves under the influence of an electric field only. Is it possible for the particle to move with a constant speed? What if the electric field is replaced with a magnetic field?

27.20 A charged particle travels with speed v, at an angle θ with respect to the z-axis. It enters at time $t = 0$ a region of space where there is a magnetic field of magnitude B in the positive z-direction. When does it emerge from this region of space?

27.21 An electron is traveling horizontally from the northwest toward the southeast in a region of space where the Earth's magnetic field is directed horizontally toward the north. What is the direction of the magnetic force on the electron?

27.22 At the Earth's surface, there is an electric field that points approximately straight down and has magnitude 150 V/m. Suppose you had a tuneable electron gun (you can release electrons with whatever kinetic energy you like) and a detector to determine the direction of motion of the electrons when they leave the gun. Explain how you could use the gun to find the direction toward the north magnetic pole. Specifically, what kinetic energy would the electrons need to have? (*Hint:* It might be easier to think about finding which direction is east or west.)

27.23 The work done by the magnetic field on a charged particle in motion in a cyclotron is zero. How, then, can a cyclotron be used as a particle accelerator, and what essential feature of the particle's motion makes it possible?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Section 27.2

27.24 A proton moving with a speed of $4.00 \cdot 10^5$ m/s in the positive y-direction enters a uniform magnetic field of 0.400 T pointing in the positive x-direction. Calculate the magnitude of the force on the proton.

27.25 The magnitude of the magnetic force on a particle with charge $-2e$ moving with speed $v = 1.00 \cdot 10^5$ m/s is $3.00 \cdot 10^{-18}$ N. What is the magnitude of the magnetic field component perpendicular to the direction of motion of the particle?

•**27.26** A particle with a charge of +10.0 μC is moving at 300. m/s in the positive z-direction.

a) Find the minimum magnetic field required to keep it moving in a straight line at constant speed if there is a uniform electric field of magnitude 100. V/m pointing in the positive y-direction.

b) Find the minimum magnetic field required to keep the particle moving in a straight line at constant speed if there is a uniform electric field of magnitude 100. V/m pointing in the positive z-direction.

•**27.27** A particle with a charge of 20.0 μC moves along the x-axis with a speed of 50.0 m/s. It enters a magnetic field given by $\vec{B} = 0.300\hat{y} + 0.700\hat{z}$, in teslas. Determine the magnitude and the direction of the magnetic force on the particle.

••**27.28** The magnetic field in a region in space (where $x > 0$ and $y > 0$) is given by $\vec{B} = (x - az)\hat{y} + (xy - b)\hat{z}$, where a and b are positive constants. An electron moving with a constant velocity, $\vec{v} = v_0\hat{x}$, enters this region. What are the coordinates of the points at which the net force acting on the electron is zero?

Section 27.3

27.29 A proton is accelerated from rest by a potential difference of 400. V. The proton enters a uniform magnetic field and follows a circular path of radius 20.0 cm. Determine the magnitude of the magnetic field.

27.30 An electron with a speed of $4.00 \cdot 10^5$ m/s enters a uniform magnetic field of magnitude 0.0400 T at an angle of 35.0° to the magnetic field lines. The electron will follow a helical path.

a) Determine the radius of the helical path.

b) How far forward will the electron have moved after completing one circle?

27.31 A particle with mass m and charge q is moving within both an electric field and a magnetic field, $\vec{E}$ and $\vec{B}$. The particle has velocity $\vec{v}$, momentum $\vec{p}$, and kinetic energy, K. Find general expressions for $d\vec{p}/dt$ and dK/dt, in terms of these seven quantities.

27.32 The Earth is showered with particles from space known as *muons*. They have a charge identical to that of an electron but are many times heavier $\left(m = 1.88 \cdot 10^{-28} \text{ kg}\right)$. Suppose a strong magnetic field is established in a lab $(B = 0.500 \text{ T})$ and a muon enters this field with a velocity of $3.00 \cdot 10^6$ m/s at a right angle to the field. What will be the radius of the muon's resulting orbit?

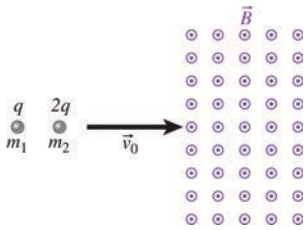
27.33 An electron in a magnetic field moves counterclockwise on a circle in the xy-plane, with a cyclotron frequency of $\omega = 1.20 \cdot 10^{12}$ Hz. What is the magnetic field, $\vec{B}$?

27.34 An electron with energy equal to $4.00 \cdot 10^2$ eV and an electron with energy equal to $2.00 \cdot 10^2$eV are trapped in a uniform magnetic field and move in circular paths in a plane perpendicular to the magnetic field. What is the ratio of the radii of their orbits?

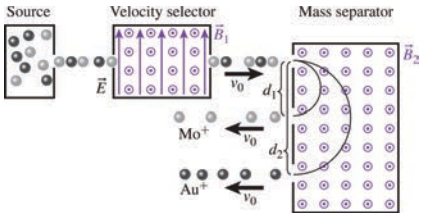
•**27.35** A proton with an initial velocity given by $\left(1.00\hat{x} + 2.00\hat{y} + 3.00\hat{z}\right)$ enters a magnetic field given by $(0.500 \text{ T})\hat{z}$. Describe the motion of the proton.

•**27.36** Initially at rest, a small copper sphere with a mass of $3.00 \cdot 10^{-6}$ kg and a charge of $5.00 \cdot 10^{-4}$ C is accelerated through a 7000.-V potential difference before entering a magnetic field of magnitude 4.00 T, directed perpendicular to its velocity. What is the radius of curvature of the sphere's motion in the magnetic field?

•**27.37** Two particles with masses m_1 and m_2 and charges q and $2q$ travel with the same velocity, v, and enter a magnetic field of strength B at the same point, as shown in the figure. In the magnetic field, they move in semicircles with radii R and $2R$. What is the ratio of their masses? Is it possible to apply an electric field that would cause the particles to move in a straight line in the magnetic field? If yes, what would be the magnitude and the direction of the field?



•**27.38** The figure shows a schematic diagram of a simple mass spectrometer, consisting of a velocity selector and a particle detector and being used to separate singly ionized atoms $\left(q = +e = 1.602 \cdot 10^{-19}\ \text{C}\right)$ of gold (Au) and molybdenum (Mo). The electric field inside the velocity selector has magnitude $E = 1.789 \cdot 10^{4}\ \text{V/m}$ and points toward the top of the page, and the magnetic field has magnitude $B_1 = 1.000\ \text{T}$ and points out of the page.



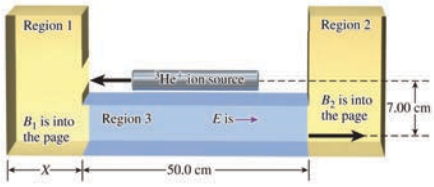
a) Draw the electric force vector, $\overrightarrow{F_E}$, and the magnetic force vector, $\overrightarrow{F_B}$, acting on the ions inside the velocity selector.

b) Calculate the velocity, v_0, of the ions that make it through the velocity selector (those that travel in a straight line). Does v_0 depend on the type of ion (gold versus molybdenum), or is it the same for both types of ions?

c) Write the equation for the radius of the semicircular path of an ion in the particle detector: $R = R(m, v_0, q, B_2)$.

d) The gold ions (represented by the dark gray spheres) exit the particle detector at a distance $d_2 = 40.00$ cm from the entrance slit, while the molybdenum ions (represented by the light gray spheres) exit the particle detector at a distance $d_1 = 19.81$ cm from the entrance slit. The mass of a gold ion is $m_{\text{gold}} = 3.271 \cdot 10^{-25}$ kg. Calculate the mass of a molybdenum ion.

•• **27.39** A small particle accelerator for accelerating $^3\text{He}^+$ ions is shown in the figure. The $^3\text{He}^+$ ions exit the ion source with a kinetic energy of 4.00 keV. Regions 1 and 2 contain magnetic fields directed into the page, and region 3 contains an electric field directed from left to right. The $^3\text{He}^+$ ion beam exits the accelerator from a hole on the right that is 7.00 cm below the ion source, as shown in the figure.



a) If $B_1 = 1.00$ T and region 3 is 50.0 cm long with $E = 60.0$ kV/m, what value should B_2 have to cause the ions to move straight through the exit hole after being accelerated twice in region 3?

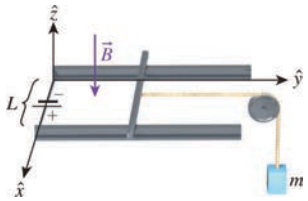
b) What minimum width X should region 1 have?

c) What is the velocity of the ions when they leave the accelerator?

Section 27.4

27.40 A straight wire of length 2.00 m carries a current of 24.0 A. It is placed on a horizontal tabletop in a uniform horizontal magnetic field. The wire makes an angle of 30.0° with the magnetic field lines. If the magnitude of the force on the wire is 0.500 N, what is the magnitude of the magnetic field?

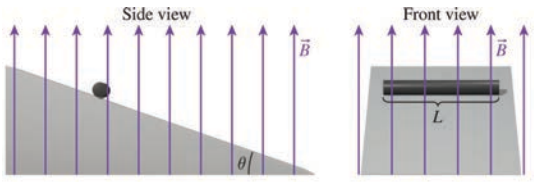
27.41 As shown in the figure, a straight conductor parallel to the x-axis can slide without friction on top of two horizontal conducting rails that are parallel to the y-axis and a distance of $L = 0.200$ m apart, in a vertical magnetic field of 1.00 T. A 20.0-A current is maintained through the conductor. If a string is connected exactly at the center of the conductor and passes over a frictionless pulley, what mass m suspended from the string allows the conductor to be at rest?



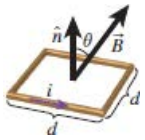
27.42 A copper wire of radius 0.500 mm is carrying a current at the Earth's Equator. Assuming that the magnetic field of the Earth has magnitude 0.500 G at the Equator and is parallel to the surface of the Earth and that the current in the wire flows toward the east, what current is required to allow the wire to levitate?

•27.43 A copper sheet with length 1.00 m, width 0.500 m, and thickness 1.00 mm is oriented so that its largest surface area is perpendicular to a magnetic field of strength 5.00 T. The sheet carries a current of 3.00 A across its length. What is the magnitude of the force on this sheet? How does this magnitude compare to that of the force on a thin copper wire carrying the same current and oriented perpendicularly to the same magnetic field?

•27.44 A conducting rod of length L slides freely down an inclined plane, as shown in the figure. The plane is inclined at an angle θ from the horizontal. A uniform magnetic field of strength B acts in the positive y-direction. Determine the magnitude and the direction of the current that would have to be passed through the rod to hold it in position on the inclined plane.



•27.45 A square loop of wire, with side length $d = 8.00$ cm, carries a current of magnitude $i = 0.150$ A and is free to rotate. It is placed between the poles of an electromagnet that produce a uniform magnetic field of 1.00 T. The loop is initially placed so that its normal vector, $\hat{n}$, is at a 35.0° angle relative to the direction of the magnetic field vector, with the angle θ defined as shown in the figure. The wire is copper (with a density of $\rho = 8960$ kg/m^3), and its diameter is 0.500 mm. What is the magnitude of the initial angular acceleration of the loop when it is released?



•**27.46** A rail gun accelerates a projectile from rest by using the magnetic force on a current-carrying wire. The wire has radius $r = 5.10 \cdot 10^{-4}$ m and is made of copper having a density of $\rho = 8960$ kg/m^3. The gun consists of rails of length $L = 1.00$ m in a constant magnetic field of magnitude $B = 2.00$ T, oriented perpendicular to the plane defined by the rails. The wire forms an electrical connection across the rails at one end of the rails. When triggered, a current of $1.00 \cdot 10^4$ A flows through the wire, which accelerates the wire along the rails. Calculate the final speed of the wire as it leaves the rails. (Neglect friction.)

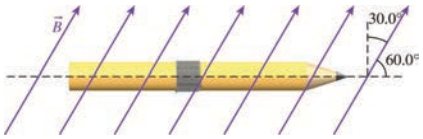
Sections 27.5 and 27.6

•**27.47** A square loop of wire of side length ℓ lies in the *xy*-plane, with its center at the origin and its sides parallel to the *x*- and *y*-axes. It carries a current, *i,* flowing in the counterclockwise direction, as viewed looking down the *z*-axis from the positive direction. The loop is in a magnetic field given by $\vec{B} = (B_0/a)\left(z\hat{x} + x\hat{z}\right)$, where B_0 is a constant field strength, *a* is a constant with the dimension of length, and $\hat{x}$ and $\hat{y}$ are unit vectors in the positive *x*-direction and positive *z*-direction. Calculate the net force on the loop.

27.48 A rectangular coil with 20 windings carries a current of 2.00 mA flowing in the counterclockwise direction. It has two sides that are parallel to the *y*-axis and have length 8.00 cm and two sides that are parallel to the *x*-axis and have length 6.00 cm. A uniform magnetic field of 50.0 μT acts in the positive *x*-direction. What torque must be applied to the loop to hold it steady?

27.49 A coil consists of 120. circular loops of wire of radius 4.80 cm. A current of 0.490 A runs through the coil, which is oriented vertically and is free to rotate about a vertical axis (parallel to the *z*-axis). It experiences a uniform horizontal magnetic field in the positive *x*-direction. When the coil is oriented parallel to the *x*-axis, a force of 1.20 N applied to the edge of the coil in the positive *y*-direction can keep it from rotating. Calculate the strength of the magnetic field.

27.50 Twenty loops of wire are tightly wound around a round pencil that has a diameter of 6.00 mm. The pencil is then placed in a uniform 5.00-T magnetic field, as shown in the figure. If a 3.00-A current is present in the coil of wire, what is the magnitude of the torque on the pencil?

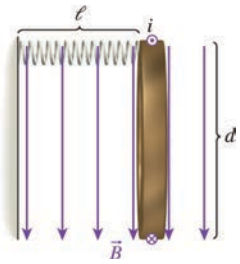


•**27.51** A copper wire with density $\rho = 8960\ \text{kg/m}^3$ is formed into a circular loop of radius 50.0 cm. The cross-sectional area of the wire is $1.00 \cdot 10^{-5}\ \text{m}^2$, and a potential difference of 0.0120 V is applied to the wire. What is the maximum angular acceleration of the loop when it is placed in a magnetic field of magnitude 0.250 T? The loop rotates about an axis in the plane of the loop that corresponds to a diameter.

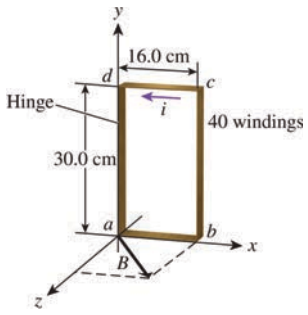
27.52 A simple galvanometer is made from a coil that consists of *N* loops of wire of area *A*. The coil is attached to a mass, *M,* by a light rigid rod of length *L*. With no current in the coil, the mass hangs straight down, and the coil lies in a horizontal plane. The coil is in a uniform magnetic field of magnitude *B* that is oriented horizontally. Calculate the angle from the vertical of the rigid rod as a function of the current, *i,* in the coil.

27.53 Show that the magnetic dipole moment of an electron orbiting in a hydrogen atom is proportional to its angular momentum, L : $\mu = -eL/(2m)$, where $-e$ is the charge of the electron and m is its mass.

•27.54 The figure shows a top view of a current-carrying ring of wire having a diameter $d = 8.00$ cm, which is suspended from the ceiling via a thin string. A 1.00-A current flows in the ring in the direction indicated in the figure. The ring is connected to one end of a spring with a spring constant of 100. N/m. When the ring is in the position shown in the figure, the spring is at its equilibrium length, ℓ. Determine the extension of the spring when a magnetic field of magnitude $B = 2.00$ T is applied parallel to the plane of the ring, as shown in the figure.



•27.55 A coil of wire consisting of 40 rectangular loops, with width 16.0 cm and height 30.0 cm, is placed in a constant magnetic field given by $\vec{B} = 0.0650\text{T}\hat{x} + 0.250\text{T}\hat{z}$. The coil is hinged to a fixed thin rod along the y-axis (along segment *da* in the figure) and is originally located in the xy-plane. A current of 0.200 A runs through the wire.



a) What are the magnitude and the direction of the force, $\vec{F}_{ab}$, that $\vec{B}$ exerts on segment *ab* of the coil?

b) What are the magnitude and the direction of force, $\vec{F}_{bc}$, that $\vec{B}$ exerts on segment *bc* of the coil?

c) What is the magnitude of the net force, F_{net}, that $\vec{B}$ exerts on the coil?

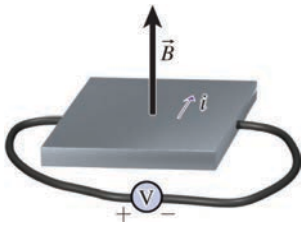
d) What are the magnitude and the direction of the torque, $\vec{\tau}$, that $\vec{B}$ exerts on the coil?

e) In what direction, if any, will the coil rotate about the y-axis (viewed from above and looking down that axis)?

Section 27.7

27.56 A high electron mobility transistor (HEMT) controls large currents by applying a small voltage to a thin sheet of electrons. The density and mobility of the electrons in the sheet are critical for the operation of the HEMT. HEMTs consisting of AlGaN/GaN/Si are being studied because they promise better performance at higher currents, temperatures, and frequencies than conventional silicon HEMTs can achieve. In one study, the Hall effect was used to measure the density of electrons in one of these new HEMTs. When a current of 10.0 μA flows through the length of the electron sheet, which is 1.00 mm long, 0.300 mm wide, and 10.0 nm thick, a magnetic field of 1.00 T perpendicular to the sheet produces a voltage of 0.680 mV across the width of the sheet. What is the density of electrons in the sheet?

•27.57 The figure shows schematically a setup for a Hall effect measurement using a thin film of zinc oxide of thickness 1.50 μm. The current, *i,* across the thin film is 12.3 mA, and the Hall potential, V_H, is -20.1 mV when a magnetic field of magnitude $B = 0.900$ T is applied perpendicular to the current flow.



a) What are the charge carriers in the thin film? [*Hint:* They can be either electrons with charge $-e$ or electron holes (missing electrons) with charge $+e$.]

b) Calculate the density of charge carriers in the thin film.

Additional Exercises

27.58 A cyclotron in a magnetic field of 9.00 T is used to accelerate protons to 50.0% of the speed of light. What is the cyclotron frequency of these protons? What is the radius of their trajectory in the cyclotron? What are the cyclotron frequency and the trajectory radius of the same protons in the Earth's magnetic field? Assume that the Earth's magnetic field is 0.500 G.

27.59 A straight wire carrying a current of 3.41 A is placed at an angle of 10.0° to the horizontal between the pole tips of a magnet producing a field of 0.220 T upward. The poles' tips each have a 10.0 cm diameter. The magnetic force causes the wire to move out of the space between the poles. What is the magnitude of that force?

27.60 An electron is moving at $v = 6.00 \cdot 10^7$ m/s perpendicular to the Earth's magnetic field. If the field strength is $0.500 \cdot 10^{-4}$ T, what is the radius of the electron's circular path?

27.61 A straight wire with a constant current running through it is in Earth's magnetic field, at a location where the magnitude is 0.430 G. What is the minimum current that must flow through the wire for a 10.0-cm length of it to experience a force of 1.00 N?

27.62 A circular coil with a radius of 10.0 cm has 100 turns of wire and carries a current, $i = 100.$ mA. It is free to rotate in a region with a constant horizontal magnetic field given by $\vec{B} = (0.0100 \text{ T})\hat{x}$. If the unit normal vector to the plane of the coil makes an angle of 30.0° with the horizontal, what is the magnitude of the net torque acting on the coil?

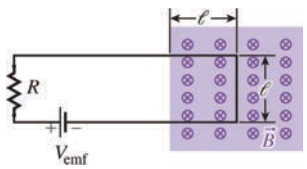
27.63 At $t = 0$ an electron crosses the positive y-axis (so $x = 0$) at 60.0 cm from the origin with velocity $2.00 \cdot 10^5$ m/s in the positive x-direction. It is in a uniform magnetic field.

a) Find the magnitude and the direction of the magnetic field that will cause the electron to cross the x-axis at $x = 60.0$ cm.

b) What work is done on the electron during this motion?

c) How long will the trip from y-axis to x-axis take?

•**27.64** A 12.0-V battery is connected to a 3.00-Ω resistor in a rigid rectangular loop of wire measuring 3.00 m by 1.00 m. As shown in the figure, a length $\ell = 1.00$ m of wire at the end of the loop extends into a 2.00 m by 2.00 m region with a magnetic field of magnitude 5.00 T, directed into the page. What is the net force on the loop?



27.65 An alpha particle $\left(m = 6.64 \cdot 10^{-27} \text{ kg}, q = +2e\right)$ is accelerated by a potential difference of 2700. V and moves in a plane perpendicular to a constant

magnetic field of magnitude 0.340 T, which curves the trajectory of the alpha particle. Determine the radius of curvature and the period of revolution.

•**27.66** In a certain area, the electric field near the surface of the Earth is given by $\vec{E} = (-150.\ \text{N/C})\hat{z}$, and the Earth's magnetic field is given by $\vec{B} = (50.0\mu\text{T})\hat{r}_\text{N} - (20.0\mu\text{T})\hat{z}$, where $\hat{z}$ is a unit vector pointing vertically upward and $\hat{r}_\text{N}$ is a horizontal unit vector pointing due north. What velocity, $\vec{v}$, will allow an electron in this region to move in a straight line at constant speed?

•**27.67** A helium leak detector uses a mass spectrometer to detect tiny leaks in a vacuum chamber. The chamber is evacuated with a vacuum pump and then sprayed with helium gas on the outside. If there is any leak, the helium molecules pass through the leak and into the chamber, whose volume is sampled by the leak detector. In the spectrometer, helium ions are accelerated and released into a tube, where their motion is perpendicular to an applied magnetic field, $\vec{B}$, and they follow a circular path of radius *r* and then hit a detector. Estimate the velocity required if the radius of the ions' circular path is to be no more than 5.00 cm, the magnetic field is 0.150 T, and the mass of a helium-4 atom is about $6.64 \cdot 10^{-27}$ kg. Assume that each ion is singly ionized (has one electron less than the neutral atom). By what factor does the required velocity change if helium-3 atoms, which have about $\frac{3}{4}$ as much mass as helium-4 atoms, are used?

•**27.68** In your laboratory, you set up an experiment with an electron gun that emits electrons with energy of 7.50 keV toward an atomic target. What deflection (magnitude and direction) will Earth's magnetic field (0.300 G) produce in the beam of electrons if the beam is initially directed due east and covers a distance of 1.00 m from the gun to the target? (*Hint:* First calculate the radius of curvature, and then determine how far away from a straight line the electron beam has deviated after 1.00 m.)

•**27.69** A proton enters the region between the two plates shown in the figure moving in the *x*-direction with a speed $v = 1.35 \cdot 10^6$ m/s. The potential of the top plate is 200. V, and the potential of the bottom plate is 0 V. What are the direction and the magnitude of the magnetic field, $\vec{B}$, that is required between the plates for the proton to continue traveling in a straight line in the *x*-direction?

•**27.70** An electron moving at a constant velocity, $\vec{v} = v_0\hat{x}$, enters a region in space where a magnetic field is present. The magnetic field, $\vec{B}$, is constant and points in the *z*-direction. What are the magnitude and the direction of the magnetic force

acting on the electron? If the width of the region where the magnetic field is present is *d,* what is the minimum velocity the electron must have in order to escape this region?

•27.71 A 30-turn square coil with a mass of 0.250 kg and a side length of 0.200 m is hinged along a horizontal side and carries a 5.00-A current. It is placed in a magnetic field pointing vertically downward and having a magnitude of 0.00500 T. Determine the angle that the plane of the coil makes with the vertical when the coil is in equilibrium. Use $g = 9.81\ \mathrm{m/s^2}$.

•27.72 A semicircular loop of wire of radius *R* is in the *xy*-plane, centered about the origin. The wire carries a current, *i,* counterclockwise around the semicircle, from $x = -R$ to $x = +R$ on the *x*-axis. A magnetic field, $\vec{B}$, is pointing out of the plane, in the positive *z*-direction. Calculate the net force on the semicircular loop.

•27.73 A proton moving at speed $v = 1.00 \cdot 10^6\ \mathrm{m/s}$ enters a region in space where a magnetic field given by $\vec{B} = (-0.500\ \mathrm{T})\hat{z}$ exists. The velocity vector of the proton is at an angle $\theta = 60.0^\circ$ with respect to the positive *z*-axis.

a) Analyze the motion of the proton and describe its trajectory (in qualitative terms only).

b) Calculate the radius, *r,* of the trajectory projected onto a plane perpendicular to the magnetic field (in the *xy*-plane).

c) Calculate the period, *T,* and frequency, *f,* of the motion in that plane.

d) Calculate the pitch of the motion (the distance traveled by the proton in the direction of the magnetic field in 1 period).

MULTI-VERSION EXERCISES

27.74 A small aluminum ball with a mass of 5.063 g and a charge of 11.03 C is moving northward at 3079 m/s. You want the ball to travel in a horizontal circle with a radius of 2.137 m and in a clockwise direction when viewed from above. Ignoring gravity, what is the magnitude of the magnetic field that must be applied to the aluminum ball to cause it to move in this way?

27.75 A small aluminum ball with a charge of 11.17 C is moving northward at 3131 m/s. You want the ball to travel in a horizontal circle with a radius of 2.015 m and in a clockwise direction when viewed from above. Ignoring gravity, the magnitude of the magnetic field that must be applied to the aluminum ball to cause it to move in this way is $B = 0.8000$ T. What is the mass of the ball?

27.76 A small charged aluminum ball with a mass of 3.435 g is moving northward at 3183 m/s. You want the ball to travel in a horizontal circle with a radius of 1.893 m and in a clockwise direction when viewed from above. Ignoring gravity, the magnitude of the magnetic field that must be applied to the aluminum ball to cause it to move in this way is $B = 0.5107$ T. What is the charge on the ball?

27.77 A velocity selector is used in a mass spectrometer to produce a beam of charged particles with uniform velocity. Suppose the fields in a selector are given by $\vec{E} = \left(1.749 \cdot 10^4 \text{ V/m}\right)\hat{x}$ and $\vec{B} = (46.23 \text{ mT})\hat{y}$. Find the speed with which a charged particle can travel through the selector in the z-direction without being deflected.

27.78 A velocity selector is used in a mass spectrometer to produce a beam of charged particles with uniform velocity. Suppose the fields in a selector are given by $\vec{E} = \left(2.207 \cdot 10^4 \text{ V/m}\right)\hat{x}$ and $\vec{B} = B_y\hat{y}$. The speed with which a charged particle can travel through the selector in the z-direction without being deflected is $4.713 \cdot 10^5$ m/s. What is the value of B_y?

27.79 A velocity selector is used in a mass spectrometer to produce a beam of charged particles of uniform velocity. Suppose the fields in a selector are given by $\vec{E} = E_x\hat{x}$ and $\vec{B} = (47.45 \text{ mT})\hat{y}$. The speed with which a charged particle can travel through the selector in the z-direction without being deflected is $5.616 \cdot 10^5$ m/s. What is the value of E_x?

We saw in Chapter 27 that a magnetic field can affect the path of a charged particle or the flow of a current. In this chapter, we consider magnetic fields *caused* by electric currents. Any charged particle generates a magnetic field, if it is moving. Various magnetic fields are caused by different distributions of current. The powerful electromagnets used in industry, in physics research, in medical diagnostics, and in other applications are primarily solenoids—coils of current-carrying wire with hundreds or thousands of loops. We'll see in this chapter why solenoids generate particularly useful magnetic fields. We will also see that an individual atom can have a permanent magnetic field. Figure 28.1 shows how the magnetic fields of iron atoms (shown in red and blue) can be used to store information. This technology is still in its infancy (the image was produced in 2012). However, if it can be scaled up, it will allow 10 terabytes of data to be stored on a square centimeter of iron surface, a density that is higher than what is currently achievable by a factor of more than 1000.

FIGURE 28.1 This array of 96 iron atoms holds 1 byte (8 bits) of information in the magnetic fields of the atoms—an impressive feat of data storage.

Sebastian Loth, CFEL Hamburg, Germany

What we will learn

- Moving charges (currents) create magnetic fields.
- The magnetic field created by a current flowing in a long, straight wire varies inversely with the distance from the wire.
- Two parallel wires carrying current in the same direction attract each other. Two parallel wires carrying current in opposite directions repel each other.
- Ampere's Law is used to calculate the magnetic field caused by certain symmetrical current distributions, just as Gauss's Law is useful in calculating electric fields in situations having spatial charge symmetry.
- The magnetic field inside a long, straight wire varies linearly with the distance from the center of the wire.
- A solenoid is an electromagnet that can be used to produce a constant magnetic field with a large volume.
- Some atoms can be thought of as small magnets created by motion of electrons in the atom.
- Materials can exhibit three kinds of intrinsic magnetism: diamagnetism, paramagnetism, and ferromagnetism.
- Superconducting magnets can be used to produce very strong magnetic fields.

28.1 Biot-Savart Law

Chapter 27 introduced magnetic fields and field lines by showing how a compass needle orients itself near a permanent magnet. In a similar demonstration, a strong current is run through a (very long, straight) wire (with or without insulation). If a compass needle is then brought close to the wire, the compass needle orients itself relative to the wire in the way shown in Figure 28.2. This observation was first made by the Danish physicist Hans Oersted (1777–1851) in 1819 while conducting a demonstration for students during a lecture. We conclude that the current in the wire produces a magnetic field. Since the direction of the compass needle indicates the direction of the magnetic field, we further conclude that the magnetic field lines form circles around this current-carrying wire. Note the difference between parts (a) and (b) of Figure 28.2: When the direction of the current is reversed, the orientation of the compass needle is also reversed. Although the figure doesn't show this, if the compass needle is moved farther and farther away from the wire, eventually it again orients itself in the direction of the magnetic field of the Earth. This indicates that the magnetic field produced by the wire gets weaker as a function of increasing distance from the wire. The next question we need to answer is this: How can we determine the magnetic field produced by a moving charge?

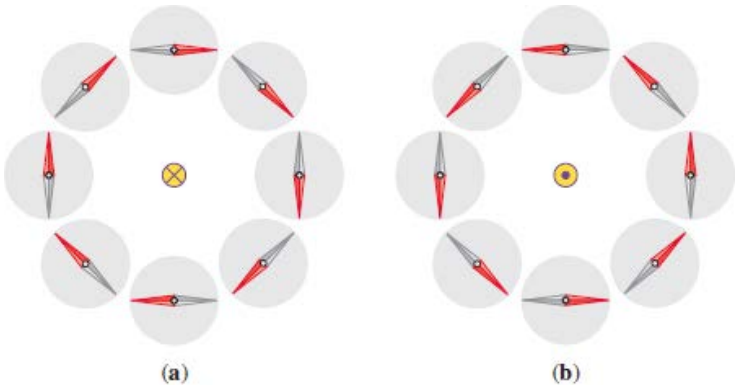

FIGURE 28.2 Wire (yellow circle) with current running through it: (a) into the page (indicated by the cross); (b) out of the page (indicated by the dot). The orientation of a compass needle placed close to the wire is shown at different locations around the wire.

To describe the electric field in terms of the electric charge, we showed that (see Chapter 22):

$$dE = \frac{1}{4\pi\epsilon_0}\frac{|dq|}{r^2},$$

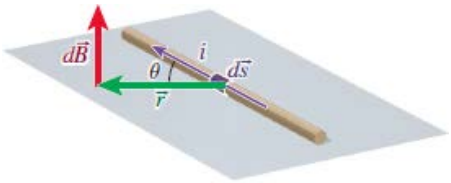
where *dq* is a charge element. The electric field points in a radial direction (inward toward or outward from the electric charge, depending on the sign of the charge), so

$$d\vec{E} = \frac{1}{4\pi\epsilon_0}\frac{dq}{r^3}\vec{r} = \frac{1}{4\pi\epsilon_0}\frac{dq}{r^2}\hat{r}.$$

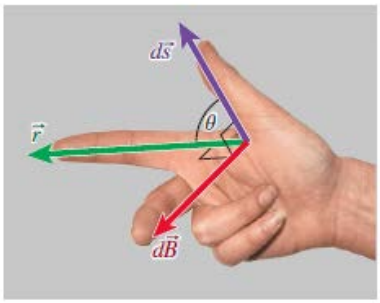
The situation is slightly more complicated for a magnetic field because a current element, $i\,d\vec{s}$, that produces a magnetic field has a direction, as opposed to a nondirectional point charge that produces an electric field. As a result of a long series of experiments involving tests similar to that depicted in Figure 28.2 and conducted in the early 19th century, the French scientists Jean-Baptiste Biot (1774–1862) and Felix Savart (1791–1841) established that the magnetic field produced by a current element, $i\,d\vec{s}$, is given by

$$d\vec{B} = \frac{\mu_0}{4\pi}\frac{i d\vec{s} \times \vec{r}}{r^3} = \frac{\mu_0}{4\pi}\frac{i d\vec{s} \times \hat{r}}{r^2}. \qquad \textbf{(28.1)}$$

Here $d\vec{s}$ is a vector of differential length *ds* pointing in the direction in which the current flows along the conductor and $\vec{r}$ is the position vector measured *from* the current element *to* the point at which the field is to be determined. Figure 28.3 depicts the physical situation described by this formula, which is called the **Biot-Savart Law.**



(a)



(b)

FIGURE 28.3 (a) Three-dimensional depiction of the Biot-Savart Law. The differential magnetic field is perpendicular to both the differential current element and the position vector. (b) Right-hand rule 1 applied to the quantities involved in the Biot-Savart Law.

b: Mark Dierker/McGraw Hill

The constant μ_0 in equation 28.1 is called the **magnetic permeability of free space** and has the value

$$\mu_0 = 4\pi \cdot 10^{-7} \frac{\text{T m}}{\text{A}}. \tag{28.2}$$

From equation 28.1 and Figure 28.3, you can see that the direction of the magnetic field produced by the current element $i\ \vec{ds}$ is perpendicular to both the position vector and the current element. The magnitude of the magnetic field is given by

$$dB = \frac{\mu_0}{4\pi} \frac{ids\ \sin\theta}{r^2}, \tag{28.3}$$

where θ (with possible values between 0° and 180°) is the angle between the direction of the position vector and the current element. The direction of the magnetic field is given by a variant of right-hand rule 1, introduced in Chapter 27. To determine the direction of the magnetic field using your right hand, point your thumb in the direction of the differential current element and your index finger in the direction of the position vector, and your middle finger will point in the direction of the differential magnetic field.

28.2 Magnetic Fields due to Current Distributions

Chapter 27 addressed the superposition principle for magnetic fields. Using this superposition principle, we can compute the magnetic field at any point in space as the sum of the differential magnetic fields described by the Biot-Savart Law. This section examines the magnetic fields generated by the most common configurations of current-carrying wires.

Magnetic Field from a Long, Straight Wire

Let's first examine the magnetic field from an infinitely long, straight wire carrying a current, i. We consider the magnetic field, $d\vec{B}$ at a point P that is a perpendicular distance $r_\perp$ from the wire (Figure 28.4). The magnitude of the field, dB, at that point due to the current element $i\,ds$ is given by equation 28.3; the direction of the field is given by $\vec{ds}\times\vec{r}$ and is out of the page. We find the magnetic field from the right half of the wire and multiply by 2 to get the magnetic field from the whole wire. Thus, the magnitude of the magnetic field at a perpendicular distance $r_\perp$ from the wire is given by

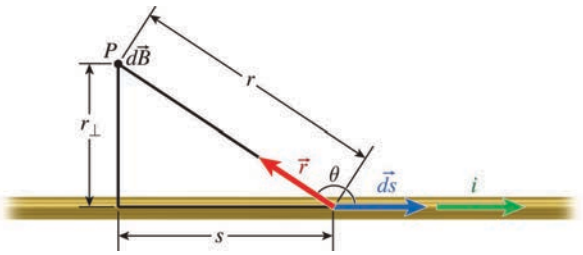


FIGURE 28.4 Magnetic field from a long, straight current carrying wire.

$$B = 2\int_0^\infty dB = 2\int_0^\infty \frac{\mu_0}{4\pi}\frac{i\,ds\sin\theta}{r^2} = \frac{\mu_0 i}{2\pi}\int_0^\infty \frac{ds\,\sin\theta}{r^2}.$$

We can relate r and θ to r_1 and s(r,s, and θ) by $r = \sqrt{s^2 + r_\perp^2}$ and $\sin\theta = \sin(\pi - \theta) = r_\perp/\sqrt{s^2 + r_\perp^2}$ (see Figure 28.4). Substituting for r and $\sin\theta$ in the preceding expression for B gives

$$B = \frac{\mu_0 i}{2\pi}\int_0^\infty \frac{r_\perp ds}{\left(s^2 + r_\perp^2\right)^{3/2}}.$$

Evaluating this definite integral, we find

$$B = \frac{\mu_0 i}{2\pi}\left[\frac{1}{r_\perp^2}\frac{r_\perp s}{\left(s^2 + r_\perp^2\right)^{1/2}}\right]_0^\infty = \frac{\mu_0 i}{2\pi r_\perp}\left[\frac{s}{\left(s^2 + r_\perp^2\right)^{1/2}}\right]_{s\to\infty} - 0.$$

For $s \gg r_\perp$, the term in the brackets approaches the value 1. Therefore, the magnitude of the magnetic field at a perpendicular distance $r_\perp$ from a long, straight wire carrying a current, i, is

$$B = \frac{\mu_0 i}{2\pi r_\perp}. \tag{28.4}$$

The direction of the magnetic field at any point is found by applying right-hand rule 1 to the current element and position vectors shown in Figure 28.4. This results in a new right-hand rule, called *right-hand rule 3,* which can be used to determine the direction of the magnetic field due to a current-carrying wire. If you grab the wire with your right hand so that your thumb points in the direction of the current, your fingers will curl in the direction of the magnetic field (Figure 28.5).

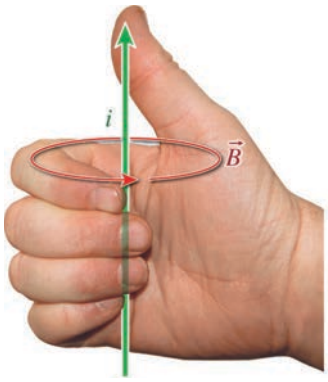

FIGURE 28.5 Right-hand rule 3 for the magnetic field from a current-carrying wire.

Mark Dierker/McGraw Hill

Looking along a current-carrying wire would reveal that the magnetic field lines form concentric circles (Figure 28.6). Notice from the distance between the field lines that the field is strongest near the wire and drops off in proportion to $1/r_\perp$, as indicated by equation 28.4.

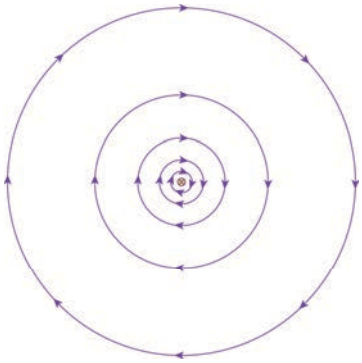

FIGURE 28.6 Magnetic field lines around a long, straight wire (yellow circle at the center) that is perpendicular to the page and carries a current flowing into the page, signified by the cross.

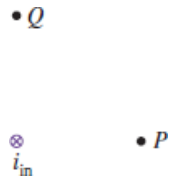
Concept Check 28.1

A wire is carrying a current, i_{in}, into the page as shown in the figure. In which direction does the magnetic field point at points *P* and *Q*?



a) to the right at *P* and upward (toward the top of the page) at *Q*

b) upward at *P* and to the right at *Q*

c) downward at *P* and to the right at *Q*

d) upward at *P* and to the left at *Q*

Concept Check 28.2

Wire 1 has a current flowing out of the page, i_{out}, as shown in the figure. Wire 2 has a current flowing into the page, i_{in}. What is the direction of the magnetic field at point P?

a) upward in the plane of the page

b) to the right

c) downward in the plane of the page

d) to the left

e) The magnetic field at point P is zero.

Two Parallel Wires

Let's examine the case in which two parallel wires are carrying current. The two wires exert magnetic forces on each other because the magnetic field of one wire exerts a force on the moving charges in the second wire. The magnitude of the magnetic field created by a current-carrying wire is given by equation 28.4. This magnetic field is always perpendicular to the wire with a direction given by right-hand rule 3 (Figure 28.5).

Let's first consider wire 1 carrying a current, i_1, toward the right, as shown in Figure 28.7a. The magnitude of the magnetic field a perpendicular distance d from wire 1 is

$$B_1 = \frac{\mu_0 i_1}{2\pi d}. \tag{28.5}$$

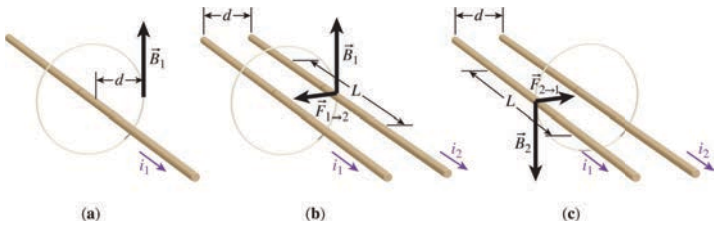


FIGURE 28.7 (a) Magnetic field line from one current-carrying wire. (b) Magnetic field created by the current in one wire exerting a force on a second current-carrying wire. (c) Magnetic field created by the current in the second wire exerting a force on the first current-carrying wire.

The direction of $\vec{B}_1$ is given by right-hand rule 3 and is shown for a particular point in Figure 28.7a.

Now consider wire 2 carrying a current, i_2, in the same direction as i_1 and placed parallel to wire 1 at a distance d from it (Figure 28.7b). The magnetic field due to wire 1 exerts a magnetic force on the moving charges in the current flowing in wire 2. In Chapter 27, we saw that the magnetic force on a current-carrying wire is given by

$$\vec{F} = i\vec{L} \times \vec{B}.$$

The magnitude of the magnetic force on a length, L, of wire 2 is then

$$F = iLB\,\sin\theta = i_2 L B_1, \tag{28.6}$$

because $\vec{B}_1$ is perpendicular to wire 2 and thus 90°. Substituting for B_1 from equation 28.5 into equation 28.6, we find the magnitude of the force exerted by wire 1 on a length L of wire 2:

$$F_{1\to 2} = i_2 L\left(\frac{\mu_0 i_1}{2\pi d}\right) = \frac{\mu_0 i_1 i_2 L}{2\pi d}. \tag{28.7}$$

According to right-hand rule 1, $\vec{F}_{1\to 2}$ points toward wire 1 and is perpendicular to both wires. An analogous calculation allows us to deduce that the force from wire 2 on a length, L, of wire 1 has the same magnitude and opposite direction: $\vec{F}_{2\to 1} = -\vec{F}_{1\to 2}$. This result is shown in Figure 28.7c and is a simple consequence of Newton's Third Law.

Concept Check 28.3

In Figure 28.2, compass needles show the magnetic field around a current-carrying wire. In the figure, the north-pointing end of the compass needle corresponds to

a) the red end.

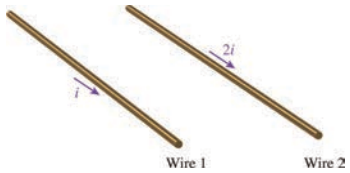
b) the gray end.

c) either the red end or the gray end, depending on how the compass is moved toward the wire.

d) The end cannot be identified from the information contained in the figure.

Concept Check 28.4

Two parallel wires are near each other, as shown in the figure. Wire 1 carries a current *i,* and wire 2 carries a current 2*i.* Which statement about the magnetic forces that the two wires exert on each other is correct?



a) The two wires exert no forces on each other.

b) The two wires exert attractive forces of the same magnitude on each other.

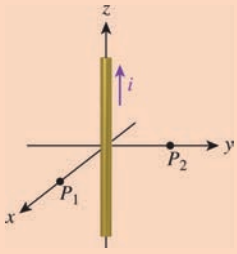
c) The two wires exert repulsive forces of the same magnitude on each other.

d) Wire 1 exerts a stronger force on wire 2 than wire 2 exerts on wire 1.

e) Wire 2 exerts a stronger force on wire 1 than wire 1 exerts on wire 2.

Self-Test Opportunity 28.1

The wire in the figure is carrying a current *i* in the positive *z*-direction. What is the direction of the resulting magnetic field at point P_1? What is the direction of the resulting magnetic field at point P_2?



Self-Test Opportunity 28.2

Consider two parallel wires carrying the same current in the same direction. Is the force between the two wires attractive or repulsive? Now consider two parallel wires carrying current in opposite directions. What is the force between the two wires?

SOLVED PROBLEM 28.1 Magnetic Field from Four Wires

Four wires are each carrying a current of magnitude $i = 1.00$ A. The wires are located at the four corners of a square with side $a = 3.70$ cm. Two of the wires are carrying current into the page, and the other two are carrying current out of the page (Figure 28.8).

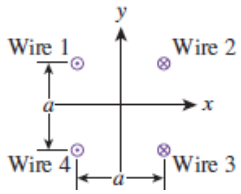


FIGURE 28.8 Four wires located at the corners of a square. Two of the wires are carrying current into the page, and the other two are carrying current out of the page.

PROBLEM

What is the y-component of the magnetic field at the center of the square?

SOLUTION

THINK

The magnetic field at the center of the square is the vector sum of the magnetic fields from the four current-carrying wires. The magnitude of the magnetic field due to each of the four wires is the same. The direction of the magnetic field from each wire is determined using right-hand rule 3.

SKETCH

Figure 28.9 shows the magnetic fields from the four wires: $\vec{B}_1$ is the magnetic field from wire 1, $\vec{B}_2$ is the magnetic field from wire 2, $\vec{B}_3$ is the magnetic field from wire 3, and $\vec{B}_4$ is the magnetic field from wire 4. Note that $\vec{B}_2$ and $\vec{B}_4$ are equal and $\vec{B}_1$ and $\vec{B}_3$ are equal.

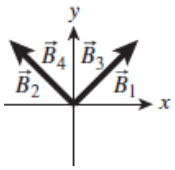

FIGURE 28.9 The magnetic fields from the four current-carrying wires.

RESEARCH

The magnitude of the magnetic field from each of the four wires is given by

$$B = \frac{\mu_0 i}{2\pi r} = \frac{\mu_0 i}{2\pi r\left(a/\sqrt{2}\right)},$$

where $a/\sqrt{2}$ is the distance from each wire to the center of the square.

Right-hand rule 3 gives us the directions of the magnetic fields, which are shown in Figure 28.9. The y-component of each of the magnetic fields is given by

$$B_y = B\ \sin 45^\circ.$$

SIMPLIFY

The sum of the y-components of the four magnetic fields is

$$B_{y,\text{sum}} = 4B_y = 4B\sin 45^\circ = 4\frac{\mu_0 i}{2\pi\left(a/\sqrt{2}\right)}\left(\frac{1}{\sqrt{2}}\right) = \frac{2\mu_0 i}{\pi a},$$

where we have used $\sin 45^\circ = 1/\sqrt{2}$.

CALCULATE

Putting in the numerical values gives us

$$B_{y,\text{sum}} = \frac{2\mu_0 i}{\pi a} = \frac{2\left(4\pi \cdot 10^{-7}\text{Tm/A}\right)(1.00\ \text{A})}{\pi\left(3.70 \cdot 10^{-2}\text{m}\right)} = 2.16216 \cdot 10^{-5}\ \text{T}.$$

ROUND

We report our result to three significant figures:

$$B_{y,\text{sum}} = 2.16 \cdot 10^{-5}\ \text{T}.$$

DOUBLE-CHECK

To double-check our result, we calculate the magnitude of the magnetic field at the center of the square due to one of the wires:

$$B = \frac{\mu_0 i}{2\pi\left(a/\sqrt{2}\right)} = \frac{\left(4\pi \cdot 10^{-7}\ \text{Tm/A}\right)(1.00\ \text{A})\sqrt{2}}{2\pi\left(3.70 \cdot 10^{-2}\ \text{m}\right)} = 7.64 \cdot 10^{-6}\ \text{T}.$$

The sum of the y-components is then

$$B_{y,\text{sum}} = \frac{4\left(7.64 \cdot 10^{-6}\text{T}\right)}{\sqrt{2}} = 2.16 \cdot 10^{-5}\ \text{T},$$

which agrees with our result.

Definition of the Ampere

The force $F_{1\to 2}$ described by equation 28.7 is used in the SI definition of the ampere: An *ampere* (A) is the constant current that, if maintained in two straight, parallel conductors of infinite length and negligible circular cross section, placed 1 m apart in vacuum, would produce between these conductors a force of 2.10^{-7}N per meter of length. This physical situation is described by equation 28.7 for the force between two parallel current-carrying wires with $i_1 = i_2 =$ exactly $A, d =$ exactly 1 m, and $F_{1\to 2} =$ exactly 2.10^{-7}N We can solve equation 28.7 for μ_0:

$$\mu_0 = \frac{(2\pi d)F_{1\to 2}}{i_1 i_2 L} = \frac{2\pi(1\text{ m})\left(2.10^{-7}\text{ N}\right)}{(1\text{ A})(1\text{ A})(1\text{ m})} = \text{exactly } 4\pi\cdot 10^{-7}\frac{\text{Tm}}{\text{A}},$$

which indicates that the magnetic permeability of free space is *defined* to be exactly $\mu_0 = 4\pi\cdot 10^{-7}\text{Tm/A}$ (see equation 28.2).

In Chapter 21, when Coulomb's Law was introduced, the value of the electric permittivity of free space, ϵ_0, was given: $\epsilon_0 = 8.85\cdot 10^{-12}\text{ C}^2/\left(\text{N m}^2\right)$. Since $1\text{ A} = 1\text{ C/s}$ and $1\text{ T} = 1\text{ (N s)/(C m)}$ (see Chapter 27), the product of the two constants, ϵ_0, and μ_0: is

$$\mu_0\epsilon_0 = \left(4\pi\cdot 10^{-7}\frac{\text{T m}}{\text{A}}\right)\left(8.85\cdot 10^{-12}\frac{\text{C}^2}{\text{N m}^2}\right) = 1.11\cdot 10^{-17}\frac{\text{s}^2}{\text{m}^2},$$

which has the units of the inverse of the square of a speed. Thus, $1/\sqrt{\mu_0\epsilon_0}$ gives the value of this speed as that of the speed of light, $c = 3.00\cdot 10^8\text{ m/s}$. This is by no means a coincidence, as we'll see in later chapters. For now, it is sufficient to state the empirical finding:

$$c = \frac{1}{\sqrt{\mu_0\epsilon_0}}.$$

Since the magnetic permeability of free space is defined to be exactly $\mu_0 = 4\pi\cdot 10^{-7}\text{Tm/A}$ and the speed of light is defined as exactly $c = 299,792,458\text{ m/s}$ (see the discussion in Chapter 1), the expression $c = 1/\sqrt{\mu_0\epsilon_0}$ also fixes the value of the electric permittivity of free space.

EXAMPLE 28.1 Force on a Loop

A long, straight wire is carrying a current of magnitude $i_1 = 5.00$ A toward the right (Figure 28.10). A square loop with sides of length $a = 0.250$ m is placed with its sides parallel and perpendicular to the wire at a distance $d = 0.100$ m from the wire. The square loop carries a current of magnitude $i_2 = 2.20$ A in the counterclockwise direction.

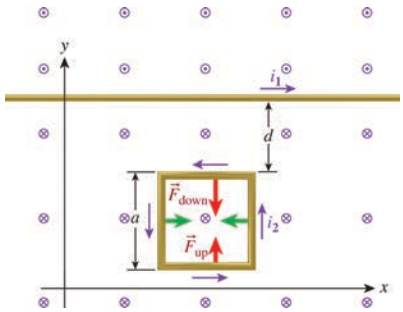

FIGURE 28.10 A current-carrying wire and a square loop.

PROBLEM

What is the net magnetic force on the square loop?

SOLUTION

The force on the square loop is due to the magnetic field created by the current flowing in the straight wire. Right-hand rule 3 tells us that the magnetic field from the current flowing in the wire is directed into the page in the region where the loop is located (see Figure 28.10). The right-hand rule and equation 28.4 tell us that the resulting force on the left side of the loop is toward the right, and the force on the right side of the loop is toward the left. In Figure 28.10, these two forces are represented by green arrows. The two forces are equal in magnitude and opposite in direction, so they sum to zero. The force on the top side of the loop is downward (red arrow in Figure 28.10, pointing in the negative y-direction), and its magnitude is given by equation 28.7:

$$F_{\text{down}} = \frac{\mu_0 i_1 i_2 a}{2\pi d},$$

where a is the length of the top side of the loop. The force on the bottom side of the loop is upward (the other red arrow in Figure 28.10, pointing in the positive y-direction), and its magnitude is given by

$$F_{\text{up}} = \frac{\mu_0 i_1 i_2 a}{2\pi (d + a)}.$$

Thus, we can express the net magnetic force on the loop as

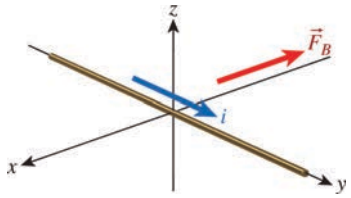
$$\vec{F} = (F_{\text{up}} - F_{\text{down}})\hat{y}.$$

Putting in the numbers results in

$$\vec{F} = \frac{(4\pi \cdot 10^{-7}\text{Tm/A})(5.00\text{ A})(2.20\text{ A})(0.250\text{ m})}{2\pi}\left(\frac{1}{0.350\text{ m}} - \frac{1}{0.100}\right.$$

Concept Check 28.5

A wire is carrying a current, *i*, in the positive *y*-direction, as shown in the figure. The wire is located in a uniform magnetic field, $\vec{B}$, oriented in such a way that the magnetic force on the wire is maximized. The magnetic force acting on the wire, $\vec{F}_B$, is in the negative *x*-direction. What is the direction of the magnetic field?



a) the positive *x*-direction
b) the negative *x*-direction
c) the negative *y*-direction
d) the positive *z*-direction
e) the negative *z*-direction

SOLVED PROBLEM 28.2 Electromagnetic Rail Accelerator

Electromagnetic rail accelerators are being developed for accelerating fuel pellets in fusion experiments and for launching spacecraft into orbit. The U.S. Navy is experimenting with electromagnetic rail accelerators that can launch projectiles at very high speeds, such as the rail gun shown in Figure 28.11. In this rail gun, currents are run through two parallel conducting rails that are connected by a movable conductor oriented perpendicular to the rails. The projectile is attached to the movable conductor. For this example, we'll assume that the rail gun consists of two parallel rails of cross-sectional radius $r = 5.00$ cm, whose centers are separated by a distance $d = 25.0$ cm and which have a length $L = 5.00$ m, and that the rail gun accelerates the projectile to a kinetic energy of $K = 32.0$ MJ. The projectile also functions as the movable conductor.

FIGURE 28.11 U.S. Navy rail gun.

PJF Military Collection/Alamy Stock Photo

PROBLEM

How much current is required to accelerate the projectile?

SOLUTION

THINK

The currents in the two rails are in opposite directions. The current flowing through the movable conductor is perpendicular to the two currents in the rails. The magnetic fields from the two rails are in the same direction and exert forces on the movable conductor in the same direction. The force from the magnetic field of each rail depends on the distance from the rail. Thus, we must integrate the force along the distance between the two rails to obtain the total force. The total force on the movable conductor is twice the force from the magnetic field from one rail. The kinetic energy gained by the projectile is the total force exerted by the magnetic fields of the two rails times the distance over which the force acts.

SKETCH

Figure 28.12 shows top and cross-sectional views of the rails and the movable conductor.

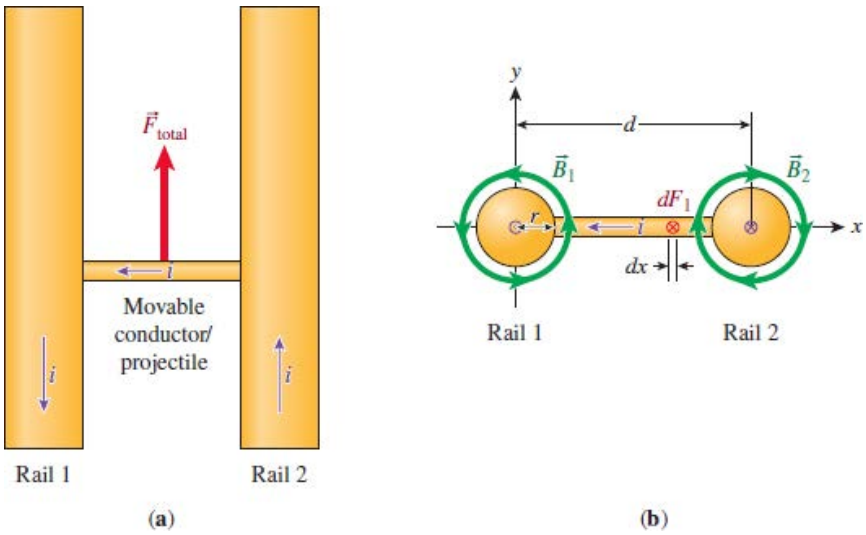


FIGURE 28.12 Schematic diagram of a rail gun: (a) top view; (b) cross-sectional view.

RESEARCH

The current-carrying movable conductor, which completes the circuit between the two rails, is also the projectile and is accelerated by the magnetic forces produced by the two rails. The force exerted on the projectile depends on the distance, *x,* from the center of a rail, as illustrated in Figure 28.12b. Thus, to calculate the total force on the projectile, we must integrate over the length of the projectile. We use equation 28.4 to find the magnitude of the magnetic field, B_1, from current i flowing in rail 1 at a distance x from the center of the rail:

$$B_1 = \frac{\mu_0 i}{2\pi x}.$$

According to equation 28.6, the magnitude of the differential force, dF_1, exerted on a differential length, *dx,* of the projectile by the magnetic field from rail 1 is

$$dF_1 = i(dx)B_1 = i(dx)\left(\frac{\mu_0 i}{2\pi x}\right).$$

The direction of the force is given by right-hand rule 3, which tells us that the force is upward in the plane of the page in Figure 28.12a and into the page in Figure 28.12b. The magnitude of the force on the projectile is given by integrating dF_1 over the length of the projectile:

$$F_1 = \int_r^{d-r} dF_1 = \int_r^{d-r} \frac{\mu_0 i^2}{2\pi}\frac{dx}{x} = \frac{\mu_0 i^2}{2\pi}[\ln\ x]_r^{d-x} = \frac{\mu_0 i^2}{2\pi}(\ln(d-$$

Because the magnetic field from rail 2 is in the same direction as the magnetic field from rail 1, the force exerted by the magnetic field from rail 2 on the projectile is the same as that from rail 1. Thus, the magnitude of the total force exerted on the projectile is

$$F_{\text{total}} = 2F_1. \qquad \text{(ii)}$$

Page 861

The kinetic energy gained by the projectile is equal (by the work-energy theorem introduced in Chapter 6) to the magnitude of the force exerted times the distance over which the force acts

$$K = F_{\text{total}}L. \qquad \text{(iii)}$$

SIMPLIFY

We can combine equations (i), (ii), and (iii) to obtain

$$K = 2F_1L = 2\left[\frac{\mu_0 i^2}{2\pi}\ln\left(\frac{d-r}{r}\right)\right]L = \frac{\mu_0 L i^2}{\pi}\ln\left(\frac{d-r}{r}\right).$$

Solving this equation for the current gives us

$$i = \sqrt{\frac{K\pi}{\mu_0 L\ln\left(\frac{d-r}{r}\right)}}.$$

CALCULATE

Putting in the numerical values, we get

$$i = \sqrt{\frac{K\pi}{\mu_0 L\ln\left(\frac{d-r}{r}\right)}} = \sqrt{\frac{(32.0\cdot 10^6\,\text{J})\pi}{\left[4\pi\cdot 10^{-7}\frac{\text{T m}}{\text{A}}\right](5.00\text{ m})\ln\left(\frac{25.0\text{ cm}-}{5.00\text{ c}}\right.}}$$

ROUND

We report our result to three significant figures:

$$i = 3.40 \cdot 10^6 \text{A} = 3.40 \text{ MA}.$$

DOUBLE-CHECK

Let's double-check our result by looking at the force exerted on the projectile. Putting our result for the current into equation (i) for the magnitude of the force exerted by the magnetic field of rail 1 gives

$$F_1 = \frac{\mu_0 i^2}{2\pi} \ln\left(\frac{d-r}{r}\right) = \frac{\left(4\pi \cdot 10^{-7} \dfrac{\text{Tm}}{\text{A}}\right)\left(3.40 \cdot 10^6 \text{A}\right)^2}{2\pi} \ln\left(\frac{25.0 \text{ cm}}{5.0}\right.$$

We can approximate the magnitude of this force by assuming that the force is constant along the conductor and is equal to the value at $x = d/2$:

$$F_1 = i(d-2r)B = i\left(\frac{\mu_0 i(d-2r)}{2\pi\left(\dfrac{d}{2}\right)}\right) = \frac{\mu_0 i^2}{\pi}\frac{d-2r}{d} = \frac{\left(4\pi \cdot 10^{-7} \dfrac{\text{T m}}{\text{A}}\right.}{}$$

This value is within a factor of 2 of our calculated value for the force, which seems reasonable. However, just to be sure, let's calculate the kinetic energy of the projectile using the calculated value of the force:

$$K = F_{\text{total}} L = 2F_1 L = 2\left(3.20 \cdot 10^6 \text{ N}\right)\left(5.00 \text{ m}\right) = 32.0 \cdot 10^6 \text{J}.$$

This result agrees with the 32.0 mJ assumed in the problem situation.

Note that if a projectile of mass $m = 5.00$ kg were given a kinetic energy of 32.0 mJ by this rail gun, its speed would be

$$v = \sqrt{\frac{2K}{m}} = \sqrt{\frac{2\left(32.0 \cdot 10^6 \text{J}\right)}{5.00 \text{ kg}}} = 3.58 \text{ km/s}.$$

The rail gun would be capable of launching a projectile at 10 times the speed of sound, which is much larger than the typical speed of a bullet, about 3 times the speed of sound.

Magnetic Field due to a Wire Loop

Now let's find the magnetic field at the center of a circular current-carrying loop of wire. Figure 28.13a shows a cross section of a circular loop with radius R carrying a current, i. Applying equation 28.3, $dB = \mu_0 i\ ds\ \sin\theta/\left(4\pi r^2\right)$, to this case, we can see that $r = R$ and $\theta = 90^\circ$ for every current element $i\,ds$ along the loop. For the magnitude of the magnetic field at the center of the loop from each current element, we get

$$dB = \frac{\mu_0}{4\pi}\frac{i\ ds\ \sin\ 90^\circ}{R^2} = \frac{\mu_0}{4\pi}\frac{i\ ds}{R^2}.$$

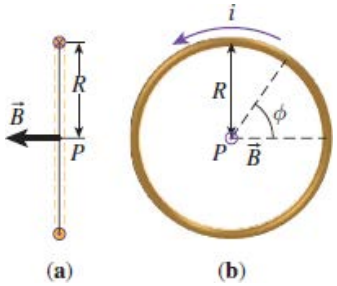

FIGURE 28.13 A circular loop of radius *R* carrying a current, *i:* (a) side view; (b) front view. The cross on the upper yellow circle in part (a) signifies that the current at the top of the loop is into the page, and the dot on the lower yellow circle in part (a) signifies that the current at the bottom of the loop is out of the page. Point *P* is located at the center of the loop

Going around the loop in Figure 28.13b, we can relate the angle ϕ to the current element by $ds = R\ d\phi$ allowing us to calculate the magnitude of the magnetic field at the center of the loop:

$$B = \int dB = \int_0^{2\pi} \frac{\mu_0}{4\pi}\frac{iR\ d\phi}{R^2} = \frac{\mu_0 i}{2R}. \qquad \textbf{(28.8)}$$

Keep in mind that equation 28.8 only gives the magnitude of the magnetic field at the center of the loop, where the magnitude is $B(r=0)=\frac{1}{2}\mu_0 i/R$. To determine the direction of the magnetic field, we again use a variant of right-hand rule 1. Using your right hand, point your thumb in the direction of the current element (into the page for the upper circle in Figure 28.13a marked with a cross), and your index finger in the direction of the radial vector from the current element (down); your middle finger then points to the left. Using right-hand rule 3 (Figure 28.5), we also find that the current shown in Figure 28.13 produces a magnetic field $\vec{B}$ directed toward the left.

Now let's find the magnetic field from the loop along the axis of the loop rather than at the center (Figure 28.14). We set up a coordinate system such that the axis of the loop lies along the x-axis and the center of the loop is located at $x=0$, $y=0$, and $z=0$. The radial vector $\vec{r}$ is the displacement to any point along the x-axis from a current element, $i\vec{ds}$, along the loop. The current element shown in Figure 28.14 lies in the negative z-direction. The radial vector $\vec{r}$ lies in the xy-plane and so is perpendicular to the current element. This situation is the same for any current element around the loop. Therefore, we can employ equation 28.3 with $\theta=90^\circ$ and obtain an expression for the magnitude of the differential magnetic field at any point along the x-axis:

$$dB=\frac{\mu_0}{4\pi}\frac{ids\sin 90^\circ}{r^2}=\frac{\mu_0}{4\pi}\frac{ids}{r^2}.$$

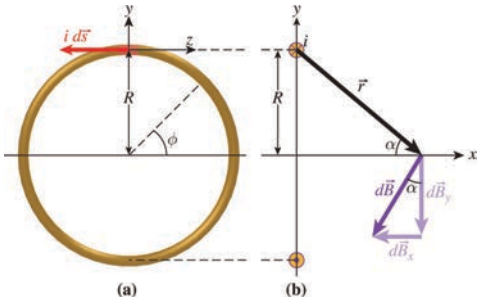

FIGURE 28.14 Geometry for calculating the magnetic field along the axis of a current-carrying loop: (a) front view, (b) side view.

A variant of right-hand rule 1 gives the direction of the differential magnetic field: Using your right hand, point your thumb in the direction of the differential current element (negative z-direction) and your index finger in the direction of the radial vector (positive x-direction and negative y-direction); the direction of the differential magnetic field will be given by your middle finger (negative x-direction and negative y-direction). The differential magnetic field is shown in Figure 28.14. To obtain the complete magnetic field, we need to integrate over the differential

current element. From the symmetry of the situation, we can see that the y-component of the differential magnetic field, dB_y, will integrate to zero. The x-component of the differential magnetic field, dB_x, is given by

$$dB_x = dB \sin\alpha = \frac{\mu_0}{4\pi}\frac{ids}{r^2}\sin\alpha,$$

where α is the angle between $\vec{r}$ and the x-axis (see Figure 28.14b). We can express the magnitude of $\vec{r}$ in terms of x and R as $r = \sqrt{x^2 + R^2}$ and express sin α in terms of x and the radius of the loop R as $\sin\alpha = R/\sqrt{x^2 + R^2}$. We can then rewrite the expression for the x-component of the differential magnetic field as

$$dB_x = \frac{\mu_0}{4\pi}\frac{ids}{x^2 + R^2}\frac{R}{\sqrt{x^2 + R^2}} = \frac{\mu_0 ids}{4\pi}\frac{R}{\left(x^2 + R^2\right)^{3/2}}.$$

This expression for B_x is independent of the location of the current element, and so the integral to find the magnitude of the total field can be simplified to

$$B_x = \int dB_x = \frac{\mu_0 iR}{4\pi\left(x^2 + R^2\right)^{3/2}}\int ds.$$

Going around the loop, we can relate the angle ϕ to the current element by $ds = R\,d\phi$ (see Figure 28.14a), allowing us to calculate the magnetic field along the axis of the loop:

$$B_x = \frac{\mu_0 iR}{4\pi\left(x^2 + R^2\right)^{3/2}}\int_0^{2\pi} Rd\phi = \frac{\mu_0 i 2\pi}{4\pi}\frac{R^2}{\left(x^2 + R^2\right)^{3/2}},$$

or

$$B_x = \frac{\mu_0 i}{2}\frac{R^2}{\left(x^2 + R^2\right)^{3/2}}. \qquad \textbf{(28.9)}$$

From our earlier application of the variant of right-hand rule 1, we know that the magnetic field along the axis of the loop is in the negative x-direction, as shown in Figure 28.14. We can also apply right-hand rule 3 to obtain the direction of the magnetic field: At any point on the loop, point your thumb tangent to the loop in the direction of the current and your fingers will curl in a direction that indicates that the field inside the loop is in the negative x-direction.

Self-Test Opportunity 28.3

Show that equation 28.9 for the magnitude of the magnetic field along the axis of a current-carrying loop reduces to equation 28.8 for the magnitude of the magnetic field at the center of a current-carrying loop.

Using more advanced techniques and with the aid of a computer, we can determine the magnetic field produced by a current-carrying loop at other points in space. The magnetic field lines from a wire loop are shown in Figure 28.15. The value for the magnetic field given by equation 28.8 is valid only at the center point of Figure 28.15. The value for the magnetic field given by equation 28.9 is valid only along the axis of the loop.

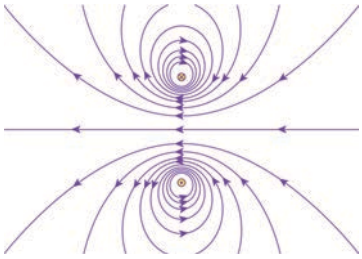

FIGURE 28.15 Magnetic field lines from a loop of wire carrying a current, looking at the loop edge-on. The upper yellow circle with a cross indicates current directed into the page, and the lower yellow circle with a dot indicates current directed out of the page.

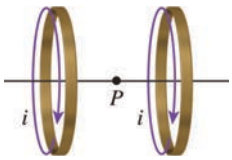
Concept Check **28.6**

Two identical wire loops carry the same current, *i,* as shown in the figure. What is the direction of the magnetic field at point *P*?



a) upward (toward the top of the page)

b) toward the right

c) downward

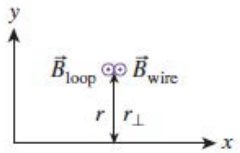
d) toward the left

e) The magnetic field at point *P* is zero.

SOLVED PROBLEM 28.3 Field from a Wire Containing a Loop

A loop with radius $r = 8.30$ mm is formed in the middle of a long, straight insulated wire carrying a current of magnitude $i = 26.5$ mA (Figure 28.16a).

(a)



(b)

FIGURE 28.16 (a) A loop with radius *r* in a long, straight insulated wire carrying a current, *i*. (b) The magnetic field from the wire and the magnetic field from the loop, displaced slightly for clarity.

PROBLEM

What is the magnitude of the magnetic field at the center of the loop?

SOLUTION

THINK

The magnetic field at the center of the loop is equal to the vector sum of the magnetic fields from the long, straight wire and from the loop.

SKETCH

The magnetic field from the long, straight wire, $\vec{B}_{\text{wire}}$, and the magnetic field from the loop, $\vec{B}_{\text{loop}}$, are shown in Figure 28.16b.

RESEARCH

Using right-hand rule 3, we find that both magnetic fields point out of the page at the center of the loop, as illustrated in Figure 28.16b. Thus, we can add the magnitudes of the magnetic field produced by the wire and the magnetic field produced by the loop. The magnetic field produced by the wire at the center of the loop has a magnitude given by equation 28.4:

$$B_{\text{wire}} = \frac{\mu_0 i}{2\pi r_\perp},$$

where $r_\perp$ is the perpendicular distance from the wire, which is equal to r, the radius of the loop. The magnitude of the magnetic field produced by the loop at its center is given by equation 28.8:

$$B_{\text{loop}} = \frac{\mu_0 i}{2r}.$$

SIMPLIFY

We add the magnitudes of the two magnetic fields since the vectors are in the same direction:

$$B = B_{\text{wire}} + B_{\text{loop}} = \frac{\mu_0 i}{2\pi r} + \frac{\mu_0 i}{2r} = \frac{\mu_0 i}{2r}\left(\frac{1}{\pi} + 1\right).$$

CALCULATE

Putting in the numerical values, we get

$$B = \frac{\mu_0 i}{2r}\left(\frac{1}{\pi} + 1\right) = \frac{\left(4\pi \cdot 10^{-7}\text{T m}/A\right)\left(26.5 \cdot 10^{-3}\text{A}\right)}{2\left(8.30 \cdot 10^{-3}\text{ m}\right)}\left(\frac{1}{\pi} + 1\right) = 2$$

ROUND

We report our result to three significant figures and note the direction of the field:

$$\vec{B} = 2.64 \cdot 10^{-6}\text{ T, out of the page.}$$

DOUBLE-CHECK

To double-check our result, we calculate the magnitudes of the magnetic fields from the wire and from the loop separately. The magnitude of the magnetic

field from the wire is

$$B_{\text{wire}} = \frac{\mu_0 i}{2\pi r} = \frac{\left(4\pi \cdot 10^{-7}\text{T m}/A\right)\left(26.5 \cdot 10^{-3}\text{A}\right)}{2\pi\left(8.30 \cdot 10^{-3}\text{ m}\right)} = 6.835 \cdot 10^{-7}\text{ T}.$$

The magnitude of the magnetic field from the loop is

$$B_{\text{loop}} = \frac{\mu_0 i}{2r} = \frac{\left(4\pi \cdot 10^{-7}\text{T m}/A\right)\left(26.5 \cdot 10^{-3}\text{A}\right)}{2\left(8.30 \cdot 10^{-3}\text{ m}\right)} = 2.006 \cdot 10^{-6}\text{ T}.$$

The sum of these two magnitudes matches our result:

$$6.385 \cdot 10^{-7}\text{T} + 2.006 \cdot 10^{-6}\text{ T} = 2.64 \cdot 10^{-6}\text{ T}.$$

28.3 Ampere's Law

Recall from Chapter 22 that calculating the electric field resulting from a distribution of electric charge can require evaluating a difficult integral. However, if the charge distribution has cylindrical, spherical, or planar symmetry, we can apply Gauss's Law and obtain the electric field in an elegant manner. Similarly, calculating the magnetic field due to an arbitrary distribution of current elements using the Biot-Savart Law (equation 28.1) may involve the evaluation of a difficult integral. Alternatively, we can avoid using the Biot-Savart Law and instead apply **Ampere's Law** to calculate the magnetic field from a distribution of current elements when the distribution has cylindrical or other symmetry. Often, problems can be solved with much less effort in this way than by using a direct integration. The mathematical statement of Ampere's Law is

$$\oint \vec{B} \bullet d\vec{s} = \mu_0 i_{\text{enc}}. \qquad \textbf{(28.10)}$$

The symbol $\oint$ means that the integrand, $\vec{B} \bullet d\vec{s}$, is integrated over a closed loop, called an **Amperian loop.** This loop is chosen so that the integral in equation 28.10 is not difficult to evaluate, a procedure similar to that used in applying Gauss's Law. The total current enclosed in this loop is i_{enc}, which is also similar to Gauss's Law, where the chosen closed surface encloses a total net charge.

Page 865

As an example of how Ampere's Law is used, consider the five currents shown in Figure 28.17, which are all perpendicular to the plane. An Amperian loop, represented by the red line, encloses currents i_1, i_2, and i_3 and excludes currents i_4 and i_3. By Ampere's Law, the closed-loop integral over the magnetic field resulting from these three currents is given by

$$\oint \vec{B} \bullet d\vec{s} = \oint B \cos\theta ds = \mu_0(i_1 - i_2 + i_3),$$

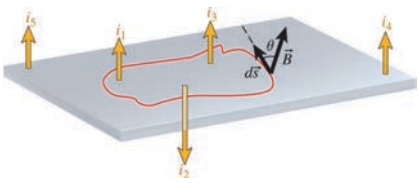


FIGURE 28.17 Five currents and an Amperian loop.

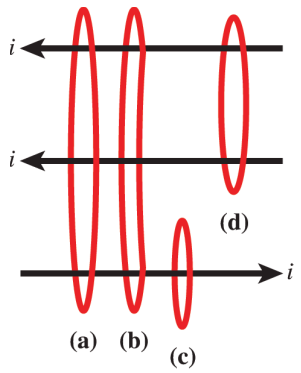
where θ is the angle between the direction of the magnetic field, $\vec{B}$, and the direction of the element of length, $\vec{ds}$, at each point along the Amperian loop. The integration over the Amperian loop can be done in either direction. Figure 28.17 indicates a direction of integration from the direction of $\vec{ds}$, along with the resulting magnetic field. The sign of the contributing currents can be determined using a right-hand rule: Curl your fingers in the direction of integration, and then currents in the same direction as your thumb are positive. Two of the three currents in the Amperian loop are positive, and one is negative. Adding the three currents is simple, but the integral $\oint B\cos\theta\, ds$ cannot be easily evaluated. However, let's examine some special situations in which Amperian loops contain symmetrical distributions of current that can be exploited to carry out the integration.

Concept Check 28.7

Three wires are carrying currents of the same magnitude, *i,* in the directions shown in the figure. Four Amperian loops (a), (b), (c), and (d) are shown. For which Amperian loop is the magnitude of $\oint \vec{B} \bullet \vec{ds}$ the greatest?



a) loop a

b) loop b

c) loop c

d) loop d

e) All four loops yield the same value of $\oint \vec{B} \bullet \vec{ds}$.

Magnetic Field inside a Long, Straight Wire

Figure 28.18 shows a current, i, flowing out of the page in a wire with a circular cross section of radius R. This current is uniformly distributed over the cross-sectional area of the wire. To find the magnetic field due to this current, we use an Amperian loop with radius $r_\perp$, represented by the red circle. If $\vec{B}$ had an outward (or inward) component, by symmetry, it would have an outward (or inward) component at all points around the loop, and the corresponding magnetic field line could never be closed. Therefore, $\vec{B}$ must be tangential to the Amperian loop. Thus, we can rewrite the integral of Ampere's Law as

$$\oint \vec{B} \bullet d\vec{s} = B \oint d\vec{s} = B2\pi r_\perp.$$

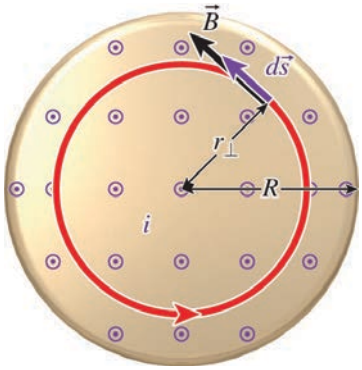


FIGURE 28.18 Using Ampere's Law to find the magnetic field produced inside a long, straight wire.

We can calculate the enclosed current from the ratio of the area of the Amperian loop to the cross-sectional area of the wire:

$$i_{\text{enc}} = i\frac{A_{\text{loop}}}{A_{\text{wire}}} = i\frac{\pi r_\perp^2}{\pi R^2}.$$

Thus, we obtain

$$2\pi B r_\perp = \mu_0 i \frac{\pi r_\perp^2}{\pi R^2},$$

or

$$B = \left(\frac{\mu_0 i}{2\pi R^2}\right) r_\perp. \qquad \textbf{(28.11)}$$

Let's compare the expressions for the magnitudes of the magnetic field outside and inside the wire—equations 28.4 and 28.11. First, substituting R for $r_\perp$ in both expressions, we obtain the same result for the magnetic field magnitude at the surface of the wire in both cases: $B(R) = \mu_0 i/2\pi R$. Both equations provide the same solution at the wire's surface. Inside the wire, we find that the magnetic field magnitude rises linearly with $r_\perp$ up to the value of $B(R) = \mu_0 i/(2\pi R)$ and from there falls off with the inverse of $r_\perp$. Figure 28.19 shows this dependence in the graph at the bottom. The upper part of the figure depicts the cross section through the wire (golden area), the magnetic field lines (black circles, spaced to indicate the strength of the magnetic field), and the magnetic field vectors at selected points in space (red arrows).

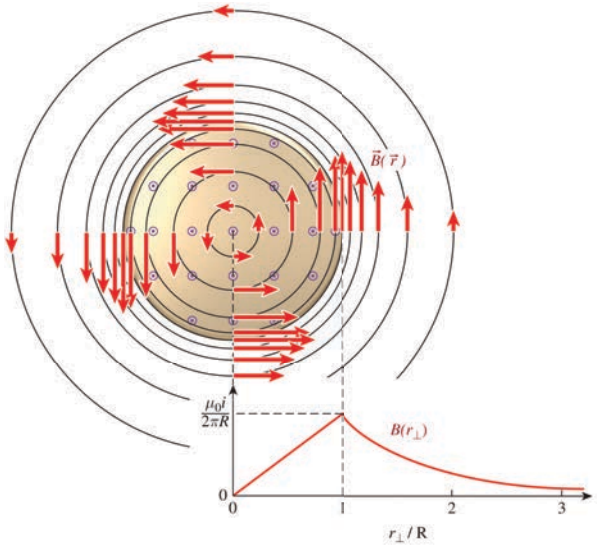

FIGURE 28.19 Radial dependence of the magnetic field for a wire with current flowing out of the page.

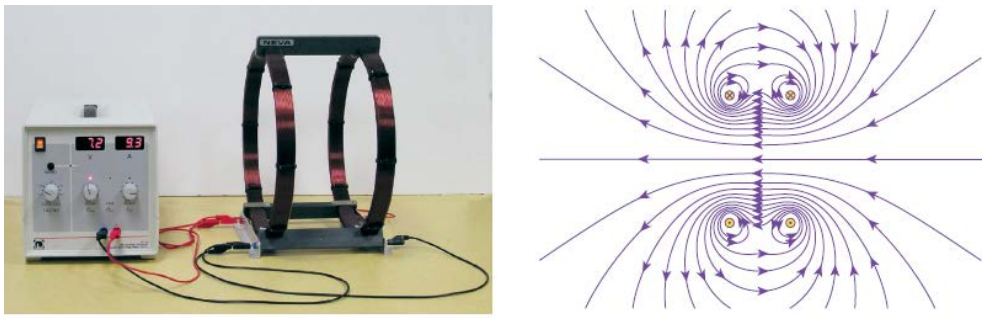
28.4 Magnetic Fields of Solenoids and Toroids

We have seen that current flowing through a single loop of wire produces a magnetic field that is not uniform, as illustrated in Figure 28.15. However, real-world applications often require a uniform magnetic field. A device commonly used to produce a uniform magnetic field is the **Helmholtz coil** (Figure 28.20a). A Helmholtz coil consists of two coaxial wire loops. Each coaxial loop consists of multiple loops (windings or turns) of a single wire, and therefore acts magnetically like a single loop.



(a) (b)

FIGURE 28.20 (a) A typical Helmholtz coil used in physics labs generates a nearly uniform magnetic field in its interior. (b) Magnetic field lines for a Helmholtz coil.

a: W. Bauer and G. D. Westfall

The magnetic field lines from a Helmholtz coil are shown in Figure 28.20b. You can see that there is a region of uniform magnetic field (characterized by horizontal parallel segments of the field lines) in the center between the loops, in contrast to the field from a single loop shown in Figure 28.15. Again, these field lines were calculated with the aid of a computer to provide a qualitative understanding of the geometry of magnetic fields.

Taking multiple loops a step further, Figure 28.21 shows the magnetic field lines from four coaxial wire loops. The region of uniform magnetic field in the center of the loops is expanded, but note that the field is not uniform near the wires and near the two ends.

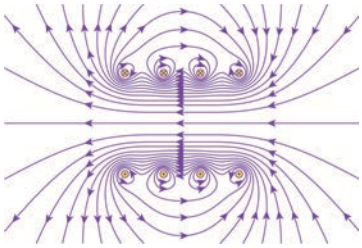


FIGURE 28.21 Magnetic field lines resulting from four coaxial wire loops with many windings.

A strong uniform magnetic field is produced by a **solenoid,** consisting of many loops of a wire wound close together. Figure 28.22 shows the magnetic field lines from a solenoid with 600 turns, or loops. You can see that the magnetic field lines are very close together on the inside of the solenoid and far apart on the outside. Like that inside the Helmholtz coil (Figure 28.20b), the magnetic field is uniform inside the solenoid coil. The spacing of the field lines is a measure of the strength of the magnetic field, and you can see that the magnetic field is much stronger inside the solenoid than outside the solenoid.

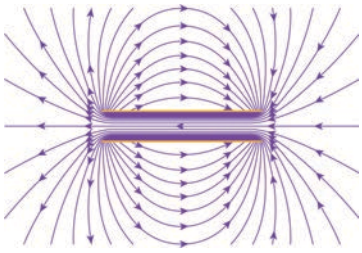

FIGURE 28.22 Magnetic field lines for a solenoid with 600 turns. The current along the top of the solenoid is flowing into the page, and the current along the bottom of the solenoid is flowing out of the page.

An *ideal* solenoid has a magnetic field of zero outside and of a uniform constant finite value inside. To determine the magnitude of the magnetic field inside an ideal solenoid, we can apply Ampere's Law (equation 28.10) to a section of a solenoid far from its ends (Figure 28.23). To do so, we first choose an Amperian loop over which to carry out the integration. A judicious choice, shown by the red rectangle in Figure 28.23, encloses some current and exploits the symmetry of the solenoid as well as simplifying the evaluation of the integral:

$$\oint \vec{B} \bullet \vec{ds} = \int_a^b \vec{B} \bullet \vec{ds} + \int_b^c \vec{B} \bullet \vec{ds} + \int_c^d \vec{B} \bullet \vec{ds} + \int_d^a \vec{B} \bullet \vec{ds}.$$

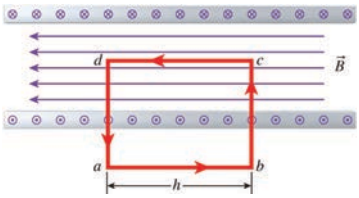

FIGURE 28.23
Amperian loop for determining the magnitude of the magnetic field of an ideal solenoid.

The value of the third integral on the right-hand side, between points *c* and *d* in the interior of the solenoid, is *Bh*. The values of the second and fourth integrals are zero because the magnetic field is perpendicular to the direction of integration. The first integral, between the points *a* and *b* in the exterior of the ideal solenoid, is zero because the magnetic field outside of an ideal solenoid is zero. Thus, the value of the integral over the entire Amperian loop is *Bh*.

The enclosed current is the current in the turns of the solenoid that are within the Amperian loop. The current is the same in each turn because the solenoid is made from one wire and the same current flows through each turn. Thus, the enclosed current is just the number of turns times the current:

$$i_{\text{enc}} = nhi,$$

where *n* is the number of turns per unit length. Therefore, according to Ampere's Law, we have

$$Bh = \mu_0 nhi.$$

Thus, the magnitude of the magnetic field inside an ideal solenoid is

$$B = \mu_0 ni. \tag{28.12}$$

Equation 28.12 is valid only away from the ends of the solenoid. Note that *B* does not depend on position inside the solenoid: An ideal solenoid creates a constant and uniform magnetic field inside itself and no field outside itself. A real-world solenoid, like the one shown in Figure 28.22, has fringe fields near its ends but can still produce a high-quality uniform magnetic field.

EXAMPLE 28.2 Solenoid

The solenoid of the STAR detector at the Brookhaven National Laboratory, New York, discussed in Chapter 27, has a magnetic field of magnitude 0.50 T when carrying a current of 0.40 kA. The solenoid is 8.0 m long.

PROBLEM

What is the number of turns in this solenoid, assuming that it is an ideal solenoid?

Page 868

SOLUTION

We use equation 28.12 to calculate the magnitude of the magnetic field of an ideal solenoid:

$$B = \mu_0 n i. \tag{i}$$

The number of turns per unit length is given by

$$n = \frac{N}{L}, \tag{ii}$$

where N is the number of turns and L is the length of the solenoid. Substituting for n from equation (ii) into equation (i), we get

$$B = \mu_0 i \frac{N}{L}. \tag{iii}$$

Solving equation (iii) for the number of turns, we obtain

$$N = \frac{BL}{\mu_0 i} = \frac{(0.50\ \text{T})(8.0\ \text{m})}{\left(4\pi \cdot 10^{-7}\,\frac{\text{Tm}}{\text{A}}\right)(0.40 \cdot 10^3\,\text{A})} = 8.0 \cdot 10^3 \text{turns}.$$

Concept Check 28.8

You have a solenoid with a fixed number of turns connected to a power supply that can supply a fixed amount of current. To double the field inside the solenoid, you can

a) double the radius of the solenoid.

b) halve the radius of the solenoid.

c) double the length of the solenoid.

d) halve the length of the solenoid.

If a solenoid is bent so that the two ends meet (Figure 28.24), it acquires a doughnut shape (a torus), with the wire forming a series of loops, each with the same current flowing through it. This device is called a *toroidal magnet,* or **toroid.** Just as for an ideal solenoid, the magnetic field outside the coils of an ideal toroidal magnet is zero. The magnitude of the magnetic field inside the toroid coil can be calculated by using Ampere's Law and choosing an Amperian loop in the form of a circle with radius *r,* such that $r_1 < r < r_2$, where r_1 and r_2 are the inner and outer radii of the toroid. The magnetic field is always tangential to the Amperian loop, so we have

$$\oint \vec{B} \bullet \vec{ds} = 2\pi r B.$$

The enclosed current is the number of loops (or turns), *N,* in the toroid times the current, *i,* in the wire (in each loop); so, Ampere's Law gives us

$$2\pi r B = \mu_0 N i.$$

Therefore, the magnitude of the magnetic field inside of the toroid is given by

$$B = \frac{\mu_0 N i}{2\pi r}. \qquad \textbf{(28.13)}$$

Note that, unlike the magnetic field inside a solenoid, the magnitude of the magnetic field inside a toroid does depend on the radius. As the radius increases, the magnitude of the magnetic field decreases. The direction of the magnetic field can be obtained using *right-hand rule 4:* If you wrap the fingers of your right hand around the toroid in the direction of the current, as shown in Figure 28.24, your thumb points in the direction of the magnetic field inside the toroid.

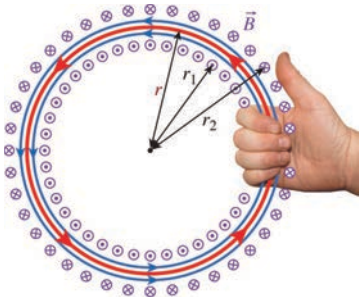

FIGURE 28.24 Toroidal magnet with Amperian loop (red) in the form of a circle with radius *r.* Right-hand rule 4 states that if you place the fingers of your right hand in the direction of the current flow, your thumb shows the direction of the magnetic field inside the toroid.

Mark Dierker/McGraw Hill

SOLVED PROBLEM 28.4 Field of a Toroidal Magnet

A toroidal magnet is made from 202 m of copper wire that is capable of carrying a current of magnitude $i = 2.40$ A. The toroid has an average radius $R = 15.0$ cm and a cross-sectional diameter $d = 1.60$ cm (Figure 28.25a).

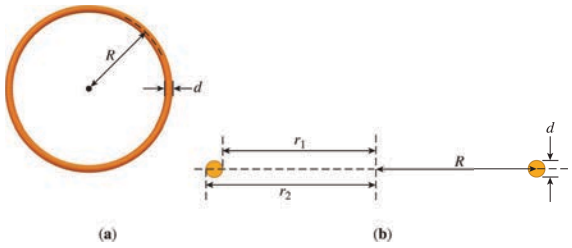

FIGURE 28.25 (a) A toroidal magnet. (b) Cross section of the toroidal magnet.

PROBLEM

What is the largest magnetic field that can be produced at the average toroidal radius, *R*?

SOLUTION

THINK

The number of turns in the toroidal magnet is given by the length of the wire divided by the circumference of the cross-sectional area of the coil. With these parameters, the magnetic field of the toroidal magnet at $r = R$ can be calculated.

SKETCH

Figure 28.25b shows a cross-sectional cut of the toroidal magnet.

RESEARCH

The magnitude of the magnetic field of a toroidal magnet is given by equation 28.13:

$$B = \frac{\mu_0 N i}{2\pi R}, \qquad \text{(i)}$$

where *N* is the number of turns and *R* is the radius at which the magnetic field is measured. The number of turns, *N*, is given by the length, *L*, of the wire divided by the circumference of the cross-sectional area:

$$N = \frac{L}{\pi d}, \qquad \text{(ii)}$$

where d is the diameter of the cross-sectional area of the toroid.

SIMPLIFY

We can combine equations (i) and (ii) to obtain an expression for B:

$$B = \frac{\mu_0 (L/\pi d) i}{2\pi R} = \frac{\mu_0 L i}{2\pi^2 R d}.$$

CALCULATE

Putting in the numerical values gives us

$$B = \frac{\mu_0 L i}{2\pi^2 R d} = \frac{\left(4\pi \cdot 10^{-7}\ \text{T m/A}\right)(202\ \text{m})(2.40\ \text{A})}{2\pi^2 \left(15.0 \cdot 10^{-2}\ \text{m}\right)\left(1.60 \cdot 10^{-2}\ \text{m}\right)} = 0.0128597\ \text{T}.$$

ROUND

We report our result to three significant figures:

$$B = 1.29 \cdot 10^{-2}\ \text{T}.$$

DOUBLE-CHECK

As a double-check, we calculate the magnitude of the field inside a solenoid that has the same length as the circumference of the toroidal magnet. The number of turns per unit length is

$$n = \frac{L/\pi d}{2\pi R} = \frac{L}{2\pi^2 R d} = \frac{(202\ \text{m})}{2\pi^2 \left(15.0 \cdot 10^{-2}\ \text{m}\right)\left(1.60 \cdot 10^{-2}\ \text{m}\right)} = 4264\ \text{tu}$$

The magnitude of the magnetic field inside a solenoid with that number of turns per unit length is

$$B = \mu_0 n i = (4\pi \cdot 10^{-7}\text{T m/A})(4264\ \text{m}^{-1})(2.40\ \text{A}) = 1.29 \cdot 10^{-2}\ \text{T}.$$

Thus, our answer for the magnitude of the field inside the toroid seems reasonable.

SOLVED PROBLEM 28.5 Electron Motion in a Solenoid

An ideal solenoid has 200. turns/cm An electron inside the coil of the solenoid moves in a circle with radius $r = 3.00$ cm perpendicular to the solenoid's axis. The electron moves with a speed of $v = 0.0500c$, where c is the speed of light.

PROBLEM

What is the current in the solenoid?

SOLUTION

THINK

The solenoid produces a uniform magnetic field, which is proportional to the current flowing in its coil. The radius of circular motion of the electron is related to the speed of the electron and the magnetic field inside the solenoid.

SKETCH

Figure 28.26 shows the circular path of the electron in the uniform magnetic field of the solenoid.

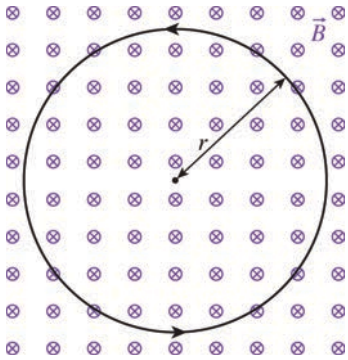

FIGURE 28.26 Electron traveling in a circular path inside a solenoid.

RESEARCH

The magnitude of the magnetic field inside the solenoid is given by

$$B = \mu_0 n i, \qquad \text{(i)}$$

where i is the current in the solenoid and n is the number of turns per unit length. The magnetic force provides the centripetal force needed for the

electron to move in a circle and so the radius of the electron's path can be related to B:

$$r = \frac{mv}{eB}, \tag{ii}$$

where m is the electron's mass, v is its speed, and e is the magnitude of the electron's charge.

SIMPLIFY

Combining equations (i) and (ii), we have

$$r = \frac{mv}{e(\mu_0 ni)}.$$

Solving this equation for the current in the solenoid, we obtain

$$i = \frac{mv}{er\mu_0 n}. \tag{iii}$$

CALCULATE

The speed of the electron was specified in terms of the speed of light:

$$v = 0.0500c = 0.0500\left(3.00 \cdot 10^8 \text{m/s}\right) = 1.50 \cdot 10^7 \text{m/s}.$$

Putting this and the other numerical values into equation (iii), we get

$$i = \frac{mv}{er\mu_0 n} = \frac{\left(9.11 \cdot 10^{-31}\text{kg}\right)\left(1.50 \cdot 10^7 \text{m/s}\right)}{\left(1.602 \cdot 10^{-19}\text{C}\right)\left(3.00 \cdot 10^{-2}\ \text{m}\right)\left(4\pi \cdot 10^{-7}\text{T m/A}\right)(200 \cdot}$$
$$= 0.113132\ \text{A}.$$

ROUND

We report our result to three significant figures:

$$i = 0.113\ \text{A}.$$

DOUBLE-CHECK

To double-check our result, we use it to calculate the magnitude of the magnetic field inside the solenoid:

$$B = \mu_0 ni = (4\pi \cdot 10^{-7}\ \text{T m/A})(200 \cdot 10^2\ \text{m}^{-1})(0.113\ \text{A}) = 0.00284\ \text{T}.$$

This magnitude of magnetic field seems reasonable. Thus, our calculated value for the current in the solenoid seems reasonable.

28.5 Atoms as Magnets

The atoms that make up all matter contain moving electrons, which form current loops that produce magnetic fields. In most materials, these current loops are randomly oriented and produce no net magnetic field. Some materials have a fraction of these current loops aligned. These materials, called *magnetic materials* (Section 28.6), do produce a net magnetic field. Other materials can have their current loops aligned by an external magnetic field and become magnetized.

Let's consider a highly simplified model of the atom: An electron moving at constant speed v in a circular orbit with radius r (Figure 28.27). We can think of the moving charge of the electron as a current, i. Current is defined as the charge passing a particular point per unit of time. For this case, the charge is the charge of the electron, with magnitude e, and the time is related to the period, T, of the electron's orbit. Thus, the magnitude of the current is given by

$$i = \frac{e}{T} = \frac{e}{2\pi r/v} = \frac{ve}{2\pi r}.$$

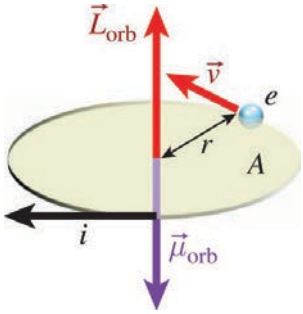

FIGURE 28.27 An electron moving with constant speed in a circular orbit in an atom.

The magnitude of the magnetic dipole moment of the orbiting electron is given by

$$\mu_{\text{orb}} = iA = \frac{ve}{2\pi r}\left(\pi r^2\right) = \frac{ver}{2}. \qquad \textbf{(28.14)}$$

The magnitude of the orbital angular momentum of the electron is

$$L_{\text{orb}} = rp = rmv,$$

where m is the mass of the electron. Solving equation 28.14 for v and substituting that expression into the expression for the orbital angular momentum gives us

$$L_{\text{orb}} = rm\left(\frac{2\mu_{\text{orb}}}{er}\right) = \frac{2m\mu_{\text{orb}}}{e}.$$

Because the magnetic dipole moment and the angular momentum are vector quantities, we can write

$$\vec{\mu}_{\text{orb}} = -\frac{e}{2m}\vec{L}_{\text{orb}}, \qquad \textbf{(28.15)}$$

where the negative sign is needed because the current is defined in terms of the direction of the flow of positive charge.

EXAMPLE 28.3 Orbital Magnetic Moment of the Hydrogen Atom

Assume that the hydrogen atom consists of an electron moving with speed v in a circular orbit with radius r around a stationary proton. Also assume that the centripetal force keeping the electron moving in a circle is the electrostatic force between the proton and the electron. The radius of the orbit of the electron is $r = 5.29 \cdot 10^{-11}$m. (This radius is derived using concepts discussed in Chapter 38 on atomic physics.)

PROBLEM

What is the magnitude of the orbital magnetic moment of the hydrogen atom?

SOLUTION

The magnitude of the orbital magnetic moment is

$$|\mu_{\text{orb}}| = \frac{e}{2m} L_{\text{orb}} = \frac{e}{2m}(rmv) = \frac{erv}{2}. \qquad \text{(i)}$$

Equating the magnitude of the centripetal force keeping the electron moving in a circle with that of the electrostatic force between the electron and the proton gives us

$$\frac{mv^2}{r} = k\frac{e^2}{r^2},$$

where k is the Coulomb constant. We can solve this equation for the speed of the electron:

$$v = e\sqrt{\frac{k}{mr}}. \qquad \text{(ii)}$$

Substituting for v from equation (ii) into equation (i) gives us

$$|\mu_{\text{orb}}| = \frac{er}{2}\left(e\sqrt{\frac{k}{mr}}\right) = \frac{e^2}{2}\sqrt{\frac{kr}{m}}.$$

When we put in the various numerical values, we get

$$|\mu_{\text{orb}}| = \frac{\left(1.602 \cdot 10^{-19}\text{C}\right)^2}{2}\sqrt{\frac{\left(8.99 \cdot 10^{9}\ \text{N m}^2/\text{C}^2\right)\left(5.29 \cdot 10^{-11}\text{m}\right)}{9.11 \cdot 10^{-31}\ \text{kg}}} =$$

This result agrees with experimental measurements of the orbital magnetic moment of the hydrogen atom. However, other predictions about the properties of hydrogen and other atoms that are based on the idea that electrons in atoms have circular orbits disagree with experimental observations. Thus, detailed description of the magnetic properties of atoms must incorporate phenomena described by quantum physics, which will be covered in Chapter 36.

Spin

The magnetic dipole moment from the orbital motion of electrons is not the only contribution to the magnetic moment of atoms. Electrons and other elementary particles have their own, intrinsic magnetic moments, due to their spin. The phenomenon of spin will be covered thoroughly in the discussion of quantum physics in Chapters 36 through 39, but some facts about spin and its connection to a particle's intrinsic angular momentum have been discovered experimentally and do not require an understanding of quantum mechanics. Electrons, protons, and neutrons all have a spin of magnitude $s = \frac{1}{2}$. The magnitude of the angular momentum of these particles is $S = \hbar\sqrt{s(s+1)}$, and the z-component of the angular momentum can have a value of either $S_z = -\frac{1}{2}\hbar$ or $S_z = +\frac{1}{2}\hbar$, where $\hbar$ is Planck's constant divided by 2π. This spin cannot be explained by orbital motion of some substructure in the particles. Electrons, for example, are apparently true point particles. Thus, spin is an intrinsic property, similar to mass or electric charge.

The magnetic character of bulk matter is determined largely by electron spin magnetic moments. The magnetic moment of a particle with spin $\vec{\mu}_s$ is related to its spin angular momentum, $\vec{S}$, via

$$\vec{\mu}_s = g\frac{q}{2m}\vec{S}, \qquad \textbf{(28.16)}$$

where q is the charge of the particle and m is its mass. The quantity g is dimensionless and is called the *g-factor*. For the electron, its numerical value is $g = -2.0023193043622(15)$, one of the most precisely measured quantities in nature. If you compare this equation to equation 28.15 for the magnetic dipole moment due to the orbital angular momentum, you see that they are very similar.

28.6 Magnetic Properties of Matter

In Chapter 27, we saw that magnetic dipoles do not experience a net force in a homogeneous external magnetic field, but do experience a torque. This torque drives a single free dipole to an orientation in which it is antiparallel to the external field, because this is the state with the lowest magnetic potential energy. We've just seen in Section 28.5 that atoms can have magnetic dipoles. What happens when matter (which is composed of atoms) is exposed to an external magnetic field?

The dipole moments of the atoms in a material can point in different directions or in the same direction. The **magnetization,** $\vec{M}$, of a material is defined as the net dipole moment created by the dipole moments of the atoms in the material per unit volume. The magnetic field, $\vec{B}$, inside the material then depends on the external magnetic field, $\vec{B}_0$, and the magnetization, $\vec{M}$:

$$\vec{B} = \vec{B}_0 + \mu_0 \vec{M}, \tag{28.17}$$

where μ_0 is again the magnetic permeability of free space. Instead of including the external magnetic field, $\vec{B}_0$, it is customary to use the **magnetic field strength,** $\vec{H}$:

$$\vec{H} = \frac{\vec{B}_0}{\mu_0}. \tag{28.18}$$

With this definition of the magnetic field strength, equation 28.17 can be written

$$\vec{B} = \mu_0 \left(\vec{H} + \vec{M} \right). \tag{28.19}$$

Since the unit of magnetic field is $[B] = \mathrm{T}$ and the unit of the magnetic permeability is $[\mu_0] = \mathrm{T\,m/A}$, the units of magnetization and magnetic field strength are $[M] = [H] = \mathrm{A/m}$.

Diamagnetism and Paramagnetism

The question not yet answered is how the magnetization depends on the external magnetic field, $\overrightarrow{B}_0$, or, equivalently, on the magnetic field strength, $\overrightarrow{H}$. For most materials (not all!) this relationship is linear:

$$\overrightarrow{M} = \chi_{\mathrm{m}} \overrightarrow{H}, \tag{28.20}$$

where the proportionality constant χ_{m} is called the **magnetic susceptibility** of the material (Table 28.1). But there are materials that do not obey the simple linear relationship of equation 28.20, and the most prominent among those are ferromagnets, which we'll discuss in the next subsection. Let's first examine diamagnetic and paramagnetic materials, for which equation 28.20 holds.

Table 28.1 Values of Magnetic Susceptibility for Some Common Diamagnetic and Paramagnetic Materials

Material	Magnetic Susceptibility, χ_{m}
Aluminum	$+2.2 \cdot 10^{-5}$
Bismuth	$-1.66 \cdot 10^{-4}$
Diamond (carbon)	$-2.1 \cdot 10^{-5}$
Graphite (carbon)	$-1.6 \cdot 10^{-5}$
Hydrogen	$-2.2 \cdot 10^{-9}$
Lead	$-1.8 \cdot 10^{-5}$
Lithium	$+1.4 \cdot 10^{-5}$
Mercury	$-2.9 \cdot 10^{-5}$
Oxygen	$+1.9 \cdot 10^{-6}$
Platinum	$+2.65 \cdot 10^{-4}$
Silicon	$-3.7 \cdot 10^{-6}$
Sodium	$+7.2 \cdot 10^{-6}$
Sodium chloride (NaCl)	$-1.4 \cdot 10^{-5}$
Tungsten	$+6.8 \cdot 10^{-5}$
Uranium	$+4.0 \cdot 10^{-4}$
Vacuum	0
Water	$-9 \cdot 10^{-6}$

If $\chi_{\mathrm{m}} < 0$, the dipoles inside the material tend to arrange themselves to oppose an external magnetic field, just like free dipoles. In this case, the magnetization vector points in the direction opposite to the magnetic field strength vector. Materials with $\chi_{\mathrm{m}} < 0$ are said to be *diamagnetic*. Most materials exhibit **diamagnetism.** In diamagnetic materials, a weak magnetic dipole moment is induced by an external magnetic field in a direction opposite to the direction of the external field. The induced magnetic field disappears when the external field is removed. If the external field is nonuniform, interaction of the induced dipole moment of the diamagnetic material with the external field creates a force directed from a region of greater magnetic field strength to a region of lower magnetic field strength.

An example of biological material exhibiting diamagnetism is shown in Figure 28.28. Diamagnetic forces induced by a nonuniform external magnetic field of 16

T are levitating a live frog. (This experience apparently did not bother the frog.) The normally negligible diamagnetic force is large enough in this case to overcome gravity.

FIGURE 28.28 A live frog being levitated by a strong magnetic field.

High Field Magnet Laboratory, Radboud University Nijmegen, The Netherlands

If the magnetic susceptibility in equation 28.20 is greater than zero, $\chi_m > 0$, the magnetization of the material points in the same direction as the magnetic field strength. Note that χ_m for a vacuum is 0. This property is **paramagnetism,** and materials that exhibit it are said to be *paramagnetic.* Materials containing certain transition elements (including actinides and rare earths) exhibit paramagnetism. Each atom of these elements has a permanent magnetic dipole, but normally these dipole moments are randomly oriented and produce no net magnetic field. However, in the presence of an external magnetic field, some of these magnetic dipole moments align in the same direction as the external field. When the external field is removed, the induced magnetic dipole moment disappears. If the external field is nonuniform, this induced magnetic dipole moment interacts with the external field to produce a force directed from a region of lower magnetic field strength to a region of higher magnetic field strength—just the opposite of the effect of diamagnetism.

Substituting the expression for $\vec{M}$ from equation 28.20 into equation 28.19 for the magnetic field, $\vec{B}$, inside a material gives

$$\vec{B} = \mu_0\left(\vec{H} + \vec{M}\right) = \mu_0\left(\vec{H} + \chi_m\vec{H}\right) = \mu_0(1 + \chi_m)\vec{H}. \qquad \textbf{(28.21)}$$

In analogy to the relative electric permittivity introduced in Chapter 24, the **relative magnetic permeability,** κ_m, is commonly defined as

$$\kappa_{\mathrm{m}} = 1 + \chi_{\mathrm{m}} \tag{28.22}$$

Then, the magnetic permeability, μ, of a material can be expressed as

$$\mu = (1 + \chi_{\mathrm{m}})\mu_0 = \kappa_{\mathrm{m}}\mu_0. \tag{28.23}$$

Replacing μ_0 with μ in the Biot-Savart Law (equation 28.1) and Ampere's Law (equation 28.10) enables us to use these laws for calculating the magnetic field in a particular material.

Finally for paramagnetic materials, the magnitude of the magnetization is temperature dependent. Conventionally, this temperature dependence is expressed via *Curie's Law:*

$$M = \frac{cB}{T}, \tag{28.24}$$

where c is Curie's constant, B is the magnitude of the magnetic field, and T is the temperature in kelvins.

Ferromagnetism

The elements iron, nickel, cobalt, gadolinium, and dysprosium—and alloys containing these elements—exhibit **ferromagnetism.** A ferromagnetic material shows long-range ordering at the atomic level, which causes the dipole moments of atoms to line up with each other in a limited region called a **domain.** Within a domain, the magnetic field can be strong. However, in bulk samples of the material, domains are randomly oriented, leaving no net magnetic field. Figure 28.29a shows randomly oriented magnetic dipole moments in a domain, and Figure 28.29b shows perfect ferromagnetic order. Figure 28.29c illustrates the interesting case of perfect antiferromagnetic order, in which the interaction between neighboring magnetic dipole moments causes them to be oriented in opposite directions. This ordering can be realized only at very low temperatures.

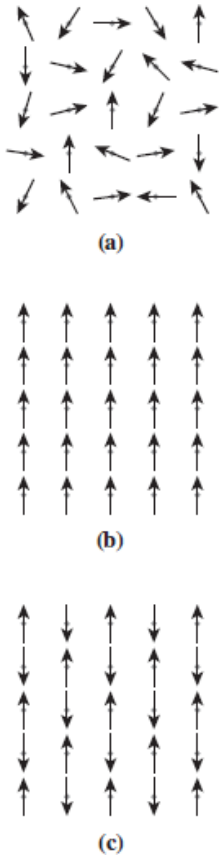

FIGURE 28.29 Magnetic domains:(a) randomly oriented; (b) perfect ferromagnetic order; (c) perfect antiferromagnetic order. (Note that this illustration only shows the directions of individual magnetic domains in an idealized scenario. The magnetic domains also can, and usually have, very different magnitudes.)

An external magnetic field can align domains as shown in Figure 28.29b, as a result of the interaction between the magnetic dipole moments of the domain and the external field. As a result, a ferromagnetic material retains all or some of its induced magnetism when the external magnetic field is removed, since the domains stay aligned. In addition, the magnetic field produced by a current in a solenoid or a toroid will be larger if a ferromagnetic material is present in the device. But in contrast to diamagnetic and paramagnetic materials, ferromagnetic materials do not obey the simple linear relationship given in equation 28.20. The domains retain their orientations, and thus the material exhibits a nonzero

magnetization even in the absence of an external magnetic field. (This is why permanent magnets exist.)

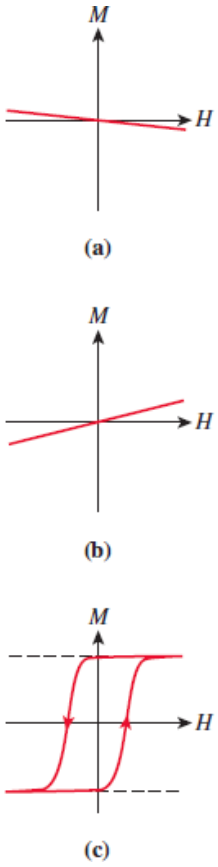

FIGURE 28.30
Magnetization as a function of the magnetic field strength: (a) for diamagnetic materials; (b) for paramagnetic materials; (c) the hysteresis loop for ferromagnetic materials.

Figure 28.30 illustrates the dependence of the magnetization on the magnetic field strength for the three types of materials we've discussed. Figure 28.30a and Figure 28.30b show the linear dependence according to equation 28.20 for diamagnetic and paramagnetic materials, respectively. Figure 28.30c shows the typical hysteresis loop obtained for ferromagnetic materials. The arrows on the red curve show the direction in which the magnetization process develops, and the dashed lines represent the maximum magnetization (positive and negative) possible. For any point on this hysteresis loop, the magnetization can be expressed in terms of an effective value of the magnetic permeability, μ, of the ferromagnetic material, similar to what is given in equation 28.23; however, this permeability is *not* a constant but depends on the applied magnetic field strength and even on the

path by which that value of the field strength was attained. Regardless, the values of the effective permeability, μ, for ferromagnetic materials can be much larger than those for paramagnetic materials (greater by a factor of up to 10^4).

Ferromagnetism exhibits temperature dependence. At a certain temperature, called the *Curie temperature,* ferromagnetic materials cease to exhibit ferromagnetism. At this point, the ferromagnetic order due to the interaction of the dipole moments in these materials is overwhelmed by the thermal motion. For iron, the Curie temperature is 768 $^\circ$C. Figure 28.31 shows a simple demonstration in which heating a permanent ferromagnet (Figure 28.31b) diminishes the attraction between it and another magnet (Figure 28.31c). As the magnet subsequently cools (Figure 28.31d), it again becomes a permanent magnet (Figure 28.31e).

FIGURE 28.31 Demonstration of the temperature dependence of ferromagnetism: (a) A permanent magnet forms the bob of a pendulum and is deflected from the vertical by another magnet (lower left corner of each frame); (b) the magnet is heated and its temperature begins to increase; (c) the temperature of the magnet is high enough that its magnetic field is diminished and it hangs at a much smaller angle; (d) as the magnet cools, it begins to recover its original magnetic field; and (e) it returns to its original position.

W. Bauer and G. D. Westfall

28.7 Magnetism and Superconductivity

Magnets for industrial applications and scientific research can be constructed using ordinary resistive wire with current flowing through it. A typical magnet of this type is a large solenoid. The current flowing through the wire of the magnet produces resistive heating, and the heat is usually removed by low-conductivity water flowing through hollow conductors. (Low-conductivity water has been purified so that it does not conduct electricity.) These room-temperature magnets typically produce magnetic fields with strengths up to 1.5 T and are usually relatively inexpensive to construct but expensive to operate because of the high cost of electricity.

Some applications, such as magnetic resonance imaging (MRI), require magnetic fields of the highest possible magnitude to ensure the best signal-to-noise ratio in the measurements. To achieve these fields, magnets are constructed using superconducting coils rather than resistive coils. Such a magnet can produce a stronger field than a room-temperature magnet, with a magnitude of 10 T or higher. Materials such as mercury and lead exhibit superconductivity at liquid helium temperatures, but some metals that are good conductors at room temperature, such as copper and gold, never become superconducting. The disadvantage of a superconducting magnet is that the conductor must be kept at the temperature of liquid helium, which is approximately 4 K (although recent discoveries described later in this section are easing this limitation). Thus, the magnet must be enclosed in a cryostat filled with liquid helium to keep it cold. An advantage of a superconducting magnet is the fact that once the current is established in the coil of the magnet, it will continue to flow until it is removed by external means. However, the energy saving realized by having no resistive loss in the coil is at least partially offset by the expenditure of energy required to keep the superconducting coil cold.

When current flows through superconducting mercury or lead, the magnetic field inside the material becomes zero. The reduction to zero of the magnetic field inside a material cooled sufficiently that it becomes a superconductor is called the *Meissner effect*. Above the critical temperature, T_c, for the transition to superconductivity, the Meissner effect disappears, and the material becomes a normal conductor (Figure 28.32).

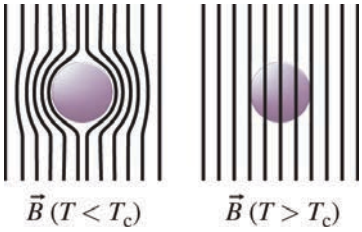

FIGURE 28.32 The Meissner effect, in which a material excludes external magnetic fields from its interior when it is cooled below the critical temperature at which it becomes superconducting.

Figure 28.33 shows an impressive demonstration of the Meissner effect: A piece of a superconductor (cooled to a temperature below its critical temperature) causes a permanent magnet to float above it by expelling the magnet's intrinsic magnetic field. It achieves this because superconducting currents on its surface produce a magnetic field opposed to the applied field, which yields a net field of zero inside the superconductor and repulsion between the fields above the superconductor.

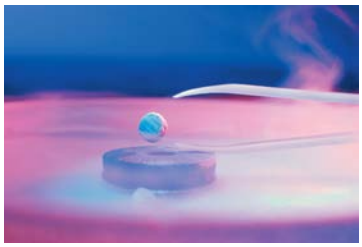

FIGURE 28.33 Through the Meissner effect, a superconductor expels the magnetic field of a permanent magnet, which thus hovers above it.

Lawrence Manning/Digital Stock/Getty Images

The conductor used in a superconducting magnet is specially designed to overcome the Meissner effect. Modern superconductors are constructed from filaments of niobiumtitanium alloy embedded in solid copper. The niobium-titanium filaments have microscopic domains in which a magnetic field can exist without being excluded. The copper serves as a mechanical support and can take over the current load should the superconductor become normally conducting.

This type of superconductor can produce magnetic fields with magnitudes as high as 15 T.

During the last two decades, physicists and engineers have discovered new materials that are superconducting at temperatures well above 4 K. Critical temperatures of up to 160 K have been reported for these *high-temperature superconductors,* which means that they can be made superconducting by cooling them with liquid nitrogen. Many researchers around the world are looking for materials that are superconducting at room temperature. These materials would revolutionize many areas of industry, in particular, transportation and the power grid. Superconducting power transmission lines are already used in some pilot projects, such as the 574-megawatt transmission line used by the Long Island Power Authority which utilizes American Superconductor's high-temperature superconducting wires and a liquid air cooling system. One major future project using superconducting wires for high-current power transmission of up to 5 gigawatts in each cable is the Tres Amigas SuperStation in Clovis, New Mexico. It will connect the two main North American power grids, the Eastern Interconnection and the Western Interconnection, with the Texas Interconnection.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- The magnetic permeability of free space, μ_0, is given by $4\pi \cdot 10^{-7}\ \mathrm{T\,m/A}$.
- The Biot-Savart Law, $d\vec{B} = \dfrac{\mu_0}{4\pi}\dfrac{i\vec{ds}\times\hat{r}}{r^2}$, describes the differential magnetic field, $d\vec{B}$, caused by a current element, $i\vec{ds}$, at a position $\vec{r}$ relative to the current element.
- The magnitude of the magnetic field at a distance $r_\perp$ from a long, straight wire carrying a current i is $B = \mu_0 i/2\pi r_\perp$.
- The magnetic field magnitude at the center of a loop with radius R carrying a current i is $B = \mu_0 i/2R$.
- Ampere's Law is given by $\oint \vec{B} \bullet \vec{ds} = \mu_0 i_{\mathrm{enc}}$, where $\vec{ds}$ is the integration path and i_{enc} is the current enclosed in a chosen Amperian loop.
- The magnitude of the magnetic field inside a solenoid carrying a current i and having n turns per unit length is $B = \mu_0 ni$.
- The magnitude of the magnetic field inside a toroid having N turns and a radius r and carrying a current is given by $B = \mu_0 Ni/2\pi r$.
- For an electron with charge $-e$ and mass m moving in a circular orbit, the magnetic dipole moment can be related to the orbital angular momentum through $\vec{\mu}_{\mathrm{orb}} = -\dfrac{e}{2m}\vec{L}_{\mathrm{orb}}$.
- For diamagnetic and paramagnetic materials, the magnetization is proportional to the magnetic field strength: $\vec{M} = \chi_{\mathrm{m}}\vec{H}$. Ferromagnetic materials follow a hysteresis loop and thus deviate from this linear relationship.
- The magnetic field inside a diamagnetic or paramagnetic material is due to the external magnetic field strength and the magnetization: $\vec{B} = \mu_0\left(\vec{H} + \vec{M}\right) = \mu_0\left(\vec{H} + \chi_{\mathrm{m}}\vec{H}\right) = \mu_0(1+\chi_{\mathrm{m}})\vec{H} = \mu_0\kappa_{\mathrm{m}}\vec{H} = \mu\vec{H}$, where κ_{m} is the relative magnetic permeability.
- The four right-hand rules related to magnetic fields are shown in Figure 28.34. Right-hand rule 1 gives the direction of the magnetic force on a charged particle moving in a magnetic field. Right-hand rule 2 gives the direction of the unit normal vector for a current-carrying loop. Right-hand rule 3 gives the direction of the magnetic field from a current-carrying wire. Right-hand rule 4 gives the direction of the magnetic field inside a toroidal magnet.

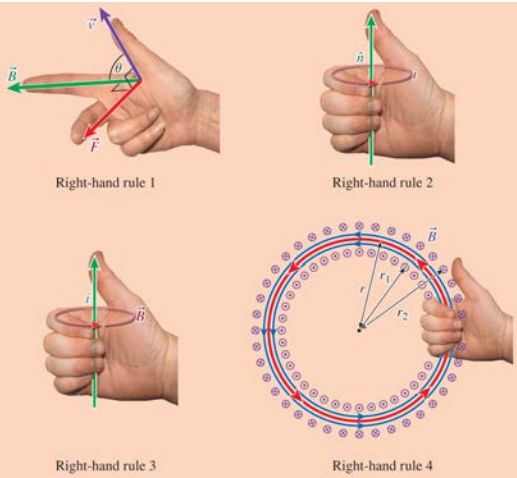

FIGURE 28.34 Four right-hand rules related to magnetic fields.

ANSWERS TO SELF-TEST OPPORTUNITIES

28.1 The magnetic field at point P_1 points in the positive y-direction. The magnetic field at point P_2 points in the negative x-direction.

28.2 Two parallel wires carrying current in the same direction attract each other. Two parallel wires carrying current in opposite directions repel each other.

28.3 $B_x = \dfrac{\mu_0 i}{2} \dfrac{R^2}{(0^2 + R^2)^{3/2}} = \dfrac{\mu_0 i}{2} \dfrac{R^2}{R^3} = \dfrac{\mu_0 i}{2R}$.

PROBLEM-SOLVING GUIDELINES

1. When using the Biot-Savart Law, you should always draw a diagram of the situation, with the current element highlighted. Check for simplifying symmetries before proceeding with calculations; you can save yourself a significant amount of work.

2. When applying Ampere's Law, choose an Amperian loop that has some geometrical symmetry, in order to simplify the evaluation of the integral. Often, you can use right-hand rule 3 to choose the direction of integration along the loop: Point your thumb in the direction of the net current through the loop and your fingers curl in the direction of integration. This method will also remind you to sum the currents through the Amperian loop to determine the enclosed current.

3. Remember the superposition principle for magnetic fields: The net magnetic field at any point in space is the vector sum of the individual magnetic fields generated by different objects. Make sure you do not simply add the magnitudes. Instead, you generally need to add the spatial components of the different sources of magnetic field separately.

4. All of the principles governing the motion of charged particles in magnetic fields and all of the problem-solving guidelines presented in Chapter 27 still apply. It does not matter if the magnetic field is due to a permanent magnet or an electromagnet.

5. In order to calculate the magnetic field in a material, you can use the formulas derived from Ampere's Law and Biot-Savart's Law, but you have to replace μ_0 with $\mu = (1 + \chi_m)\mu_0 = \kappa_m \mu_0$.

MULTIPLE-CHOICE QUESTIONS

28.1 Two long, straight wires are parallel to each other. The wires carry currents of different magnitudes. If the amount of current flowing in each wire is doubled, the magnitude of the force between the wires will be

a) twice the magnitude of the original force.

b) four times the magnitude of the original force.

c) the same as the magnitude of the original force.

d) half of the magnitude of the original force.

28.2 A current element produces a magnetic field in the region surrounding it. At any point in space, the magnetic field produced by this current element points in a direction that is

a) radial from the current element to the point in space.

b) parallel to the current element.

c) perpendicular to the current element and to the radial direction.

28.3 The number of turns in a solenoid is doubled, and its length is halved. How does its magnetic field change?

a) It doubles.

b) It is halved.

c) It quadruples.

d) It remains unchanged.

28.4 Consider two parallel current-carrying wires. The magnetic fields cause attractive forces between the wires, so it appears that the magnetic field due to one wire is doing work on the other wire. How is this explained?

a) The magnetic force can do no work on isolated charges; this says nothing about the work it can do on charges confined in a conductor.

b) Since only an electric field can do work on charges, it is actually the electric fields doing the work here.

c) This apparent work is due to another type of force.

28.5 In a solenoid in which the wires are wound such that each loop touches the adjacent ones, which of the following will increase the magnetic field inside the magnet?

a) making the radius of the loops smaller

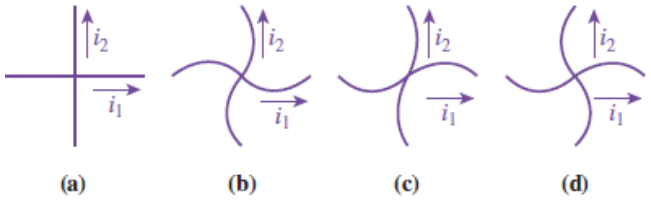
b) increasing the radius of the wire

c) increasing the radius of the solenoid

d) decreasing the radius of the wire

e) immersing the solenoid in gasoline

28.6 Two insulated wires cross at a 90° angle. Currents are sent through the two wires. Which one of the figures best represents the configuration of the wires if the current in the horizontal wire flows in the positive x-direction and the current in the vertical wire flows in the positive y-direction?



28.7 What is a good rule of thumb for designing a simple magnetic coil? Specifically, given a circular coil of radius ~ 1 cm, what is the approximate magnitude of the magnetic field, in gausses per amp per turn? (*Note:* $1\ \text{G} = 0.0001\ \text{T}$.)

a) $0.0001\ \text{G}/(\text{A-turn})$

b) $0.01\ \text{G}/(\text{A-turn})$

c) $1\ \text{G}/(\text{A-turn})$

d) $100\ \text{G}/(\text{A-turn})$

28.8 A solid cylinder carries a current that is uniform over its cross section. Where is the magnitude of the magnetic field the greatest?

a) at the center of the cylinder's cross section

b) in the middle of the cylinder

c) at the surface

d) none of the above

28.9 Two long, straight wires have currents flowing in them in the same direction, as shown in the figure. The force between the wires is

a) attractive.

b) repulsive.

c) zero.

28.10 In a magneto-optic experiment, a liquid sample in a 10-mL spherical vial is placed in a highly uniform magnetic field, and a laser beam is directed through the sample. Which of the following should be used to create the uniform magnetic field required by the experiment?

a) a 5-cm-diameter flat coil consisting of one turn of 4-gauge wire

b) a 10-cm-diameter, 20-turn, single-layer, tightly wound coil made of 18-gauge wire

c) a 2-cm-diameter, 10-cm-long, tightly wound solenoid made of 18-gauge wire

d) a set of two coaxial 10-cm-diameter coils at a distance of 5 cm apart, each consisting of one turn of 4-gauge wire

28.11 Assume that a lightning bolt can be modeled as a long, straight line of current. If 15.0 C of charge passes by a point in $1.50 \cdot 10^{-3}$ s, what is the magnitude of the magnetic field at a distance of 26.0 m from the lightning bolt?

a) $7.69 \cdot 10^{-5}$ T

b) $9.22 \cdot 10^{-3}$ T

c) $4.21 \cdot 10^{-2}$ T

d) $1.11 \cdot 10^{-1}$ T

e) $2.22 \cdot 10^{2}$ T

28.12 Two solenoids have the same length, but solenoid 1 has 15 times more turns and $\frac{1}{9}$ as large a radius and carries 7 times as much current as solenoid 2. Calculate the ratio of the magnitude of the magnetic field inside solenoid 1 to that of the magnetic field inside solenoid 2.

a) 105

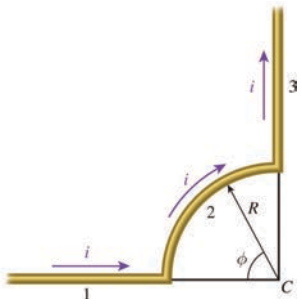
b) 123

c) 144

d) 168

e) 197

28.13 The wire in the figure carries a current *i* and contains a circular arc of radius *R* and angle $\pi/2$ and two straight sections that are mutually perpendicular and, if extended, would intersect the center, *C*, of the arc. What is the magnetic field at point *C* due to the wire?



a) $B = \dfrac{\mu_0 i}{2R}$

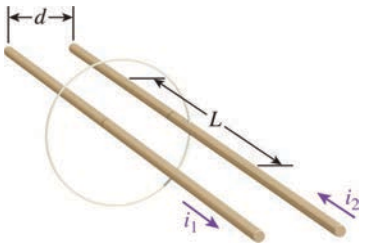
b) $B = \dfrac{\mu_0 i}{4R}$

c) $B = \dfrac{\mu_0 i}{6R}$

d) $B = \dfrac{\mu_0 i}{8R}$

e) $B = \dfrac{\mu_0 i}{12R}$

28.14 Wire 1 carries a current i_1, and wire 2 carries a current i_2 in the opposite direction, as shown in the figure. What is the direction of the force exerted by wire 1 on a length L of wire 2?



a) toward wire 1

b) away from wire 1

c) Wire 1 does not exert a force on wire 2 in this situation.

CONCEPTUAL QUESTIONS

28.15 Many electrical applications use twisted-pair cables in which the ground and signal wires spiral about each other. Why?

28.16 Discuss how the accuracy of a compass needle in showing the true direction of north can be affected by the magnetic field due to currents in wires and appliances in a residential building.

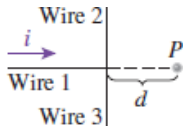
28.17 Can an ideal solenoid, one with no magnetic field outside the solenoid, exist? If not, does that invalidate the derivation of the magnetic field inside the solenoid (Section 28.4)?

28.18 Conservative forces tend to act on objects in such a way as to minimize a system's potential energy. Use this principle to explain the direction of the force on the current-carrying loop described in Example 28.1.

28.19 Two particles, each with charge q and mass m, are traveling in a vacuum on parallel trajectories a distance d apart and at a speed v (much less than the speed of light). Calculate the ratio of the magnitude of the magnetic force that each exerts on the other to the magnitude of the electric force that each exerts on the other: F_m/F_e.

28.20 A long, straight, cylindrical tube of inner radius a and outer radius b carries a total current i uniformly across its cross section. Determine the magnitude of the magnetic field due to the tube at the midpoint between the inner and outer radii.

28.21 Three identical straight wires are connected in a T, as shown in the figure. If current i flows into the junction, what is the magnetic field at point P, a distance d from the junction?



28.22 In a certain region, there is a constant and uniform magnetic field, $\vec{B}$. Any electric field in the region is also unchanging in time. Find the current density, $\vec{J}$, in this region.

28.23 The magnetic character of bulk matter is determined largely by electron spin magnetic moments, rather than by orbital dipole moments. (Nuclear contributions are negligible, as the proton's spin magnetic moment is about 658 times smaller than that of the electron.) If the atoms or molecules of a substance have unpaired electron spins, the associated magnetic moments give rise to paramagnetism or to ferromagnetism if the interactions between atoms or molecules are strong enough to align them in domains. If the atoms or molecules

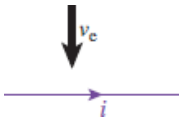
have no net unpaired spins, then magnetic perturbations of electrons' orbits give rise to diamagnetism.

a) Molecular hydrogen gas (H_2) is weakly diamagnetic. What does this imply about the spins of the two electrons in the hydrogen molecule?

b) What would you expect the magnetic behavior of atomic hydrogen gas (H) to be?

28.24 Exposed to sufficiently high magnetic fields, materials *saturate,* or approach a maximum magnetization. Would you expect the saturation (maximum) magnetization of paramagnetic materials to be much less than, roughly the same as, or much greater than that of ferromagnetic materials? Explain why.

28.25 A long, straight wire carries a current, as shown in the figure. A single electron is shot directly toward the wire from above. The trajectory of the electron and the wire are in the same plane. Will the electron be deflected from its initial path, and if so, in which direction?



28.26 A square loop, with sides of length *L,* carries current *i.* Find the magnitude of the magnetic field from the loop at the center of the loop, as a function of *i* and *L.*

28.27 A current of constant density, J_0, flows through a very long cylindrical conducting shell with inner radius a and outer radius b. What is the magnetic field in the regions $r < a$, $a < r < b$, and $r > b$? Does $B_{a<r<b} = B_{r>b}$ for $r = b$?

28.28 Parallel wires, a distance *D* apart, carry a current, *i,* in opposite directions as shown in the figure. A circular loop, of radius $R = D/2$, has the same current flowing in a counterclockwise direction. Determine the magnitude and the direction of the magnetic field from the loop and the parallel wires at the center of the loop, as a function of *i* and *R.*

28.29 The current density in a cylindrical conductor of radius *R* varies as $J(r) = J_0 e^{-r/R}$ (in the region from zero to *R*). Express the magnitude of the magnetic field in the regions $r < R$ and $r > R$. Produce a sketch of the radial dependence, $B(r)$.

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.

Sections 28.1 and 28.2

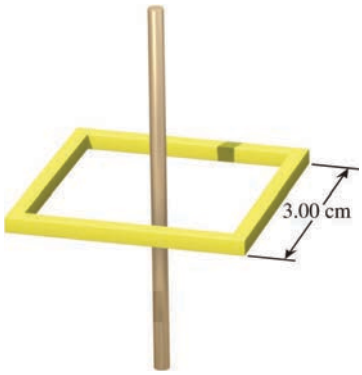
28.30 Two long parallel wires are separated by 3.0 mm. The current flowing in one of the wires is twice that in the other wire. If the magnitude of the force on a 1.0-m length of one of the wires is 7.0 μN, what are the magnitudes of the two currents?

28.31 An electron is shot from an electron gun with a speed of $4.0 \cdot 10^5$ m/s and moves parallel to and at a distance of 5.0 cm above a long, straight wire carrying a current of 15 A. Determine the magnitude and the direction of the acceleration of the electron the instant it leaves the electron gun.

28.32 An electron moves in a straight line at a speed of $5.00 \cdot 10^6$ m/s. What are the magnitude and the direction of the magnetic field created by the moving electron at a distance $d = 5.00$ m ahead of it on its line of motion? How does the answer change if the moving particle is a proton?

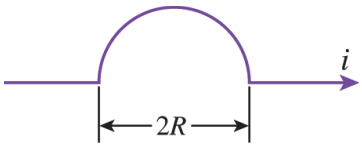
28.33 Suppose that the magnetic field of the Earth were due to a single current moving in a circle of radius $2.00 \cdot 10^3$ km through the Earth's molten core. The strength of the Earth's magnetic field on the surface near a magnetic pole is about $6.00 \cdot 10^5$ T. About how large a current would be required to produce such a field?

28.34 A square ammeter has sides of length 3.00 cm. The sides of the ammeter are capable of measuring the magnetic field they are subject to. When the ammeter is clamped around a wire carrying a direct current, as shown in the figure, the average value of the magnetic field measured in the sides is 3.00 G. What is the current in the wire?

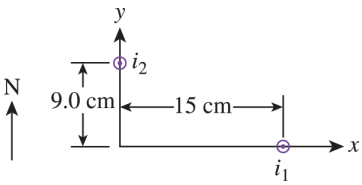


•**28.35** A long, straight wire carrying a 2.00-A current lies along the x-axis. A particle with charge $q = -3.00$ μC moves parallel to the y-axis through the point $(x, y, z) = (0, 2, 0)$. Where in the xy-plane should another long, straight wire be placed so that there is no magnetic force on the particle at the point where it crosses the plane?

•**28.36** Find the magnetic field in the center of a wire semicircle like that shown in the figure, with radius $R = 10.0$ cm, if the current in the wire is $i = 12.0$ A.



•**28.37** Two very long wires run parallel to the z-axis, as shown in the figure. They each carry a current, $i_1 = i_2 = 25.0$ A, flowing in the direction of the positive z-axis. The magnetic field of the Earth is given by $\vec{B} = \left(2.60 \cdot 10^{-5}\right)\hat{y}$ T (in the xy-plane and pointing due north). A magnetic compass needle is placed at the origin. Determine the angle θ between the compass needle and the x-axis. (*Hint:* The compass needle will align its axis along the direction of the net magnetic field.)

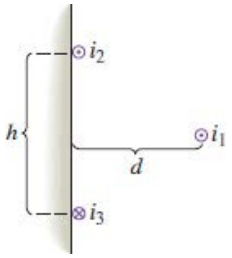


•**28.38** Two identical coaxial coils of wire of radius 20.0 cm are directly on top of each other, separated by a 2.00-mm gap. The lower coil is on a flat table and has a current i in the clockwise direction; the upper coil carries an identical current and has a mass of 0.0500 kg. Determine the magnitude and the direction that the current in the upper coil has to have to keep it levitated at the distance 2.00 mm above the lower coil.

•**28.39** A long, straight wire lying along the x-axis carries a current, i, flowing in the positive x-direction. A second long, straight wire lies along the y-axis and has a current i in the positive y-direction. What are the magnitude and the direction of the magnetic field at point $z = b$ on the z-axis?

•**28.40** A square loop of wire with a side length of 10.0 cm carries a current of 0.300 A. What is the magnetic field in the center of the square loop?

•**28.41** The figure shows the cross section through three long wires with a linear mass distribution of 100. g/m. They carry currents i_1, i_2, and i_3 in the directions shown. Wires 2 and 3 are 10.0 cm apart and are attached to a vertical surface, and each carries a current of 600. A. What current, i_1, will allow wire 1 to "float" at a perpendicular distance $d = 10.0$ cm from the vertical surface? (Neglect the thickness of the wires.)



•**28.42** A hairpin configuration is formed of two semi-infinite straight wires that are 2.00 cm apart and joined by a semicircular piece of wire (whose radius must

be 1.00 cm and whose center is at the origin of *xyz*-coordinates). The top wire lies along the line $y = 1.00$ cm, and the bottom wire lies along the line $y = -1.00$ cm; these two wires are in the left side $(x < 0)$ of the *xy*-plane. The current in the hairpin is 3.00 A, and it is directed toward the right in the top wire, clockwise around the semicircle, and to the left in the bottom wire. Find the magnetic field at the origin of the coordinate system.

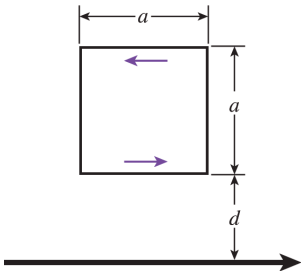
•28.43 A long, straight wire is located along the *x*-axis ($y = 0$ and $z = 0$). The wire carries a current of 7.00 A in the positive *x*-direction. What are the magnitude and the direction of the force on a particle with a charge of 9.00 C located at $(+1.00\text{ m},\ +2.00\text{ m},\ 0)$, when it has a velocity of 3000. m/s in each of the following directions?

a) the positive *x*-direction

b) the positive *y*-direction

c) the negative *z*-direction

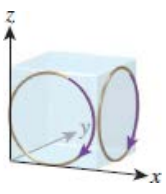
•28.44 A long, straight wire has a 10.0-A current flowing in the positive *x*-direction, as shown in the figure. Close to the wire is a square loop of copper wire that carries a 2.00-A current in the direction shown. The near side of the loop is $d = 0.500$ m away from the wire. The length of each side of the square is $a = 1.00$ m.



a) Find the net force between the two current-carrying objects.

b) Find the net torque on the loop.

28.45 A square box with sides of length 1.00 m has one corner at the origin of a coordinate system, as shown in the figure. Two coils are attached to the outside of the box. One coil is on the box face that is in the *xz*-plane at $y = 0$, and the second is on the box face in the *yz*-plane at $x = 1.00$ m. Each of the coils has a diameter of 1.00 m and contains 30.0 turns of wire carrying a current of 5.00 A in each turn. The current in each coil is clockwise when the coil is viewed from outside the box. What are the magnitude and the direction of the magnetic field at the center of the box?

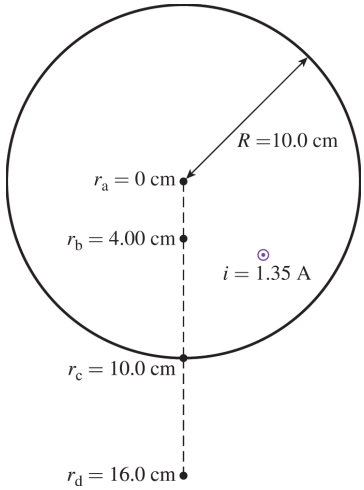


Section 28.3

28.46 The current density in a cylindrical conductor of radius R varies as $J(r) = J_0 r/R$ (in the region from zero to R). Express the magnitude of the magnetic field in the regions $r < R$ and $r > R$. Produce a sketch of the radial dependence, $B(r)$.

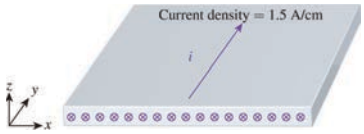
Page 880

28.47 The figure shows a cross section across the diameter of a long, solid, cylindrical conductor. The radius of the cylinder is $R = 10.0$ cm. A current of 1.35 A is uniformly distributed throughout the conductor and is flowing out of the page. Calculate the direction and the magnitude of the magnetic field at positions $r_a = 0.0$ cm, $r_b = 4.00$ cm, $r_c = 10.0$ cm, and $r_d = 16.0$ cm.



•• **28.48** A coaxial wire consists of a copper core of radius 1.00 mm surrounded by a copper sheath of inside radius 1.50 mm and outside radius 2.00 mm. A current, i, flows in one direction in the core and in the opposite direction in the sheath. Graph the magnitude of the magnetic field as a function of the distance from the center of the wire.

•**28.49** A very large sheet of conducting material located in the xy-plane, as shown in the figure, has a uniform current flowing in the y-direction. The current density is 1.5 A/cm. Use Ampere's Law to calculate the direction and the magnitude of the magnetic field just above the center of the sheet (not close to any edges).



Section 28.4

28.50 A current of 2.00 A is flowing through a 1000-turn solenoid of length $L = 40.0$ cm. What is the magnitude of the magnetic field inside the solenoid?

28.51 Solenoid A has twice the diameter, three times the length, and four times the number of turns of solenoid B. The two solenoids have currents of equal magnitudes flowing through them. Find the ratio of the magnitude of the magnetic field in the interior of solenoid A to that of solenoid B.

28.52 A long solenoid (diameter of 6.00 cm) is wound with 1000 turns per meter of thin wire through which a current of 0.250 A is maintained. A wire carrying a current of 10.0 A is inserted along the axis of the solenoid. What is the magnitude of the magnetic field at a point 1.00 cm from the axis?

28.53 A long, straight wire carries a current of 2.5 A.

a) What is the strength of the magnetic field at a distance of 3.9 cm from the wire?

b) If the wire still carries 2.5 A, but is used to form a long solenoid with 32 turns per centimeter and a radius of 3.9 cm, what is the strength of the magnetic field inside the solenoid?

28.54 Figure 28.20a shows a Helmholtz coil used to generate uniform magnetic fields. Suppose the Helmholtz coil consists of two sets of coaxial wire loops with 15 turns of radius $R = 75.0$ cm, which are separated by R, and each coil carries a current of 0.123 A flowing in the same direction. Calculate the magnitude and the direction of the magnetic field in the center between the coils.

•28.55 A particle detector utilizes a solenoid that has 550 turns of wire per centimeter. The wire carries a current of 22 A. A cylindrical detector that lies within the solenoid has an inner radius of 0.80 m. Electron and positron beams are directed into the solenoid parallel to its axis. What is the minimum momentum perpendicular to the solenoid axis that a particle can have if it is to be able to enter the detector?

Sections 28.5 through 28.7

28.56 An electron has a spin magnetic moment of magnitude $\mu = 9.285 \cdot 10^{-24} \text{A m}^2$. Consequently, it has energy associated with its orientation in a magnetic field. If the difference between the energy of an electron that is "spin up" in a magnetic field of magnitude B and the energy of one that is "spin down" in the same magnetic field (where "up" and "down" refer to the direction of the magnetic field) is $9.460 \cdot 10^{-25}$ J, what is the field magnitude, *B?*

28.57 When a magnetic dipole is placed in a magnetic field, it has a natural tendency to minimize its potential energy by aligning itself with the field. If there is sufficient thermal energy present, however, the dipole may rotate so that it is no longer aligned with the field. Using $k_\text{B}T$ as a measure of the thermal energy, where k_B is Boltzmann's constant and T is the temperature in kelvins, determine the temperature at which there is sufficient thermal energy to rotate the magnetic dipole associated with a hydrogen atom from an orientation parallel to an applied magnetic field to one that is antiparallel to the applied field. Assume that the strength of the field is 0.15 T.

28.58 Aluminum becomes superconducting at a temperature around 1.0 K if exposed to a magnetic field of magnitude less than 0.0105 T. Determine the maximum current that can flow in an aluminum superconducting wire with radius $R = 1.0$ mm.

28.59 If you want to construct an electromagnet by running a current of 3.00 A through a solenoid with 500. windings and length 3.50 cm and you want the magnetic field inside the solenoid to have the magnitude $B = 2.96$ T, you can insert a ferrite core into the solenoid. What value of the relative magnetic permeability should this ferrite core have in order to make this work?

28.60 What is the magnitude of the magnetic field inside a long, straight tungsten wire of circular cross section with diameter 2.4 mm and carrying a current of 3.5 A, at a distance of 0.60 mm from its central axis?

•**28.61** You charge up a small rubber ball of mass 200. g by rubbing it over your hair. The ball acquires a charge of 2.00 μC. You then tie a 1.00-m-long string to it and swing it in a horizontal circle, providing a centripetal force of 25.0 N. What is the magnetic moment of the system?

•**28.62** Consider a model of the hydrogen atom in which an electron orbits a proton in the plane perpendicular to the proton's spin angular momentum (and magnetic dipole moment) at a distance equal to the Bohr radius, $a_0 = 5.292 \cdot 10^{-11}$ m. (This is an oversimplified classical model.) The spin of the electron is allowed to be either parallel to the proton's spin or antiparallel to it; the orbit is the same in either case. But since the proton produces a magnetic field at the electron's location, and the electron has its own intrinsic magnetic dipole moment, the energy of the electron differs depending on its spin. The magnetic field produced by the proton's spin may be modeled as a dipole field, like the electric field due to an electric dipole discussed in Chapter 22. Calculate the energy difference between the two electron-spin configurations. Consider only the

interaction between the magnetic dipole moment associated with the electron's spin and the field produced by the proton's spin.

•• 28.63 Consider an electron to be a uniformly dense sphere of charge, with a total charge of $-e = -1.602 \cdot 10^{-19}\text{C}$, spinning at an angular frequency, ω.

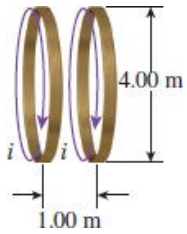
a) Write an expression for its classical angular momentum of rotation, L.

b) Write an expression for its magnetic dipole moment, μ.

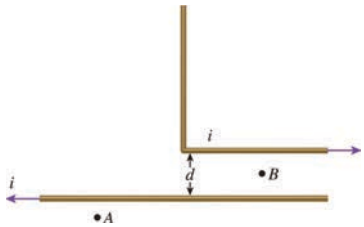
c) Find the ratio, $\gamma_e = \mu/L$, known as the *gyromagnetic ratio*.

Additional Exercises

28.64 Two 50-turn coils, each with a diameter of 4.00 m, are placed 1.00 m apart, as shown in the figure. A current of 7.00 A is flowing in the wires of both coils; the direction of the current is clockwise for both coils when viewed from the left. What is the magnitude of the magnetic field in the center between the two coils?



28.65 The wires in the figure are separated by a vertical distance d. Point B is at the midpoint between the two wires; point A is a distance $d/2$ from the lower wire. The horizontal distance between A and B is much larger than d. Both wires carry the same current, i. The strength of the magnetic field at point A is 2.00 mT. What is the strength of the field at point B?

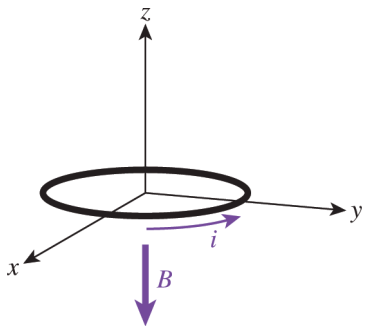


28.66 You are standing at a spot where the magnetic field of the Earth is horizontal, points due northward, and has magnitude 40.0 μT. Directly above your head, at a height of 12.0 m, a long, horizontal cable carries a steady direct current of 500. A due northward. Calculate the angle θ by which your magnetic compass needle is deflected from true magnetic north by the effect of the cable. Don't forget the *sign* of θ—is the deflection eastward or westward?

28.67 The magnetic dipole moment of the Earth is approximately $8.0 \cdot 10^{22}$ A m^2. The source of the Earth's magnetic field is not known; one possibility might be the circulation of ions in the Earth's molten outer core. Assume that the circulating ions move a circular loop of radius 2500 km. What "current" must they produce to yield the observed field?

28.68 A circular wire loop has a radius $R = 0.12$ m and carries a current $i = 0.10$ A. The loop is placed in the xy-plane in a uniform magnetic field given by $\vec{B} = -1.5\hat{z}$ T, as shown in the figure. Determine the direction and the magnitude of the loop's magnetic moment and calculate the potential energy of the loop in the position shown. If the wire loop can move freely, how will it orient itself to

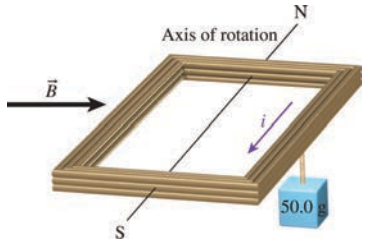
minimize its potential energy, and what is the value of the lowest potential energy?



28.69 A 0.90-m-long solenoid has a radius of 5.0 mm. When the wire carries a 0.20-A current, the magnetic field inside the solenoid is 5.0 mT. How many turns of wire are there in the solenoid?

28.70 In a coaxial cable, the solid core carries a current i. The sheath also carries a current i but in the opposite direction, and it has an inner radius a and an outer radius b. The current density is equally distributed over each conductor. Find an expression for the magnetic field at a distance $a < r < b$ from the center of the core.

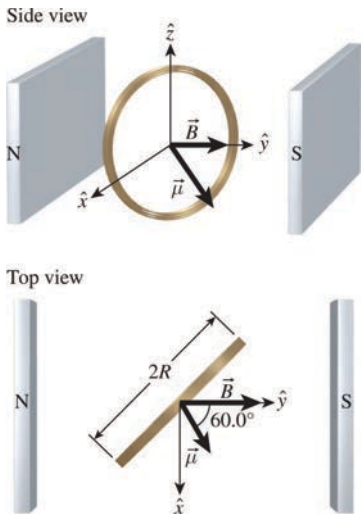
•**28.71** A 50-turn rectangular coil of wire with dimensions 10.0 cm by 20.0 cm lies in a horizontal plane, as shown in the figure. The axis of rotation of the coil is aligned north and south. It carries a current $i = 1.00$ A and is in a magnetic field pointing from west to east. A mass of 50.0 g hangs from one side of the coil. Determine the strength the magnetic field has to have to keep the coil in the horizontal orientation.



•**28.72** Two long, straight parallel wires are separated by a distance of 20.0 cm. Each wire carries a current of 10.0 A in the same direction. What is the magnitude of the resulting magnetic field at a point that is 12.0 cm from each wire?

•**28.73** A particle with a mass of 1.00 mg and a charge q is moving at a speed of 1000. m/s along a horizontal path 10.0 cm below and parallel to a straight current-carrying wire. Determine q if the magnitude of the current in the wire is 10.0 A.

•**28.74** A conducting coil consisting of n turns of wire is placed in a uniform magnetic field given by $\vec{B} = 2.00\hat{y}$ T, as shown in the figure. The radius of the coil is $R = 5.00$ cm, and the angle between the magnetic field vector and the unit normal vector to the coil is $\theta = 60.0^\circ$. The current through the coil is $i = 5.00$ A.



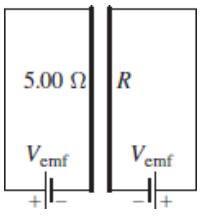
a) Specify the direction of the current in the coil, given the direction of the magnetic dipole moment, $\vec{\mu}$, shown in the figure.

b) Calculate the number of turns, *n,* the coil must have for the torque on the loop to be 3.40 N m.

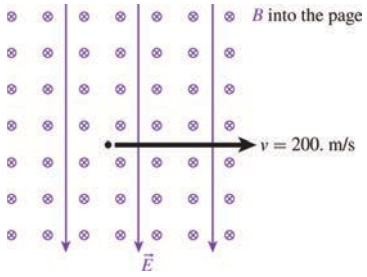
c) If the radius of the loop is decreased to $R = 2.50$ cm, what should the number of turns, *N,* be for the torque to remain unchanged? Assume that *i, B,* and θ stay the same.

•**28.75** A loop of wire of radius $R = 25.0$ cm has a smaller loop of radius $r = 0.900$ cm at its center, with the planes of the two loops perpendicular to each other. When a current of 14.0 A is passed through both loops, the smaller loop experiences a torque due to the magnetic field produced by the larger loop. Determine this torque, assuming that the smaller loop is sufficiently small that the magnetic field due to the larger loop is the same across its entire surface.

•**28.76** Two wires, each 25.0 cm long, are connected to two separate 9.00-V batteries, as shown in the figure. The resistance of the first wire is 5.00 Ω, and that of the other wire is unknown (*R*). If the separation between the wires is 4.00 mm, what value of *R* will produce a force of magnitude $4.00 \cdot 10^{-5}$ N between them? Is the force attractive or repulsive?



•**28.77** A proton is moving under the combined influence of an electric field ($E = 1000.$ V/m) and a magnetic field ($B = 1.20$ T), as shown in the figure.

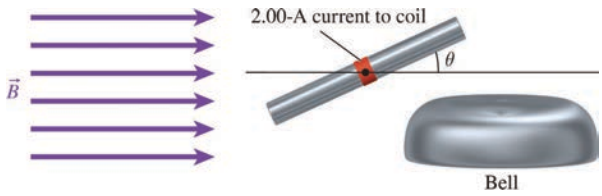


a) What is the acceleration of the proton at the instant it enters the crossed fields?

b) What would the acceleration be if the direction of the proton's motion were reversed?

•**28.78** A toy airplane of mass 0.175 kg, with a charge of 36 mC, is flying with a speed of 2.8 m/s at a height of 17.2 cm above and parallel to a wire, which is carrying a 25-A current. The airplane experiences some acceleration. Determine this acceleration.

•**28.79** An electromagnetic doorbell has been constructed by wrapping 70 turns of wire around a long, thin rod, as shown in the figure. The rod has a mass of 30.0 g, a length of 8.00 cm, and a cross-sectional area of 0.200 cm^2. The rod is free to pivot about an axis through its center, which is also the center of the coil. Initially, the rod makes an angle of $\theta = 25.0^\circ$ with the horizontal. When $\theta = 0.00^\circ$, the rod strikes a bell. A uniform magnetic field of 900. G is directed at an angle $\theta = 0.00^\circ$.

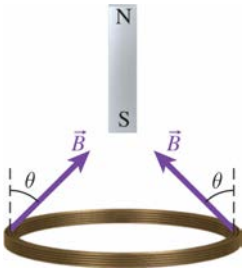


a) If a current of 2.00 A is flowing in the coil, what is the torque on the rod when $\theta = 25.0^\circ$?

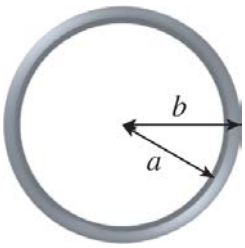
b) What is the angular velocity of the rod when it strikes the bell?

•**28.80** Two long, parallel wires separated by a distance *d* carry currents in opposite directions. If the left-hand wire carries a current $i/2$ and the right-hand wire carries a current *i,* determine where the magnetic field is zero.

•**28.81** A horizontally oriented coil of wire of radius 5.00 cm that carries a current, *i,* is being levitated by the south pole of a vertically oriented bar magnet suspended above its center, as shown in the figure. If the magnetic field on all parts of the coil makes an angle $\theta = 45.0^\circ$ with the vertical, determine the magnitude and the direction of the current needed to keep the coil floating in midair. The magnitude of the magnetic field is $B = 0.0100$ T, the number of turns in the coil is $N = 10.0$, and the total coil mass is 10.0 g.



•**28.82** As shown in the figure, a long, hollow, conducting cylinder of inner radius a and outer radius b carries a current that is flowing out of the page. Suppose that $a = 5.00$ cm, $b = 7.00$ cm, and the current $i = 1.00.$ mA, uniformly distributed over the cylinder wall (between a and b). Find the magnitude of the magnetic field at each of the following distances r from the center of the cylinder:



a) $r = 4.00$ cm

b) $r = 6.50$ cm

c) $r = 9.00$ cm

•**28.83** A wire of radius R carries a current i. The current density is given by $J = J_0(1 - r/R)$, where r is measured from the center of the wire and J_0 is a constant. Use Ampere's Law to find the magnetic field inside the wire at a distance $r < R$ from the central axis.

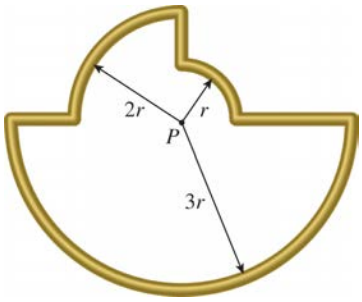
•**28.84** A circular wire of radius 5.0 cm has a current of 3.0 A flowing in it. The wire is placed in a uniform magnetic field of 5.0 mT.

a) Determine the maximum torque on the wire.

b) Determine the range of the magnetic potential energy of the wire.

MULTI-VERSION EXERCISES

28.85 The loop shown in the figure is carrying a current of 3.857 A, and the distance $r = 1.411$ m. What is the magnitude of the magnetic field at point P inside the loop?



28.86 The loop shown in the figure is carrying a current of 3.961 A. The magnitude of the magnetic field at point P inside the loop is $7.213 \cdot 10^{-7}$ T. What is the value of r?

28.87 In the current-carrying loop shown in the figure, the distance $r = 2.329$ m. The magnitude of the magnetic field at point P inside the loop is $5.937 \cdot 10^{-7}$ T. What is the current in the loop?

28.88 A toroidal magnet has an inner radius of 1.895 m and an outer radius of 2.075 m. When the wire carries a 33.45-A current, the magnetic field at a distance of 1.985 m from the center of the toroid is 66.78 mT. How many turns of wire are there in the toroid?

28.89 A toroidal magnet has an inner radius of 1.121 m and an outer radius of 1.311 m. The magnetic field at a distance of 1.216 m from the center of the toroid is 78.30 mT. There are 22,381 turns of wire in the toroid. What is the current in the toroid?

28.90 A toroidal magnet has an inner radius of 1.351 m and an outer radius of 1.541 m. The wire carries a 49.13-A current, and there are 24,945 turns in the toroid. What is the magnetic field at a distance of 1.446 m from the center of the toroid?

Most of us take electric power for granted—we flip a switch and we have power for lighting, heating, and entertainment. But the vast network that supplies this power—called *the grid*—depends on large generators that convert mechanical energy into electrical energy (Figure 29.1). The physical principles that enable this conversion are the subject of this chapter.

FIGURE 29.1 The Grand Coulee Dam on the Columbia River in the state of Washington is the largest single producer of electricity in the United States. Shown here are the giant generators, which apply the physical principle of induction to produce electricity.

Cavan Images/Alamy Stock Photo

In Chapter 27, we saw that a magnetic field can affect the path of charged particles, or electric currents, and in Chapter 28, we saw that

an electric current generates a magnetic field. In this chapter, we'll see that a changing magnetic field generates an electric current, and thus an electric field. Note the word "changing" here; just as a magnetic field is generated only when electrical charges are in motion, an electric field is generated only when a magnetic field is in motion (relative to a conductor) or otherwise changes as a function of time. This symmetry will turn out to be a key part of the unified description of electricity and magnetism presented in Chapter 31.

WHAT WE WILL LEARN

- A changing magnetic field inside a conducting loop induces a current in the loop.
- A changing current in a loop induces a current in a nearby loop.
- Faraday's Law of Induction states that a potential difference is induced in a loop when there is a change in the magnetic flux through the loop.
- Magnetic flux is the product of the magnitude of the average magnetic field and the perpendicular area that it penetrates.
- Lenz's Law states that the current induced in a loop by a changing magnetic flux produces a magnetic field that opposes this change in magnetic flux.
- A changing magnetic field induces an electric field.
- The inductance of a device is a measure of its opposition to changes in current flowing through it.
- Electric motors and electric generators are everyday applications of magnetic induction.
- A simple single-loop circuit with an inductor and a resistor has a characteristic time constant given by the inductance divided by the resistance.
- Energy is stored in a magnetic field.

29.1 Faraday's Experiments

Some of the great discoveries about electricity and magnetism took place in the late 18th and early 19th centuries. In 1750, the American Benjamin Franklin showed that lightning is a form of electricity, with his famous kite-flying experiment. (Perhaps the most amazing aspect of that experiment was that he was not killed by the lightning strike.) In 1799, the Italian Alessandro Volta constructed the first battery, called a *voltaic pile* at the time. In 1820, the Danish physicist Hans Christian Oersted demonstrated that an electric current could produce a magnetic field strong enough to deflect a compass needle. (He performed his experiment during a lecture to his students, making it one of the most productive lecture demonstrations in the history of science.)

However, the experiments that are most relevant to this chapter were performed in the 1830s by the British chemist and physicist Michael Faraday and independently by the American physicist Joseph Henry. Their work demonstrated that a changing magnetic field could generate a potential difference in a conductor, strong enough to produce an electric current. This discovery is of basic importance to all the electrical and magnetic devices we use every day, from computers to cell phones, from televisions to credit cards, from the tiniest batteries to the largest electrical power grids. Both Faraday and Henry had fundamental electrical units named after them, and justifiably so.

To understand Faraday's experiments, consider a wire loop connected to an ammeter. A bar magnet is some distance from the loop with its north pole pointing toward the loop. While the magnet is stationary, no current flows in the loop. However, if the magnet is moved toward the loop (Figure 29.2a), a counterclockwise current flows in the loop as indicated by the positive current in the ammeter. If the magnet is moved toward the loop faster, a larger current is induced in the loop. If the magnet is reversed, so the south pole points toward the loop (Figure 29.2b), and moved toward the loop, current flows in the loop in the opposite direction. If the north pole of the magnet points toward the loop, and the magnet is then moved

away from the loop (Figure 29.3a), a negative clockwise current, as indicated on the meter in Figure 29.3a, is induced in the loop. If the south pole of the magnet points toward the loop, and the magnet is moved away from the loop (Figure 29.3b), a positive current is induced.

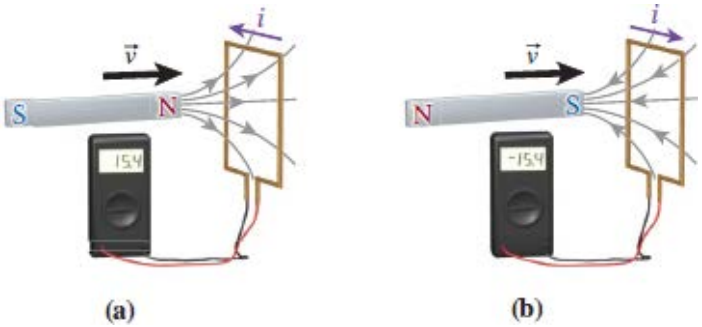

FIGURE 29.2 Moving a magnet toward a wire loop induces a current to flow in the loop. (a) With the north pole of the magnet pointing toward the loop, a positive current results. (b) With the south pole of the magnet pointing toward the loop, a negative current results.

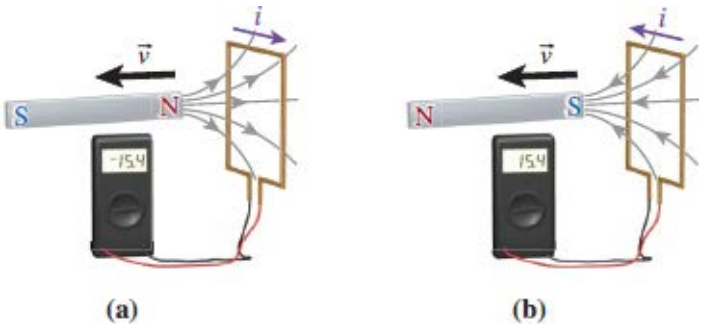

FIGURE 29.3 Moving a magnet away from a wire loop also induces a current to flow in the loop. (a) With the north pole of the magnet pointing toward the loop, a negative current results. (b) With the south pole of the magnet pointing toward the loop, a positive current results.

The four results illustrated in Figures 29.2 and 29.3 can be replicated by holding the magnets stationary and moving the loops. For example, with the arrangement shown in Figure 29.2a, if the loop is moved toward the stationary magnet, a positive current flows in the loop.

Similar effects can be observed using two conducting loops (Figure 29.4). If a constant current is flowing through loop 1, no current is induced in loop 2. If the current in loop 1 is increased, a current is induced in loop 2 in the opposite direction. Thus, not only does the increasing current in the first loop induce a current in the second loop, but the induced current is in the opposite direction. Furthermore, if current is flowing in loop 1 in the same direction as before and is then *decreased* (Figure 29.5), the current induced in loop 2 flows in the *same* direction as the current in loop 1.

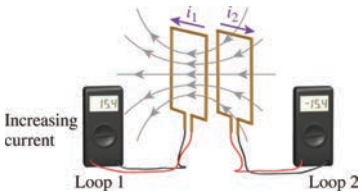

FIGURE 29.4 An increasing current in loop 1 induces a current in the opposite direction in loop 2. (The magnetic field lines shown are those produced by the current 1 flowing through loop 1.)

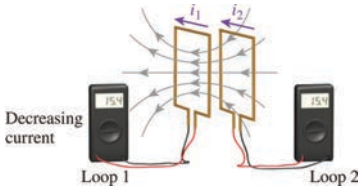

FIGURE 29.5 A decreasing current in loop 1 induces a current in the same direction in loop 2.

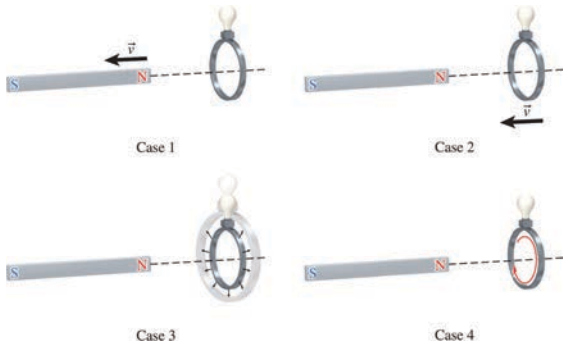
All of the phenomena illustrated in these four figures can be explained by Faraday's Law of Induction, discussed in Section 29.2, and by Lenz's Law, discussed in Section 29.3.

Concept Check 29.1

The four figures show a bar magnet and a low-voltage light bulb connected to the ends of a conducting loop. The plane of the loop is perpendicular to the dashed line. In case 1, the loop is stationary, and the magnet is moving away from the loop. In case 2, the magnet is stationary, and the loop is moving toward the magnet. In case 3, both the magnet and the loop are stationary, but the area of the loop is increasing. In case 4, the magnet is stationary, and the loop is rotating about its center. In which of these situations will the bulb light up?



a) case 1

b) cases 1 and 2

c) cases 1, 2, and 3

d) cases 1, 2, and 4

e) all four cases

29.2 Faraday's Law of Induction

From the observations in the preceding section, we see that a changing magnetic field through a loop induces a current in the loop. We can visualize the change in magnetic field as a change in the number of magnetic field lines passing through the loop. **Faraday's Law of Induction** in its qualitative form states:

> A potential difference is induced in a loop when the number of magnetic field lines passing through the loop changes with time.

The rate of change of the magnetic field lines determines the induced potential difference. The existence of this potential difference means that the changing magnetic field actually creates an electric field around the loop! Thus, there are two ways of producing an electric field: from electric charges and from a changing magnetic field. If the electric field arises from a charge, the resulting electric force on a test charge is conservative. Conservative forces do no work when they act on an object whose path starts and ends at the same point in space. In contrast, electric fields generated by changing magnetic fields give rise to electric forces that are *not* conservative. Thus, a test particle that moves around a circular loop once will have work done on it by this electric field. In fact, the amount of the work done is the induced potential difference times the charge of the test particle.

The magnetic field lines are quantified by the magnetic flux, in analogy with the electric flux. Chapter 22 introduced Gauss's Law for electric fields and defined the electric flux as the surface integral of an electric field passing through a differential element of area, dA. Mathematically, $\Phi_E = \int\int \vec{E} \bullet d\vec{A}$, where $d\vec{A}$ is a vector of magnitude dA that is perpendicular to the differential area. By analogy, for a magnetic field, **magnetic flux** is defined as the

surface integral of the magnetic field passing through a differential element of area:

$$\Phi_B = \iint \vec{B} \bullet d\vec{A}, \qquad \textbf{(29.1)}$$

where $\vec{B}$ is the magnetic field at each differential area element, $d\vec{A}$, of a closed surface. The loop in the symbol for a surface integral means that the integration is over a closed surface. The two integrals signify integration over two variables. The differential area element, $d\vec{A}$, must be described by two spatial variables, such as x and y in Cartesian coordinates or θ and ϕ in spherical coordinates. With a closed surface, the differential area vector, $d\vec{A}$, always points out of the enclosed volume and is perpendicular to the surface everywhere.

Integration of the electric flux over a closed surface (see Chapter 22) yields Gauss's Law: $\oiint \vec{E} \bullet d\vec{A} = q/\epsilon_0$. That is, the integral of the electric flux over a closed surface is equal to the enclosed electric charge, q, divided by the electric permittivity of free space, ϵ_0. Integration of the magnetic flux over a *closed* surface yields zero:

$$\oiint \vec{B} \bullet d\vec{A} = 0. \qquad \textbf{(29.2)}$$

This result is often termed **Gauss's Law for Magnetic Fields.** You might think that the integral of the magnetic flux over a closed surface would be equal to the enclosed "magnetic charge" divided by the magnetic permeability of free space. However, there are no free magnetic charges, no magnetic monopoles, no separate north poles or separate south poles. Magnetic poles are always found in pairs. Thus, Gauss's Law for Magnetic Fields is another way of stating that magnetic monopoles do not exist. (Extensive searches for magnetic monopoles have been conducted since the 1980s, but not successfully. However, several string theories and grand unified theories—more on those in Chapter 39—predict that magnetic

monopoles exist.) Another way to state Gauss's Law for Magnetic Fields is that magnetic field lines have no beginning or end but form a continuous loop.

Figure 29.6 shows a nonuniform magnetic field, $\vec{B}$ passing through a differential area element, $d\vec{A}$. A portion of the closed surface is also shown. The angle between the magnetic field and the differential area vector is θ.

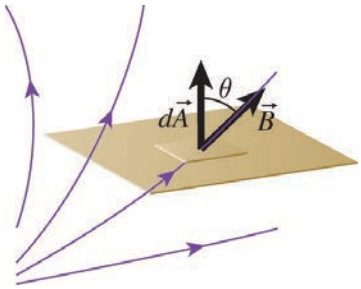


FIGURE 29.6 A nonuniform magnetic field $\vec{B}$ passing through a differential area, $d\vec{A}$.

Consider the special case of a flat loop of area A in a constant magnetic field, as illustrated in Figure 29.7. For this case, we can rewrite equation 29.1 as

$$\Phi_B = BA\cos\theta, \qquad \textbf{(29.3)}$$

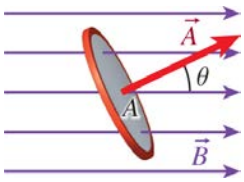

FIGURE 29.7 A flat loop of area A in a constant magnetic field, $\vec{B}$ The magnetic field makes an angle θ with respect to the surface normal vector of the loop.

where B is the magnitude of the constant magnetic field, A is the area of the loop, and θ is the angle between the surface normal vector to the plane of the loop and the magnetic field lines. Thus, if the magnetic field is perpendicular to the plane of the loop, $\theta = 0^\circ$ and $\Phi_B = BA$. If the magnetic field is parallel to the plane of the loop, $\theta = 90^\circ$ and $\Phi_B = 0$.

The unit of magnetic flux is $[\Phi_B] = [B][A] = \text{T m}^2$. This unit has received a special name, the **weber (Wb):**

$$1\ \text{Wb} = 1\ \text{T m}^2. \tag{29.4}$$

Faraday's Law of Induction is stated quantitatively, in terms of the magnetic flux, as follows:

> The magnitude of the potential difference, ΔV_{ind}, induced in a conducting loop is equal to the time rate of change of the magnetic flux through the loop.

Faraday's Law of Induction is thus expressed by the equation

$$\Delta V_{\text{ind}} = -\frac{d\Phi_B}{dt}. \qquad \textbf{(29.5)}$$

The negative sign in equation 29.5 is necessary because the induced potential difference establishes an induced current whose magnetic field tends to oppose the flux change. Section 29.3 on Lenz's Law discusses this phenomenon in detail.

The magnetic flux can be changed in several ways, including changing the magnitude of the magnetic field, changing the area of the loop, or changing the angle the loop makes with respect to the magnetic field. In all situations that involve some form of motion of a conductor relative to the source of a magnetic field, the induced potential difference is called a **motional emf.**

Induction in a Flat Loop inside a Magnetic Field

Let's apply equation 29.5 to a flat wire loop inside a uniform magnetic field, where *uniform* means that the field has the same value (same magnitude and same direction) at all points in space at a given time but can vary in time. This arrangement is the simplest case we can address. According to equation 29.3, the magnetic flux in this case is given by $\Phi_B = BA\cos\theta$. According to equation 29.5, the induced potential difference is then

$$\Delta V_{\text{ind}} = -\frac{d\Phi_B}{dt} = -\frac{d}{dt}(BA\cos\theta). \qquad \textbf{(29.6)}$$

We can use the product rule from calculus to expand this derivative:

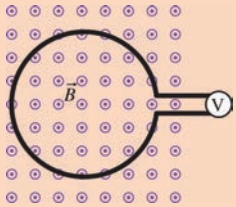
$$\Delta V_{\text{ind}} = -A\cos\theta\frac{dB}{dt} - B\cos\theta\frac{dA}{dt} + AB\sin\theta\frac{d\theta}{dt}. \textbf{(29.7)}$$

Because the time derivative of the angular displacement is the angular velocity, $d\theta/dt = \omega$, the induced potential difference in a flat loop inside a uniform magnetic field is

$$\Delta V_{\text{ind}} = -A\cos\theta\frac{dB}{dt} - B\cos\theta\frac{dA}{dt} + \omega AB\sin\theta. \textbf{(29.8)}$$

Self-Test Opportunity 29.1

The plane of the circular loop shown in the figure is perpendicular to a magnetic field with magnitude $B = 0.500\ \text{T}$. The magnetic field goes to zero at a constant rate in 0.250 s. The induced voltage in the loop is 1.24 V during that time. What is the radius of the loop?



Holding two of the three variables in equation 29.8 (A, B, and θ) constant results in the following *three special* cases:

1. Holding the area of the loop and its orientation relative to the magnetic field constant but varying the magnetic field in time yields

$$A \text{ and } \theta \text{ constant:} \quad \Delta V_{\text{ind}} = -A\cos\theta\frac{dB}{dt}. \textbf{(29.9)}$$

2. Holding the magnetic field as well as the orientation of the loop relative to the magnetic field constant but changing the area of the loop that is exposed to the magnetic field yields

$$B \text{ and } \theta \text{ constant:} \quad \Delta V_{\text{ind}} = -B\cos\theta\frac{dA}{dt}. \textbf{(29.10)}$$

3. Holding the magnetic field constant and keeping the area of the loop fixed but allowing the angle between the two to change as a function of time yields

$$A \text{ and } B \text{ constant:} \quad \Delta V_{\text{ind}} = \omega AB \sin\theta. \textbf{ (29.11)}$$

The following examples illustrate the first two cases. Section 29.4 addresses the third case, which has the most useful technical applications, leading directly to electric motors and generators.

EXAMPLE 29.1 Potential Difference Induced by a Changing Magnetic Field

A current of 600 mA is flowing in an ideal solenoid, resulting in a magnetic field of 0.025 T inside the solenoid. Then the current increases with time, t, according to

$$i(t) = i_0\left[1 + \left(2.4\,\mathrm{s}^{-2}\right)t^2\right].$$

PROBLEM

If a circular coil of radius 3.4 cm with $N = 200$ windings is located inside the solenoid with its normal vector parallel to the magnetic field (Figure 29.8), what is the induced potential difference in the coil at $t = 2.0$ s?

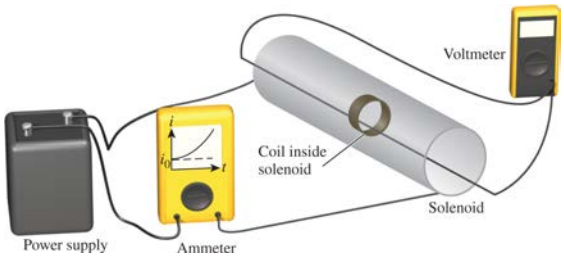


FIGURE 29.8 A time-varying current applied to a solenoid induces a potential difference in a coil.

SOLUTION

First, we compute the area of the coil. Since it is circular, its area is πR^2. However, it has N windings, and thus the area is that of N loops of area πR^2. The net effect is that the number of windings acts as a simple multiplier for the loop area, and the total effective area of the coil is

$$A = N\pi R^2 = 200\pi(0.034\,\mathrm{m})^2 = 0.73\,\mathrm{m}^2. \qquad \textbf{(i)}$$

The magnetic field inside an ideal solenoid is $B = \mu_0 n i$, where n is the number of windings per unit length, and i is the current (see Chapter 28). Because the magnetic field is proportional to the current, we immediately obtain for the time dependence of the magnetic field in this case

$$B(t) = B_0 \left[1 + \left(2.4\,\mathrm{s}^{-2}\right)t^2\right],$$

with $B_0 = \mu_0 n i_0 = 0.025\,\mathrm{T}$, according to the problem statement.

Further, in this case, the area of the coil and the angle between each loop and the magnetic field (which is zero) are constant. Therefore, equation 29.9 applies. We then find for the induced potential difference, where the area A already accounts for the number of windings, as shown in equation (i):

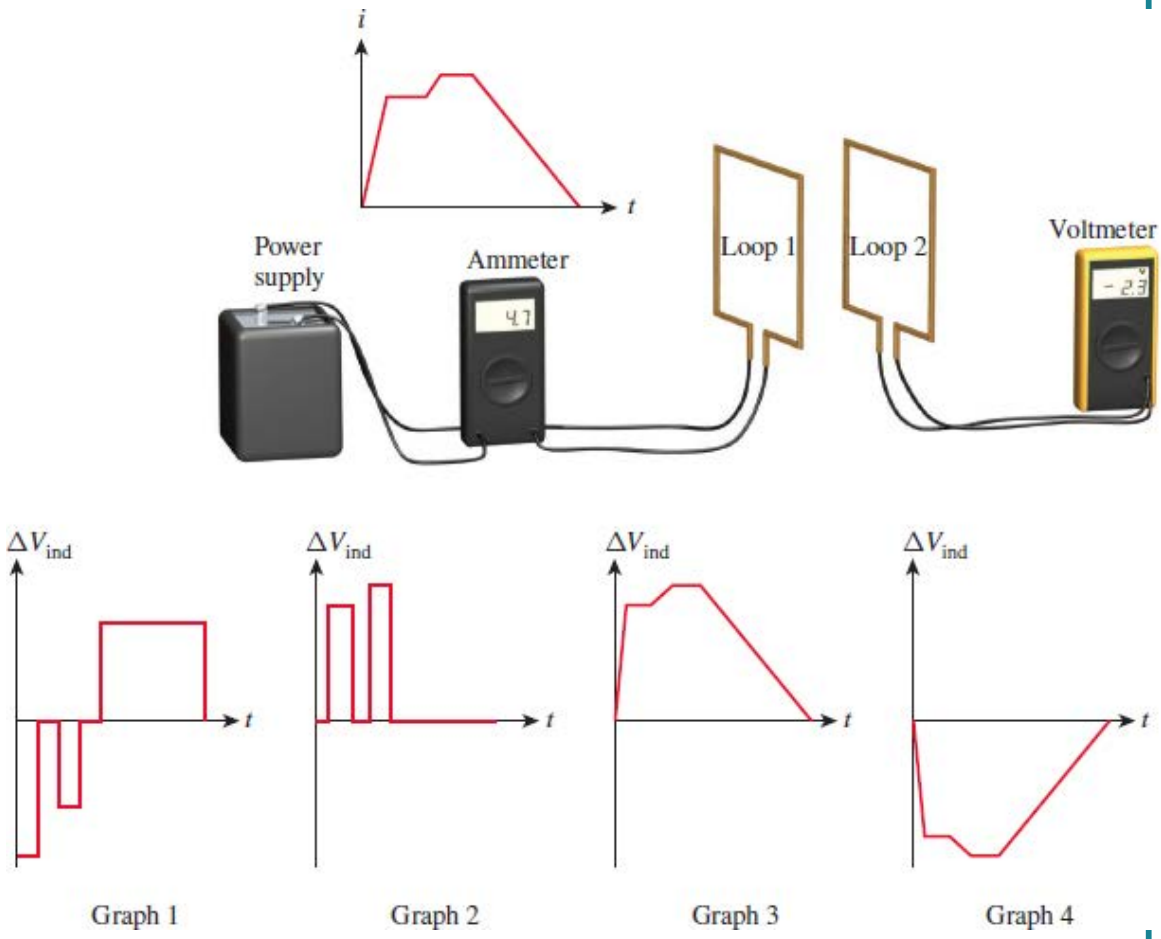
$$\begin{aligned}
\Delta V_{\text{ind}} &= -A\cos\theta\frac{dB}{dt} \\
&= -A\cos\theta\frac{d}{dt}\left[B_0(1 + (2.4\,\mathrm{s}^{-2})t^2)\right] \\
&= -AB_0\cos\theta(2(2.4\,\mathrm{s}^{-2})t) \\
&= -(0.73\,\mathrm{m}^2)(0.025\,\mathrm{T})(\cos 0^\circ)(4.8\,\mathrm{s}^{-2})t \\
&= (-0.088\mathrm{V/s})t.
\end{aligned}$$

At time $t = 2.0\,\mathrm{s}$, the induced potential difference in the coil is $\Delta V_{\text{ind}} = -0.18\,\mathrm{V}$.

An important general point is made by Example 29.1: The potential difference induced in a coil with N windings and area A is simply N times the potential difference induced in a single loop of area A. Equations 29.8 through 29.11 are valid for multiloop coils, and the only way that the number of windings enters the calculations is as a multiplier in determining the effective area of the coil.

Concept Check 29.2

A power supply is connected to loop 1 and an ammeter as shown in the figure. Loop 2 is close to loop 1 and is connected to a voltmeter. A graph of the current *i* through loop 1 as a function of time, *t,* is also shown in the figure. Which graph best describes the induced potential difference, ΔV_{ind}, in loop 2 as a function of time, *t?*



a) graph 1

b) graph 2

c) graph 3

d) graph 4

EXAMPLE 29.2 Potential Difference Induced by a Moving Loop

A rectangular wire loop of width $w = 3.1\,\text{cm}$ and depth $d_0 = 4.8\,\text{cm}$ is pulled out of the gap between two permanent magnets. A magnetic field of magnitude $B = 0.073\,\text{T}$ is present throughout the gap (Figure 29.9).

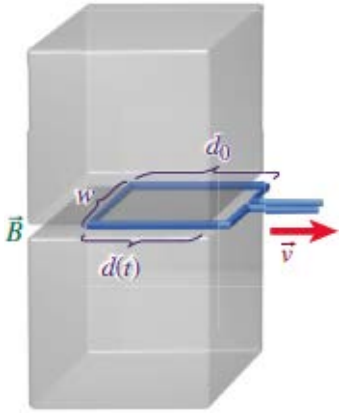


FIGURE 29.9 A wire loop (blue) is pulled out of a gap between two magnets.

PROBLEM

If the loop is removed at a constant speed of 1.6 cm/s, what is the induced voltage in the loop as a function of time?

SOLUTION

This situation corresponds to the special case of induction due to an area change, governed by equation 29.10. The magnetic field and the orientation of the loop relative to the field remain constant. We assume that the angle between the magnetic field vector and the area vector is zero. What changes is the area of the loop that is exposed to the magnetic field. With a gap as narrow as that shown in Figure 29.9, very little field occurs outside the gap, so the effective area of the loop exposed to the field is $A(t) = (w)(d(t))$, where $d(t) = d_0 - vt$ is the depth of the part

of the loop inside the magnetic field at time t. While the entire loop is still inside the gap, no voltage is produced. Letting the time of arrival of the right edge of the loop at the right end of the gap be $t = 0$, we have

$$A(t) = (w)(d(t)) = w(d_0 - vt).$$

Page 890

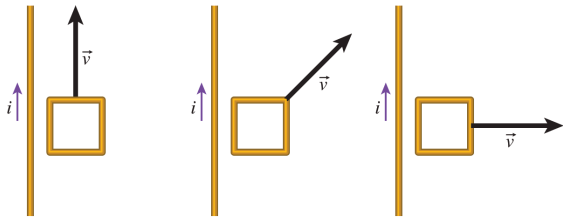
This formula holds until the left edge of the loop reaches the right end of the gap, after which the area of the loop exposed to the magnetic field is zero. The left edge arrives at time $t_\mathrm{f} = d/v = (4.8\,\mathrm{cm})/(1.6\,\mathrm{cm/s}) = 3.0\,\mathrm{s}$, and $A(t > t_\mathrm{f}) = 0$. From equation 29.10, we find

$$\begin{aligned}
\Delta V_\mathrm{ind} &= -B\cos\theta\frac{dA}{dt} \\
&= -B\cos\theta\frac{d}{dt}[w(d_0 - vt)] \\
&= wvB\cos\theta \\
&= (0.031\,\mathrm{m})(0.016\,\mathrm{m/s})(0.073\,\mathrm{T})\cos 0^\circ \\
&= 3.610^{-5}\mathrm{V}.
\end{aligned}$$

During the time interval between 0 and 3 s, a constant potential difference of 36 μV is induced, and no potential difference is induced outside this time interval.

Concept Check 29.3

A long wire carries a current, *i,* as shown in the figure. A square loop moves in the same plane as the wire, as indicated. In which cases will the loop have an induced current?



a) cases 1 and 2

b) cases 1 and 3

c) cases 2 and 3

d) None of the loops will have an induced current.

e) All of the loops will have an induced current.

29.3 Lenz's Law

Lenz's Law provides a rule for determining the direction of an induced current in a loop. An induced current will have a direction such that the magnetic field *due* to the induced current *opposes* the change in the magnetic flux that *induces* the current. The direction of the induced current can be used to determine the locations of higher and lower potential.

Let's apply Lenz's Law to the situations described in Section 29.1. The physical situation shown in Figure 29.2a involves moving a magnet toward a loop with the north pole pointed toward the loop. In this case, the magnetic field lines point away from the north pole of the magnet. As the magnet moves toward the loop, the magnitude of the magnetic field within the loop, in the direction pointing toward the loop, increases as depicted in Figure 29.10a. Lenz's Law states that the current induced in the loop tends to oppose the change in magnetic flux. The induced magnetic field, $\vec{B}_{\text{ind}}$, then points in the opposite direction from that of the field due to the magnet.

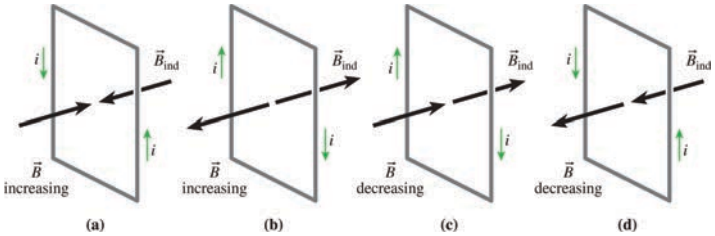


FIGURE 29.10 Relationship of an external magnetic field, $\vec{B}$, the induced current, *i*, and the magnetic field, $\vec{B}_{\text{ind}}$, resulting from that induced current: (a) An increasing magnetic field pointing to the right induces a current that creates a magnetic field pointing to the left. (b) An increasing magnetic field pointing to the left induces a current that creates a magnetic field pointing to the right. (c) A decreasing magnetic field pointing to the right induces a current that creates a magnetic field pointing to the right. (d) A decreasing magnetic field pointing to the left induces a current that creates a magnetic field pointing to the left.

In Figure 29.2b, a magnet is moved toward a loop with the south pole pointed toward the loop. In this case, the magnetic field lines point toward the south pole of the magnet. As the magnet moves toward the loop, the magnitude of the field in the direction pointing toward the south pole increases, as depicted in Figure 29.10b. Lenz's Law states that the induced current creates a magnetic field that tends to oppose the increase in magnetic flux. This induced field points in the opposite direction from that of the field lines due to the magnet.

Similarly, Figure 29.10c and Figure 29.10d represent the physical situations depicted in Figure 29.3a and Figure 29.3b, respectively. In these two cases, the magnitude of the magnetic flux is decreasing, and a current is induced that produces a magnetic field opposing this decrease. In both cases, a current is induced in the loop that creates a

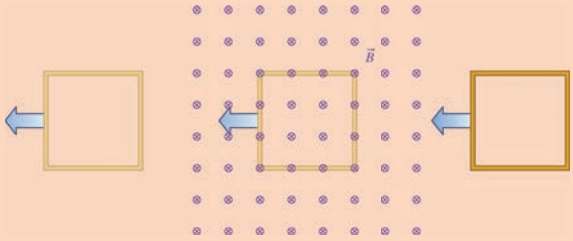
magnetic field pointing in the same direction as the magnetic field from the magnet.

Page 891

For two loops with one having a changing current, Lenz's Law is applied in the same way. The increasing current in loop 1 in Figure 29.4 induces a current in loop 2 that creates a magnetic field opposing the increase in magnetic flux, as depicted in Figure 29.10b. The decreasing current in loop 1 in Figure 29.5 induces a current in loop 2 that creates a magnetic field opposing the decrease in magnetic flux, as depicted in Figure 29.10d.

Self-Test Opportunity 29.2

A square conducting loop with very small resistance is moved at constant speed from a region with no magnetic field through a region of constant magnetic field and then into a region with no magnetic field, as shown in the figure. As the loop enters the magnetic field, what is the direction of the induced current? As the loop leaves the magnetic field, what is the direction of the induced current?



Self-Test Opportunity 29.3

Suppose Lenz's Law instead stated that the induced magnetic field augments the magnetic flux, meaning that Faraday's Law of Induction would be written as $\Delta V_{\text{ind}} = +d\Phi_B/dt$, that is, with a positive instead of a negative sign. What would be the consequences? Can you explain why this would lead to a contradiction?

Eddy Currents

Let's consider two pendulums, each with a nonmagnetic conducting metal plate at the end that is designed to pass through the gap between strong permanent magnets (Figure 29.11). One metal plate is solid, and the other has slots cut in it. The pendulums are pulled to one side and released. The pendulum with the solid metal plate stops in the gap, while the slotted plate passes through the magnetic field, only slowing slightly. This demonstration illustrates the very important phenomenon of induced **eddy currents.** As the pendulum with the solid plate enters the magnetic field between the magnets, Lenz's Law says that the changing magnetic flux induces currents that tend to oppose the change in flux. These currents produce induced magnetic fields opposing the external field that created the currents. These induced magnetic fields interact with the external magnetic field (via their spatial gradients) to stop the pendulum. Larger induced currents produce larger induced magnetic fields and thus lead to more rapid deceleration of the pendulum. In the slotted plate, the induced eddy currents are broken up by the slots, and the slotted plate passes through the magnetic field, only slowing slightly. Eddy currents are not like the undirected and uniform current induced in the loop in Example 29.2 but are instead swirling eddies like those seen in turbulent flowing water.

FIGURE 29.11 Two pendulums, one consisting of an arm and a solid metal plate and a second consisting of an arm and a slotted metal plate. The five frames are in time sequence from left to right, with the two pendulums starting their motion together in the second frame from the left. The pendulum with the solid plate stops in the gap, while the pendulum with the slotted plate passes through the gap.

W. Bauer and G. D. Westfall

Where does the energy contained in the motion of the pendulum with the solid plate in Figure 29.11 go—in other words, how do the eddy currents stop the pendulum? The answer is that the eddy currents disperse heat in the metal because of its finite resistance, as discussed in Chapter 25. The stronger the induced eddy currents are, the more rapidly energy is converted from the pendulum's motion into heat. This is why the slotted plate, with its much smaller induced eddy currents, is only slowed slightly as it passes through the gap between the magnets (although the slowing will stop it eventually).

Eddy currents are often undesirable, forcing equipment designers to minimize them by segmenting or laminating electrical devices that must operate in an environment of changing magnetic fields. However, eddy currents can also be useful and are employed in certain practical applications, such as the brakes of train cars.

Metal Detector

Passing through metal detectors, especially at airports, is an unavoidable part of life these days. A metal detector works by using electromagnetic induction, often called *pulse induction*. A metal detector has a transmitter coil and a receiver coil. An alternating current is applied to the transmitter coil, which then produces an alternating magnetic field. (*Alternating* means varying as a function of time between positive and negative values. Chapter 30 will provide more precise definitions, physical consequences, and mathematical details concerning alternating current.) As the magnetic field of the transmitter coil increases and decreases, it induces a current in the receiving coil that tends to counteract the change in the magnetic flux produced by the transmitter coil. The induced current in the receiver coil is measured when nothing but air is between the coils. If a conductor in the form of a metal object passes between transmitter and receiver coils, a current will be induced in the metal object in the form of eddy currents. These eddy currents will act to counter the increases and decreases of the changing magnetic field produced by the transmitter coil, which in turn induces a current in the receiver coil that tends to counter the increase in current in the metal. The measured current in the receiver coil will be less when any metal object is present between the two coils.

A schematic diagram of an airport metal detector is shown in Figure 29.12. A transmitter coil and a receiver coil are located on opposite sides of an entry door. The person or object to be scanned passes through the door between the two coils. Suppose that the current in the transmitter coil is flowing in the direction shown and increasing. A current will be induced in the metal plate in the opposite direction and will tend to oppose the increase in the current in the transmitter coil. The increasing current in the metal plate will induce a current in the receiver coil that is in the opposite direction and tends to oppose the increase in the current in the metal plate (not shown in the diagram). Thus, the metal plate induces a current in the receiver coil that flows in the same direction as the current in the transmitter coil. Without the metal plate, the increasing current in the transmitter coil induces a current in the opposite direction in the receiver coil that tends to oppose the increase in the current in the transmitter coil (as shown in the diagram). Thus, the overall effect of the metal plate in the metal detector is to decrease the

observed current in the receiver coil. The metal object does not have to be a flat plate; any piece of metal, provided it is large enough, will have currents induced in it that can be detected by measuring the induced current in the receiver coil.

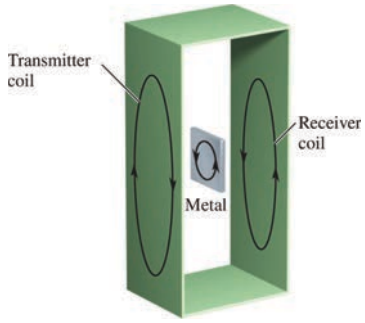


FIGURE 29.12
Schematic diagram of an airport metal detector.

Metal detectors are also used to control traffic lights. In this application, a rectangular wire loop, which serves as both transmitter and receiver coil, is embedded in the road surface. A pulse of current is passed through the loop, which induces eddy currents in any metal near the loop. The current in the loop is measured after the current pulse is completed. When a car moves onto the road surface above the loop, eddy currents induced in the metal of the car cause a different current to be measured between pulses, which then triggers the traffic light to switch to green (after an appropriate delay to allow other vehicles to clear the intersection, of course!). On older road surfaces, you can often see rectangular-shaped scars in the asphalt resulting from retrofitting intersections with these induction loops.

Induced Potential Difference on a Wire Moving in a Magnetic Field

Consider a conducting wire of length ℓ moving with constant velocity $\vec{v}$ perpendicular to a constant magnetic field, $\vec{B}$ directed into the page (Figure 29.13). The wire is oriented so that it is perpendicular to the velocity and to the magnetic field. The magnetic field exerts a force, $\vec{F}_B$, on the conduction electrons in the wire, causing them to move downward. This motion of the electrons produces a net negative charge at the bottom end of the wire and a net positive charge at the top end of the wire. This charge separation produces an electric field, $\vec{E}$ which exerts on the conduction electrons a force, $\vec{F}_E$, that tends to cancel the magnetic force. After some time, the two forces become equal in magnitude (but opposite in direction) producing a zero net force:

$$F_B = evB = F_E = eE. \tag{29.12}$$

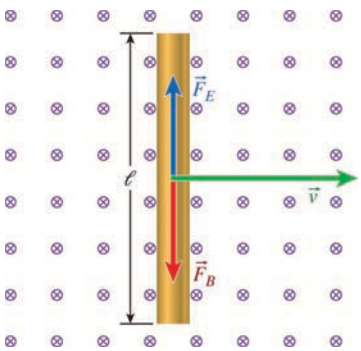

FIGURE 29.13 A moving conductor in a constant magnetic field. The magnetic and electric forces on the conduction electrons are shown.

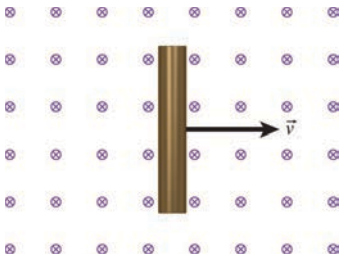
Thus, the induced electric field can be expressed by

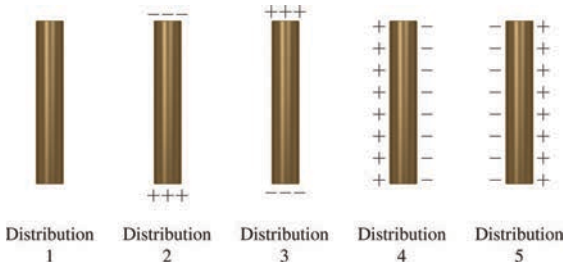
$$E = vB. \qquad \textbf{(29.13)}$$

Concept Check 29.4

A metal bar is moving with constant velocity $\vec{v}$ through a uniform magnetic field pointing into the page, as shown in the figure.



Which of the following most accurately represents the charge distribution on the surface of the metal bar?



a) distribution 1

b) distribution 2

c) distribution 3

d) distribution 4

e) distribution 5

Because the electric field is constant in the wire, it produces a potential difference between the two ends of the wire given by

$$E = \frac{\Delta V_{\text{ind}}}{\ell} = vB. \tag{29.14}$$

The induced potential difference between the ends of the wire is then

$$\Delta V_{\text{ind}} = v\ell B. \tag{29.15}$$

This is one form of motional emf, mentioned in Section 29.2.

EXAMPLE 29.3 Satellite Tethered to a Space Shuttle

In 1996, the Space Shuttle *Columbia* deployed a tethered satellite on a wire out to a distance of 20. km (Figure 29.14). The wire was oriented perpendicular to the Earth's magnetic field at that point, and the magnitude of the field was $B = 5.1 \cdot 10^{-5}$ T. *Columbia* was traveling at a speed of 7.6 km/s.

(a)

(b)

FIGURE
29.14 (a) An artists's conception of the Space Shuttle *Columbia* and the tethered satellite. (b) A Photograph of the tethered satellite being deployed from *Columbia.*

NASA

PROBLEM

What was the potential difference induced between the ends of the wire?

SOLUTION

We can use equation 29.15 to determine the induced potential difference between the ends of the wire. The length of the wire is $L = 20.0\,\text{km}$, and the speed of the wire through the magnetic field of the Earth $\left(B = 5.1 \cdot 10^{-5}\,\text{T}\right)$ is the same as the speed of the Space Shuttle, which is $v = 7.6\,\text{km/s}$. Thus, we have

$$\Delta V_{\text{ind}} = vLB = \left(7.6 \cdot 10^{3}\,\text{m/s}\right)\left(20.0 \cdot 10^{3}\,\text{m}\right)\left(5.1 \cdot 10^{-5}\,\text{T}\right.$$

The astronauts on the Space Shuttle measured a current of about 0.5 A at a voltage of 3.5 kV. The circuit consisted of the deployed wire and ionized atoms in space as the return path for the current. The wire broke just as the deployment length reached 20 km, but the generation of electric current from the motion of a spacecraft had been demonstrated.

Solved Problem 28.2 concerned an electromagnetic rail accelerator. The next example focuses on the phenomenon of induction in a similar system.

EXAMPLE 29.4 Pulled Conducting Rod

A conducting rod is pulled horizontally by a constant force of magnitude, $F = 5.00\,\text{N}$, along a set of conducting rails separated by a distance $a = 0.500\,\text{m}$ (Figure 29.15). The two rails are connected, and no friction occurs between the rod and the rails. A uniform magnetic field with magnitude $B = 0.500\,\text{T}$. is directed into the page. The rod moves at constant speed, $v = 5.00\,\text{m/s}$.

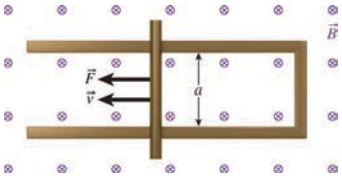


FIGURE 29.15 A conducting rod is pulled along two conducting rails with a constant velocity in a constant magnetic field directed into the page.

PROBLEM

What is the magnitude of the induced potential difference in the loop formed by the connected rails and the moving rod?

SOLUTION

The induced potential difference is given by equation 29.10, which applies to a loop in a magnetic field when the angle and magnetic field are held constant and the area of the loop changes with time:

$$\Delta V_{\text{ind}} = -B\cos\theta\frac{dA}{dt}.$$

In this case, $\theta = 0$ and $B = 0.500\,\text{T}$. The area of the loop is increasing with time. We can express the area of the loop in terms of A_0, the area before the rod started moving, and an additional area given by the product of the speed of the loop and the time for which the loop has been moving times the distance, a, between the rails:

$$A = A_0 + a(vt) = A_0 + vta.$$

The change of the loop's area as a function of time is then

$$\frac{dA}{dt} = \frac{d}{dt}(A_0 + vta) = va.$$

Thus, the magnitude of the induced potential difference is

$$\Delta V_{\text{ind}} = \left| -B\cos\theta \frac{dA}{dt} \right| = vaB. \qquad \text{(i)}$$

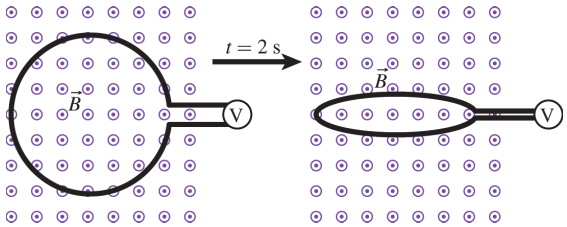
Inserting the numerical values, we obtain

$$\Delta V_{\text{ind}} = (5.00\,\text{m/s})(0.500\,\text{m})(0.500\,\text{T}) = 1.25\,\text{V}.$$

Note that equation (i), $\Delta V_{\text{ind}} = vaB$, which we derived from Faraday's Law of Induction, has the same form as equation 29.15 for the potential difference induced in a wire moving in a magnetic field, which was derived using the magnetic force on moving charges.

Concept Check 29.5

A wire loop is placed in a uniform magnetic field. Over a period of 2 s, the loop is shrunk. Which statement about the induced potential difference is correct?



a) There will be some induced potential difference.

b) There will be no induced potential difference because the loop changes size along one axis and not the other.

c) There will be no induced potential difference because the loop is not closed.

d) There will be no induced potential difference because the loop is shrinking.

SOLVED PROBLEM 29.1 Power from a Rotating Rod

A conducting rod with length $\ell = 8.17\,\text{cm}$ rotates around one of its ends in a uniform magnetic field that has a magnitude $B = 1.53\,\text{T}$ and is directed parallel to the rotation axis of the rod (Figure 29.16). The other end of the rod slides on a frictionless conducting ring. The rod makes 6.00 revolutions per second. A resistor, $R = 1.63\,\text{m}\Omega$, is connected between the rotating rod and the conducting ring.

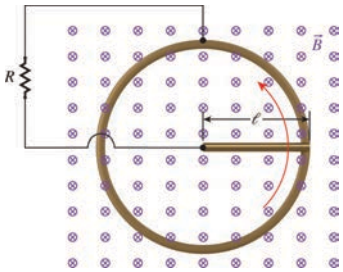


FIGURE 29.16 Conducting rod rotating in a constant magnetic field directed into the page.

PROBLEM

What is the power dissipated in the resistor due to magnetic induction?

SOLUTION

THINK

We can calculate the potential difference induced in a conductor of length ℓ moving with speed v perpendicular to a magnetic field of magnitude B. However, the rotating rod has different speeds at different radii, $v(r)$. Therefore, we must calculate the potential difference induced in the rod by integrating $Bv(r)$ over the length of the rod. From the induced potential difference, we can calculate the power dissipated in the resistor.

SKETCH

Figure 29.17 shows the speed as a function of radius for the conducting rod.

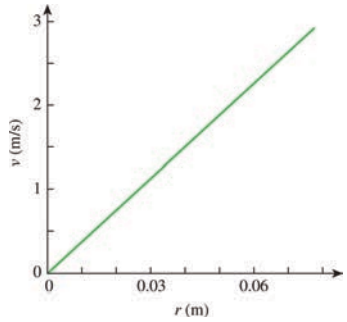

FIGURE 29.17
Speed as a function of radius for the conducting rod.

RESEARCH

The potential difference, ΔV_{ind}, induced on a conductor of length ℓ moving with speed v perpendicular to a magnetic field of magnitude B is given by equation 29.15:

$$\Delta V_{\text{ind}} = v\ell B.$$

However, in this case, different parts of the conducting rod are moving at different speeds. We can express the speed of the different parts of the rod as a function of distance r from the axis of rotation:

$$v(r) = \frac{2\pi r}{T},$$

where $v(r)$ is the speed of the rod at distance r and T is the period of the rotation. We can then find the potential difference induced in the rotating rod over its length, ℓ:

$$\Delta V_{\text{ind}} = \int_0^{\ell} v(r) B dr. \qquad \text{(i)}$$

The power dissipated in the resistor is given by

$$P = \frac{\Delta V_{\text{ind}}^2}{R}. \qquad \text{(ii)}$$

SIMPLIFY

Evaluating the definite integral in equation (i) gives

$$\Delta V_{\text{ind}} = \int_0^{\ell} \left(\frac{2\pi r}{T} \right) B dr = \frac{2\pi B}{T} \frac{\ell^2}{2} = \frac{\pi B \ell^2}{T}. \qquad \text{(iii)}$$

Substituting the expression for ΔV_{ind} from equation (iii) into equation (ii) leads to an expression for the power dissipated in the resistor:

$$P = \frac{\left(\pi B \ell^2 / T\right)^2}{R} = \frac{\pi^2 B^2 \ell^4}{R T^2}.$$

CALCULATE

The period is the inverse of the frequency. The frequency is $f = 6.00\ \text{Hz}$, so the period is

$$T = \frac{1}{f} = \frac{1}{6.00}\ \text{s}.$$

Putting in the numerical values gives us

$$P = \frac{\pi^2 B^2 \ell^4}{RT^2} = \frac{\pi^2 (1.53\ \text{T})^2 (0.0817\ \text{m})^4}{(1.63 \cdot 10^{-3}\ \Omega)\left(\frac{1}{6.00}\ \text{s}\right)^2} = 22.7345\ \text{W}.$$

ROUND

We report our result to three significant figures:

$$P = 22.7\ \text{W}.$$

DOUBLE-CHECK

To double-check our result, we consider a conducting rod of the same length moving perpendicularly to the same magnetic field with a speed equal to the speed of the center of the rotating rod, which is

$$v(\ell/2) = \frac{2\pi(\ell/2)}{T} = \frac{2\pi L}{2T} = \frac{2\pi(0.0817\ \text{m})}{2\left(\frac{1}{6.00}\ \text{s}\right)} = 1.54\text{m/s}.$$

The induced potential difference across the conducting rod moving perpendicularly would be

$$\Delta V_{\text{ind}} = v\ell B = (1.54\ \text{m/s})(0.0817\ \text{m})(1.53\ \text{T}) = 0.193\ \text{V}.$$

The power dissipated in the resistor would then be

$$P = \frac{\Delta V_{\text{ind}}^2}{R} = \frac{(0.193\ \text{V})^2}{1.63 \cdot 10^{-3}\ \Omega} = 22.9\ \text{W},$$

which is close to our result within rounding error. Thus, our result seems reasonable.

Finally, note that there is a possible additional source of potential difference between the two ends of the rod. Our solution assumed that the potential difference between the two ends is due exclusively to the magnetic induction. However, all charge carriers inside the rod are forced on a circular path due to the rotation. This requires a centripetal force, which should in principle reduce the potential difference between the two ends of the rod. However, for the small angular velocity of the rod in this problem, this effect is negligible.

29.4 Generators and Motors

The third special case of the basic induction process described in Section 29.2 is by far the most interesting technologically. In this case, the angle between the conducting loop and the magnetic field is varied over time, while keeping the area of the loop as well as the magnetic field strength constant. In this situation, equation 29.11 can be used to apply Faraday's Law of Induction to the generation and application of electric current. A device that produces electric current from mechanical motion is called an **electric generator.** A device that produces mechanical motion from electric current is called an **electric motor.** Figure 29.18 shows a very simple electric motor.

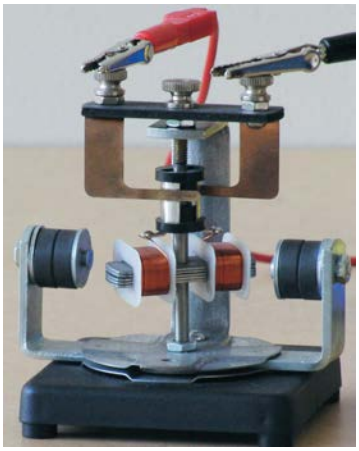

FIGURE 29.18 A very simple electric motor used for lecture demonstrations. It consists of a pair of permanent magnets on the outside and two solenoids, through which current is sent, on the inside.

W. Bauer and G. D. Westfall

A simple generator consists of a loop forced to rotate in a fixed magnetic field. The force that causes the loop to rotate can be supplied by hot steam running over a turbine, as occurs in nuclear and coal-fired power plants. (Power plants actually use multiple loops in order to increase the power output.) On the other hand, the loop can be made to rotate by flowing water or wind to generate electricity in a pollution-free way.

Figure 29.19 shows two types of simple generators. In a direct-current generator, the rotating loop is connected to an external circuit through a split commutator ring, as illustrated in Figure 29.19a. As the loop turns, the connection is reversed twice per revolution, so the induced potential difference always has the same sign. Figure 29.19b shows a similar arrangement used to produce an alternating current. An alternating current is a current that varies in

time between positive and negative values, with the variation often showing a sinusoidal form. Each end of the loop is connected to the external circuit through its own solid slip ring. Thus, this generator produces an induced potential difference that varies from positive to negative and back. A generator that produces alternating voltages and the resulting alternating current is also called an **alternator.** Figure 29.20 shows the induced potential difference as a function of time for each type of generator.

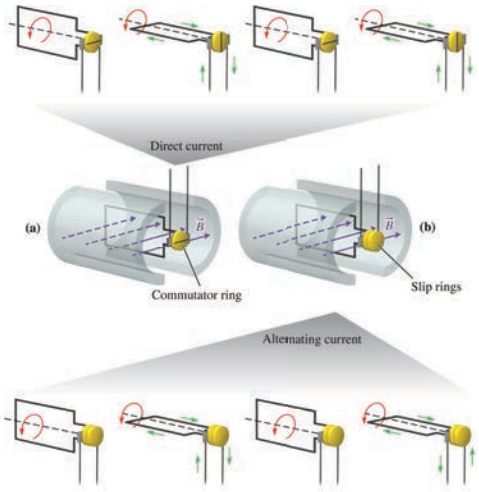

FIGURE 29.19 (a) A simple direct-current (DC) generator/motor. (b) A simple alternating-current (AC) generator/motor.

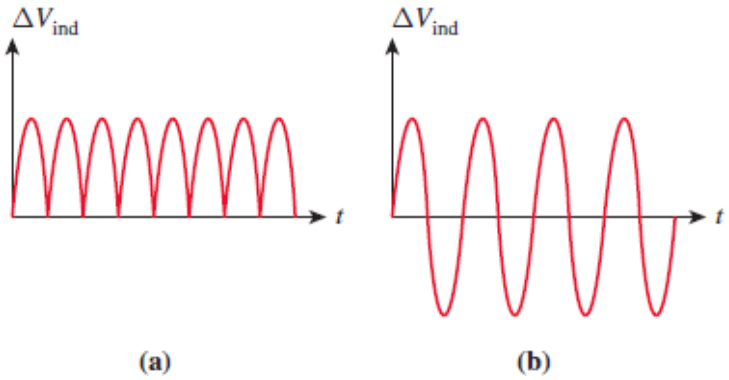

FIGURE 29.20 Induced potential difference as a function of time for (a) a simple direct-current generator; (b) a simple alternating-current generator.

The devices in Figure 29.19 could also be used as motors by supplying current to the loop and using its resulting motion to do work.

Self-Test Opportunity 29.4

A generator is operated by rotating a coil of N turns in a constant magnetic field of magnitude B at a frequency f. The resistance of the coil is R, and the cross-sectional area of the coil is A. Decide whether each of the following statements is true or false.

a) The average induced potential difference doubles if the frequency, f, is doubled.

b) The average induced potential difference doubles if the resistance, R, is doubled.

c) The average induced potential difference doubles if the magnetic field's magnitude, B, is doubled.

d) The average induced potential difference doubles if the area, A, is doubled.

Real-world generators and motors are considerably more complex than the simple examples in Figure 29.19. For example, instead of permanent magnets, current flowing in coils creates the required magnetic field. Many closely spaced loops are employed to make more efficient use of the rotational motion. Multiple loops also resolve the problem that a simple, one-loop motor could stop in a position where the current through the loop produces no torque. The magnetic field may also change with time in phase with the rotating loop. In some generators and motors, the loops (coils) are fixed and the magnet rotates.

Regenerative Braking

Hybrid cars are propelled by a combination of gasoline power and electrical power. One attractive feature of a hybrid vehicle is that it is capable of **regenerative braking.** When the brakes are used to slow or stop a nonhybrid vehicle, the kinetic energy of the vehicle is turned into heat in the brake pads. This heat dissipates into the environment, and energy is lost. In a hybrid car, the brakes are connected to an electric motor (Figure 29.21), which functions as a generator, charging the car's battery. Thus, the kinetic energy of the car is partially recovered during braking, and this energy can later be used to propel the car, contributing to its efficiency and greatly increasing its gas mileage in stop-and-go driving. Of course, all-electric vehicles also take advantage of regenerative braking.

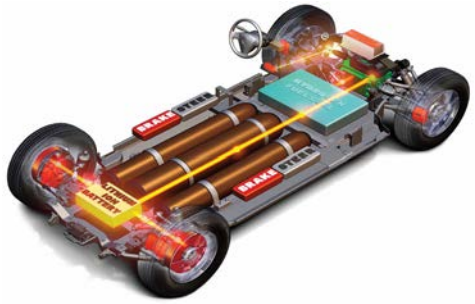

FIGURE 29.21
Regenerative brakes on the rear wheels of a hybrid vehicle are used to slow the vehicle and convert the vehicle's kinetic energy into electrical energy that is stored in a lithium ion battery.

©General Motors, LLC 2012

29.5 Induced Electric Field

Faraday's Law of Induction states that a changing magnetic flux produces an induced potential difference, which can lead to an induced current. What are the consequences of this effect?

Consider a positive charge q moving in a circular path with radius r in an electric field, $\vec{E}$. The work done on the charge is equal to the integral of the scalar product of the force and the differential displacement vector. For now, let's assume that the electric field $\vec{E}$ is constant, that it has field lines that are circular, and that the charge moves along one of these lines. In one revolution of the charge, the work done on it is given by

$$\oint \vec{F} \bullet \vec{ds} = \oint q\vec{E} \bullet \vec{ds} = \oint q \cos 0^\circ E ds = qE \oint ds = qE(2\pi r)$$

Since the work done by a constant electric field is $\Delta V_{\text{ind}} q$, we get

$$\Delta V_{\text{ind}} = 2\pi r E.$$

We can generalize this result by considering the work done on a charge q moving along an arbitrary closed path:

$$W = \oint \vec{F} \bullet \vec{ds} = q \oint \vec{E} \bullet \vec{ds}.$$

Again substituting $\Delta V_{\text{ind}} q$ for the work done, we obtain

$$\Delta V_{\text{ind}} = \oint \vec{E} \bullet \vec{ds}. \qquad \textbf{(29.16)}$$

Now we can express the induced potential difference in a different way by combining equation 29.5 with equation 29.16:

$$\oint \vec{E} \bullet \vec{ds} = -\frac{d\Phi_B}{dt}. \qquad \textbf{(29.17)}$$

Equation 27.17 states that a changing magnetic flux induces an electric field. This equation can be applied to any closed path in a changing magnetic field, even if no conductor exists in the path.

29.6 Inductance of a Solenoid

Consider a long solenoid with N turns carrying a current, i. This current creates a magnetic field in the center of the solenoid, resulting in a magnetic flux, Φ_B. The same magnetic flux goes through each of the N windings of the solenoid. It is customary to define the **flux linkage** as the product of the number of windings and the magnetic flux, or $N\Phi_B$. Equation 29.1 defined the magnetic flux as $\Phi_B = \iint \vec{B} \bullet d\vec{A}$. Inside the solenoid, the magnetic field vector and the surface normal vector, $d\vec{A}$, are parallel. And we saw in Chapter 28 that the magnitude of the magnetic field inside the solenoid is $B = \mu_0 ni$, where $\mu_0 = 4\pi \cdot 10^{-7}\,\mathrm{T\,m/A}$ is the magnetic permeability of free space, i is the current, and n is the number of windings per unit length ($n = N/\ell$). Therefore, the magnetic flux in the interior of a solenoid is proportional to the current flowing through the solenoid, which trivially means that the flux linkage is also proportional to the current. We can express this proportionality as

$$N\Phi_B = Li, \tag{29.18}$$

using a proportionality constant, L, called the **inductance.** (*Note:* Use of the letter L to represent the inductance is the convention. Although L is also used for the physical quantity of length and the physical quantity of angular momentum, inductance is not connected to either of these in any way.)

Inductance is a measure of the flux linkage produced by a solenoid per unit of current. The unit of inductance is the **henry** (H), named after American physicist Joseph Henry (1797–1878) and given by

$$[L] = \frac{[\Phi_B]}{i} \Rightarrow 1\,\mathrm{H} = \frac{1\,\mathrm{T\,m^2}}{1\,\mathrm{A}}. \qquad \textbf{(29.19)}$$

The definition of the henry given in equation 29.19 means that the magnetic permeability of free space can also be given as $\mu_0 = 4\pi \cdot 10^{-7}\,\mathrm{H/m}$.

Now let's use equation 29.18 to find the inductance of a solenoid with cross-sectional area A and length ℓ. The flux linkage for this solenoid is

$$N\Phi_B = (n\ell)(BA), \qquad \textbf{(29.20)}$$

where n is the number of turns per unit length and B is the magnitude of the magnetic field inside the solenoid. Thus, the inductance is given by

$$L = \frac{N\Phi_B}{i} = \frac{(n\ell)(\mu_0 n i)(A)}{i} = \mu_0 n^2 \ell A. \qquad \textbf{(29.21)}$$

This expression for the inductance of a solenoid is good for long solenoids because fringe field effects at the ends of such a solenoid are small. You can see from equation 29.21 that the inductance of a solenoid depends only on the geometry (length, area, and number of turns) of the device. This dependence of inductance on geometry alone holds for all coils and solenoids, just as the capacitance of any capacitor depends only on its geometry.

Any solenoid has an inductance, and when a solenoid is used in an electric circuit, it is called an *inductor,* simply because its inductance is its most important property as far as the current flow is concerned.

29.7 Self-Induction and Mutual Induction

Consider the situation in which two coils, or inductors, are close to each other, and a changing current in the first coil produces a magnetic flux in the second coil. However, the changing current in the first coil also induces a potential difference in that coil, and thus the magnetic field from that coil also changes. This phenomenon is called **self-induction.** The resulting potential difference is termed the *self-induced potential difference*. Changing the current in the first coil also induces a potential difference in the second coil. This phenomenon is called **mutual induction.**

According to Faraday's Law of Induction, the self-induced potential difference for any inductor is given by

$$\Delta V_{\text{ind},L} = -\frac{d(N\Phi_B)}{dt} = -\frac{d(Li)}{dt} = -L\frac{di}{dt}, \quad \textbf{(29.22)}$$

where equation 29.18 allows us to substitute Li for $N\Phi_B$. Thus, in any inductor, a self-induced potential difference appears when the current changes with time. This self-induced potential difference depends on the time rate of change of the current and the inductance of the device.

Lenz's Law provides the direction of the self-induced potential difference. The negative sign in equation 29.22 provides the clue that the induced potential difference always opposes any change in current. For example, Figure 29.22a shows current flowing through an inductor and increasing with time. Thus, the self-induced potential difference will oppose the increase in current. In Figure 29.22b, the current flowing through an inductor is decreasing with time. Thus, a self-induced potential difference will oppose the decrease in current. We have assumed that these inductors are ideal inductors; that is, they have no resistance. All induced potential differences manifest themselves across the connections of the inductor. Inductors with resistance are treated in Section 29.8.

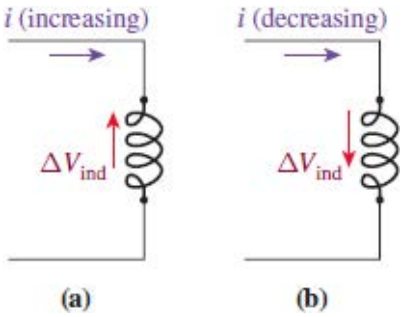

FIGURE 29.22
(a) Self-induced potential difference in an inductor when the current is increasing. (b) Self-induced potential difference in an inductor when the current is decreasing.

Now let's consider two adjacent coils with their central axes aligned (Figure 29.23). Coil 1 has N_1 turns, and coil 2 has N_2 turns. The current in coil 1 produces a magnetic field, $\vec{B}_1$. The flux linkage in coil 2 resulting from the magnetic field in coil 1 is $N_2\Phi_{1\to2}$. The mutual inductance, $M_{1\to2}$, of coil 2 due to coil 1 is defined as

$$M_{1\to2} = \frac{N_2\Phi_{1\to2}}{i_1}. \qquad \textbf{(29.23)}$$

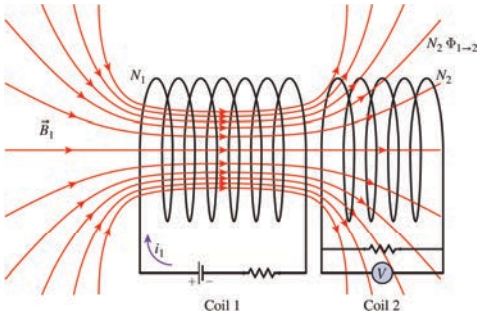

FIGURE 29.23 Coil 1 has current i_1 Coil 2 has a voltmeter capable of measuring small, induced potential differences.

Multiplying both sides of equation 29.23 by i_1 yields

$$i_1 M_{1\to2} = N_2 \Phi_{1\to2}.$$

If the current in coil 1 changes with time, we can write

$$M_{1\to2}\frac{di}{dt} = N_2\frac{d\Phi_{1\to2}}{dt}.$$

The right-hand side of this equation is similar to the right-hand side of Faraday's Law of Induction (equation 29.5). Thus, we can write

$$\Delta V_{\text{ind},2} = -M_{1\to2}\frac{di_1}{dt}. \qquad \textbf{(29.24)}$$

Now let's reverse the roles of the two coils (Figure 29.24). The current, i_2, in coil 2 produces a magnetic field, $\vec{B}_2$. The flux linkage in coil 1 resulting from the magnetic field in coil 2 is $N_1\Phi_{2\to1}$. Using the same analysis we applied to determine the mutual inductance of coil 2 due to coil 1, we find

$$\Delta V_{\text{ind},1} = -M_{2\to1}\frac{di_2}{dt}, \qquad \textbf{(29.25)}$$

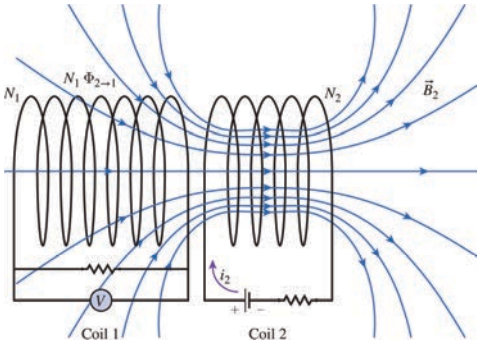

FIGURE 29.24 Coil 2 has current i_2, Coil 1 has a voltmeter capable of measuring small, induced potential differences

where $M_{2\to1}$ is the mutual inductance of coil 1 due to coil 2.

We see that the potential difference induced in one coil is proportional to the change of current in the other coil. The proportionality constant is the mutual induction. If we switched the indexes 1 and 2 and repeated the entire analysis of the coils' effects on each other, we could show that

$$M_{1\to2} = M_{2\to1} = M.$$

We can then rewrite equations 29.24 and 29.25 as

$$\Delta V_{\text{ind},2} = -M\frac{di_1}{dt} \tag{29.26}$$

and

$$\Delta V_{\text{ind},1} = -M\frac{di_2}{dt}, \tag{29.27}$$

where M is the **mutual inductance** between the two coils. The SI unit of mutual inductance is the henry. One major application of mutual inductance is in transformers, which are discussed in Chapter 30.

SOLVED PROBLEM 29.2 Mutual Induction of a Solenoid and a Coil

A long solenoid with a circular cross section of radius $r_1 = 2.80$ cm and $n = 290$ turns/cm is inside and coaxial with a short coil that has a circular cross section of radius $r_2 = 4.90$ cm and $N = 31$ (Figure 29.25a). The current in the solenoid is increased at a constant rate from zero to $i = 2.20$ A over a time interval of 48.0 ms.

PROBLEM

What is the potential difference induced in the short coil while the current is changing?

SOLUTION

THINK

The potential difference induced in the short coil is due to the changing current flowing in the solenoid. According to equation 29.23, the mutual inductance of the short coil due to the solenoid is the number of turns in the short coil times the magnetic flux of the solenoid, divided by the current flowing in the solenoid. Having determined the mutual inductance, we can then calculate the potential difference induced in the short coil.

SKETCH

Figure 29.25b shows a view of the two coils looking down their central axis.

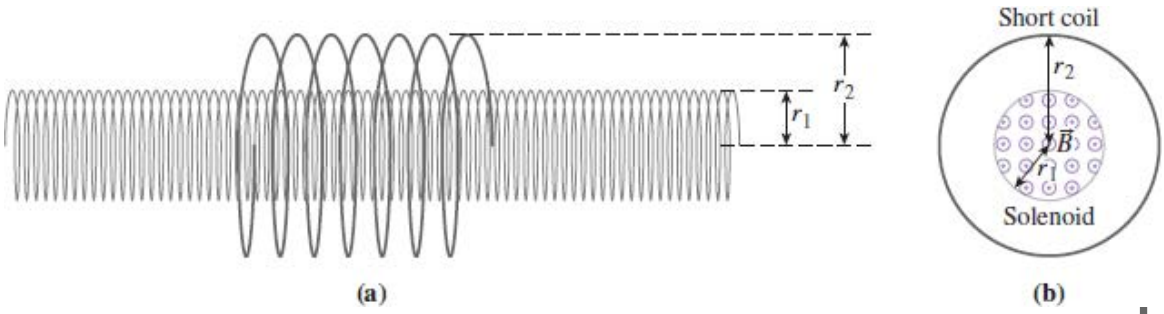

FIGURE 29.25 (a) A long solenoid of radius r_1 inside a short coil of radius r_2. (b) View of the two coils looking down the central axis.

RESEARCH

We can formulate the mutual inductance between the coil and the solenoid as

$$M = \frac{N\Phi_{\mathrm{s}\to\mathrm{C}}}{i}, \qquad \text{(i)}$$

where N is the number of turns in the short coil, $N\Phi_{\mathrm{s}\to\mathrm{C}}$ is the flux linkage in the coil resulting from the magnetic field of the solenoid, and i is the current in the solenoid. The flux can be expressed as

$$\Phi_{\mathrm{s}\to\mathrm{c}} = BA, \qquad \text{(ii)}$$

where B is the magnitude of the magnetic field inside the solenoid and A is its cross-sectional area. Recall from Chapter 28 that for a solenoid, the magnitude of the magnetic field is

$$B = \mu_0 n i,$$

where n is the number of turns per unit length. The cross-sectional area of the solenoid is

$$A = \pi r_1^2. \qquad \text{(iii)}$$

The potential difference induced in the short coil is then

$$\Delta V_{\text{ind}} = -M\frac{di}{dt}.$$

SIMPLIFY

We can combine equations (i), (ii), and (iii) to obtain the mutual inductance between the two coils:

$$M = \frac{NBA}{i} = \frac{N(\mu_0 ni)\left(\pi r_1^2\right)}{i} = N\pi\mu_0 n r_1^2.$$

Then the potential difference induced in the short coil is

$$\Delta V_{\text{ind}} = -\left(N\pi\mu_0 n r_1^2\right)\frac{di}{dt}.$$

CALCULATE

The change in the current is constant, so

$$\frac{di}{dt} = \frac{2.20\text{ A}}{48.0 \cdot 10^{-3}\text{ s}} = 45.8333\text{ A/s}.$$

The mutual inductance between the two coils is

$$M = (31)\pi\left(4\pi \cdot 10^{-7}\text{T m/A}\right)\left(290 \cdot 10^2\text{ m}^{-1}\right)\left(2.80^{-2}\text{ m}\right)^2$$

The potential difference induced in the short coil is then

$$\Delta V_{\text{ind}} = -(0.0027825\text{ H})(45.8333\text{ A/s}) = -0.127531\text{ V}.$$

ROUND

We report our result to three significant figures:

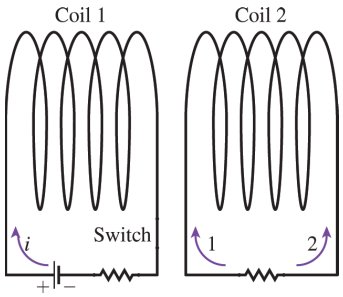
$$\Delta V_{\text{ind}} = -0.128 \text{ V}.$$

DOUBLE-CHECK

The magnitude of the potential difference induced in the short outer coil is 128 mV, which is a magnitude that could be attained by moving a strong bar magnet in and out of a coil. Thus, our result seems reasonable.

Concept Check 29.6

Two identical coils are shown in the figure. Coil 1 has a current *i* flowing in the direction shown. When the switch in the circuit containing coil 1 is opened, what happens in coil 2?



a) A current is induced in coil 2 that flows in direction 1.

b) A current is induced in coil 2 that flows in direction 2.

c) No current is induced in coil 2.

29.8 RL Circuits

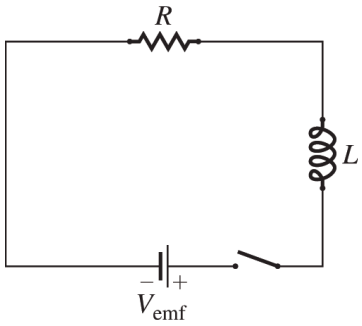
In Chapter 26, we saw that if a source of emf supplying a voltage, V_{emf}, is put into a single-loop circuit containing a resistor of resistance R and a capacitor of capacitance C, the charge, q, on the capacitor builds up over time according to

$$q = CV_{\text{emf}}\left(1 - e^{-t/\tau_{\text{RC}}}\right),$$

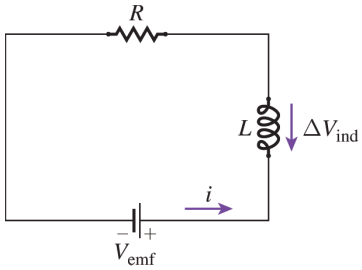
where the time constant of the circuit, $\tau_{\text{RC}} = RC$, is the product of the resistance and the capacitance. The same time constant governs the decrease of the initial charge, q_0, on the capacitor if the source of emf is suddenly removed and the circuit is short-circuited:

$$q = q_0 e^{-t/\tau_{\text{RC}}}.$$

If a source of emf is placed in a single-loop circuit containing a resistor with resistance R and an inductor with inductance L, called an **RL circuit,** a similar phenomenon occurs. Figure 29.26 shows a circuit in which a source of emf is connected to a resistor and an inductor in series. If the circuit included only the resistor and not the inductor, the current would increase almost instantaneously to the value given by Ohm's Law, $i = V_{\text{emf}}/R$, as soon as the switch was closed. However, in the circuit with both the resistor and the inductor, the increasing current flowing through the inductor creates a self-induced potential difference that tends to oppose the increase in current. As time passes, the change in current decreases, and the opposing self-induced potential difference also decreases. After a long time, the current becomes steady at the value V_{emf}/R.



(a)



(b)

FIGURE 29.26
Single-loop circuit with a source of emf, a resistor, and an inductor: (a) switch open; (b) switch closed. When the switch is closed, the current flowing in the direction shown increases. A potential difference is induced across the inductor in the opposite direction, as shown.

We can use Kirchhoff's Loop Rule to analyze this circuit, assuming that the current, i, at any given time is flowing through the circuit in a counterclockwise direction. With current flowing counterclockwise around the circuit, the source of emf provides a gain in potential, $+V_{\text{emf}}$, and the resistor causes a drop in potential, $-iR$. The self-inductance of the inductor produces a drop in

potential because it is opposing the increase in current. The drop in potential due to the inductor is proportional to the time rate of change of the current, as given by equation 29.22. Thus, we can write the sum of the potential drops around the circuit as

$$V_{\text{emf}} - iR - L\frac{di}{dt} = 0.$$

We can rewrite this equation as

$$L\frac{di}{dt} + iR = V_{\text{emf}}. \tag{29.28}$$

The solution to this differential equation is obtained in exactly the same way as the solution to the differential equation for the RC circuit was obtained in Chapter 26. The solution, which can be checked by substituting it into equation 29.28 is

$$i(t) = \frac{V_{\text{emf}}}{R}\left(1 - e^{-t/(L/R)}\right). \tag{29.29}$$

The quantity L/R is the time constant of the RL circuit:

$$\tau_{\text{RL}} = \frac{L}{R}. \tag{29.30}$$

This time dependence of the current in an RL circuit is shown in Figure 29.27a for three different values of the time constant.

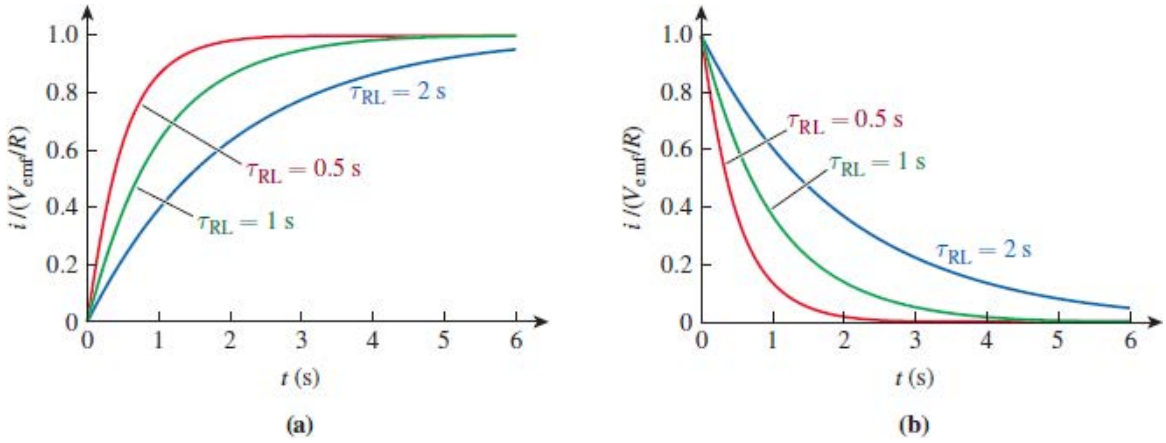


FIGURE 29.27 Time dependence of the current flowing through an RL circuit. (a) Current as a function of time when a resistor, an inductor, and a source of emf are connected in series. (b) Current as a function of time when the source of emf is suddenly removed from an RL circuit that has been connected for a long time.

Looking at equation 29.29, you can see that for $t = 0$, the current is zero. For $t \to \infty$, the current is given by $i = V_{\text{emf}}/R$, which is as expected.

Now consider the circuit depicted in Figure 29.28, in which a source of emf was first connected and then suddenly removed. We can use equation 29.28 with $V_{\text{emf}} = 0$ to describe the time dependence of this circuit:

$$L\frac{di}{dt} + iR = 0. \qquad \textbf{(29.31)}$$

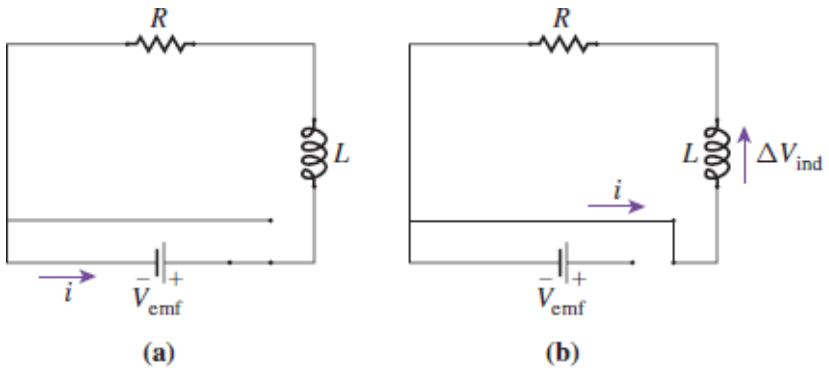

FIGURE 29.28 Single-loop circuit with a source of emf, a resistor, and an inductor. (a) The circuit with the source of emf connected. Current is flowing in the direction shown. (b) The source of emf is removed, and the resistor and the inductor are connected. Current flows in the same direction as before but is decreasing. A potential difference is induced across the inductor in the same direction as the current, as shown.

The resistor causes a potential drop, and the inductor has a self-induced potential difference that tends to oppose the decrease in current. The solution of equation 29.31 is

$$i(t) = i_0 e^{-t/\tau_{\mathrm{RL}}}. \qquad \textbf{(29.32)}$$

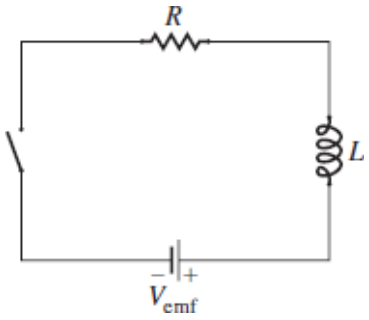
The initial conditions when the source of emf is connected can be used to determine the initial current: $i_0 = V_{\mathrm{emf}}/R$. Equation 29.32 describes a single-loop circuit with a resistor and an inductor that initially has a current i_0. The current drops exponentially with time with a time constant $\tau_{\mathrm{RL}} = L/R$, and after a long time, the current in the circuit is zero. The current in this RL circuit as a function of

time for three different values of the time constant is plotted in Figure 29.27b.

RL circuits can be used as timers to turn on devices at particular intervals and can also be used to filter out noise. However, these applications are usually handled with similar RC circuits because small capacitors are available in a wider range of capacitances than are inductors. The real value of inductors becomes apparent in circuits with all three components, resistors, capacitors, and inductors, which are covered in Chapter 30.

Concept Check 29.7

Consider the RL circuit shown in the figure. When the switch is closed, the current in the circuit increases exponentially to the value $i = V_{\text{emf}}/R$. If the inductor in this circuit is replaced with an inductor having three times the number of turns per unit length, the time required to reach a current of magnitude $0.9i$



a) increases.

b) decreases.

c) stays the same.

SOLVED PROBLEM 29.3 Work Done by a Battery

A series circuit contains a battery that supplies $V_{\text{emf}} = 40.0$ V, an inductor with $L = 2.20$ H, a resistor with $R = 160.0\ \Omega$, and a switch, connected as shown in Figure 29.29.

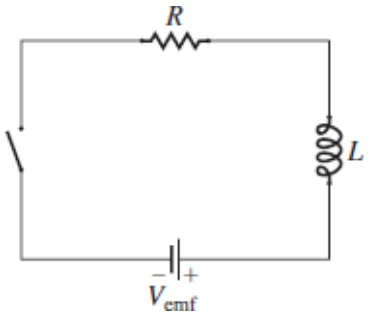


FIGURE 29.29
An RL circuit with a switch.

PROBLEM

The switch is closed at time $t = 0$. How much work is done by the battery between $t = 0.$ and $t = 1.65 \cdot 10^{-2}$ s?

SOLUTION

THINK

When the switch is closed, current begins to flow and power is provided by the battery. Power is defined as the voltage times the current at any given time. Work is the integral of the power over the time during which the circuit operates.

SKETCH

Figure 29.30 shows a plot of the current in the RL circuit as a function of time.

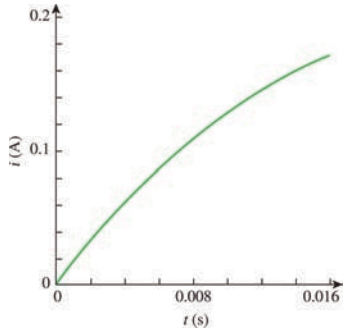

FIGURE 29.30
Current in the RL circuit as a function of time.

RESEARCH

The power in the circuit at any time t after the switch is closed is given by

$$P(t) = V_{\text{emf}} i(t), \qquad \text{(i)}$$

where $i(t)$ is the current in the circuit. The current as a function of time for this circuit is given by equation 29.29,

$$i(t) = \frac{V_{\text{emf}}}{R}\left(1 - e^{-t/\tau_{\text{RL}}}\right). \qquad \text{(ii)}$$

where $\tau_{\text{RL}} = L/R$. The work done by the battery is the integral of the power over the time in which the circuit has been in operation:

$$W = \int_0^T P(t)dt, \qquad \text{(iii)}$$

where T is the time after the switch is closed.

SIMPLIFY

We can combine equations (i), (ii), and (iii) to obtain

$$W = \int_0^T \frac{V_{emf}^2}{R}\left(1 - e^{-t/\tau_{\mathrm{RL}}}\right)dt.$$

Evaluating the definite integral gives us

$$W = \frac{V_{\mathrm{emf}}^2}{R}\left[t + \tau_{\mathrm{RL}}e^{-t/\tau_{\mathrm{RL}}}\right]_0^T = \frac{V_{\mathrm{emf}}^2}{R}\left[T + \tau_{\mathrm{RL}}\left(\epsilon\right.\right.$$

CALCULATE

First, we calculate the value of the time constant:

$$\tau_{\mathrm{RL}} = \frac{L}{R} = \frac{2.20\ \mathrm{H}}{160.0\ \Omega} = 1.375 \cdot 10^{-2}\ \mathrm{s}.$$

Putting all the numerical values into equation (iv) then gives

$$W = \frac{(40.0\ \mathrm{V})^2}{160.0\ \ \mathrm{O}}\left[(1.65 \cdot 10^{-2}\ \mathrm{s}) + (1.375 \cdot 10^{-2}\ \mathrm{s})(e^{-(1.65 \cdot 10}\right.$$

ROUND

We report our result to three significant figures:

$$W = 6.89 \cdot 10^{-2}\ \mathrm{J}.$$

DOUBLE-CHECK

To double-check our result, we assume that the current in the circuit is constant in time and equal to half of the final current:

$$i_{\text{ave}} = \frac{i(T)}{2} = \frac{(V_{\text{emf}}/R)(1 - e^{-T/t_{\text{RL}}})}{2} = \frac{(40.0\ \text{V}/160.0\ \text{C}}{}$$

This current would correspond to the average current if the current increased linearly with time. The work done would then be

$$W = PT = i_{\text{ave}} V_{\text{emf}} T = (0.0874\ \text{A})(40.0\ \text{V})(1.65 \cdot 10^{-2}\ \text{s})$$

This value is less than, but close to, our calculated result. Thus, our result seems reasonable.

29.9 Energy and Energy Density of a Magnetic Field

We can think of an inductor as a device that can store energy in a magnetic field, similar to the way a capacitor can store energy in an electric field. The energy stored in the electric field of a capacitor is given by

$$U_E = \frac{1}{2}\frac{q^2}{C}.$$

Consider an inductor connected to a source of emf. Current begins to flow through the inductor, producing a self-induced potential difference opposing the increase in current. The instantaneous power provided by the source of emf is the product of the current and the voltage of the emf source, V_{emf}. Using equation 29.28 with $R = 0$, we can write

$$P = V_{\text{emf}} i = \left(L\frac{di}{dt}\right) i. \qquad \textbf{(29.33)}$$

Page 906

Integrating this power over the time it takes to reach a final current i in the circuit yields the energy provided by the source of emf. Since there are no resistive losses in this circuit, this amount of energy must be stored in the magnetic field of the inductor. Therefore,

$$U_B = \int_0^t P\,dt = \int_0^i Li'\,di' = \frac{1}{2}Li^2. \qquad \textbf{(29.34)}$$

Equation 29.34 has a form similar to the analogous equation for a capacitor's electric field, with q replaced by i and $1/C$ replaced by L.

Concept Check 29.8

A long solenoid has a circular cross section of radius $r = 8.10\ \text{cm}$, a length $\ell = 0.540\ \text{m}$, and $n = 2.00 \cdot 10^4\ \text{turns/m}$. The solenoid stores 42.5 mJ of energy when it carries a current i. If the current is doubled, to $2i$, the energy stored in the solenoid

a) decreases by a factor of 4.

b) decreases by a factor of 2.

c) remains the same.

d) increases by a factor of 2.

e) increases by a factor of 4.

Now let's consider an ideal solenoid with length ℓ, cross-sectional area A, and n turns per unit length, carrying current i. The energy stored in the magnetic field of the solenoid according to equation 29.21 is

$$U_B = \frac{1}{2}Li^2 = \frac{1}{2}\mu_0 n^2 \ell A i^2.$$

The magnetic field occupies the volume enclosed by the solenoid, which is given by ℓA. Thus, the energy density, u_B, of the magnetic field of the solenoid is

$$u_B = \frac{\frac{1}{2}\mu_0 n^2 \ell A i^2}{\ell A} = \frac{1}{2}\mu_0 n^2 i^2.$$

Since $B = \mu_0 n i$ for a solenoid, the energy density of the magnetic field of a solenoid can be expressed as

$$u_B = \frac{1}{2\mu_0} B^2. \tag{29.35}$$

Although we derived this expression for the special case of a solenoid, it applies to magnetic fields in general.

29.10 Applications to Information Technology

Computers and many consumer electronics devices use magnetization and induction to store and retrieve information. Examples are computer hard drives, videotapes, audiotapes, and the magnetic strips on credit cards. During the last decade, the use of storage media based on other technologies, such as the optical storage of information on CDs and DVDs and the flash memory cards in digital cameras, has increased; however, magnetic storage devices are still a technological mainstay and the basis of a multibillion dollar industry.

Computer Hard Drive

One device that stores information using magnetization and induction is the computer hard drive. The hard drive stores information in the form of *bits,* the binary code consisting of zeros and ones. Eight bits make a *byte,* which can represent a number or an alphanumeric character. A modern hard drive can hold up to 18 terabytes ($2 \cdot 10^{12}$ bytes) of information. A hard drive consists of one or more rotating platters with a ferromagnetic coating accessed by a movable read/write head, as shown in Figure 29.31.

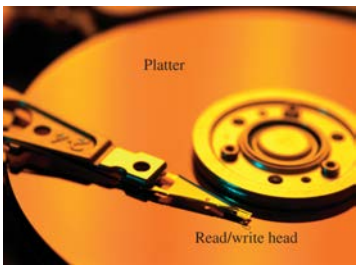

FIGURE 29.31 The read/write head and spinning platter inside a computer hard drive.

Daisuke Morita/Getty Images

The read/write head can be positioned to access any one of many tracks on the rotating platter. The operation of a read/write head in a conventional hard drive is illustrated in Figure 29.32a. As the coated platter moves below the read/write head, a pulse of current in one direction magnetizes the surface of the platter to represent a binary one, or a pulse of current in the opposite direction magnetizes the surface to represent a binary zero. In Figure 29.32a, a binary one is shown as a red arrow pointing to the right, and a binary zero is shown as a green arrow pointing to the left. In read mode, when the magnetized areas of the platter pass beneath the read sensor, a positive or negative current is induced, and the electronics of the hard drive can tell if the information is a zero or a one. The method used to encode and read back data shown in Figure 29.32a is called *longitudinal encoding* because the magnetic fields of the magnetized areas of the platter are parallel or antiparallel to the motion of the

platter. The data storage capacity of hard drives was increased by making the magnetized areas smaller and by adding more platters and read/write heads. However, manufacturers found it difficult to construct hard drives holding more than 250 gigabytes ($250 \cdot 10^9$ bytes) using this technique. As the manufacturers made the bits smaller, the bits interfered with each other, causing some bits to flip randomly and introduce errors in the stored data.

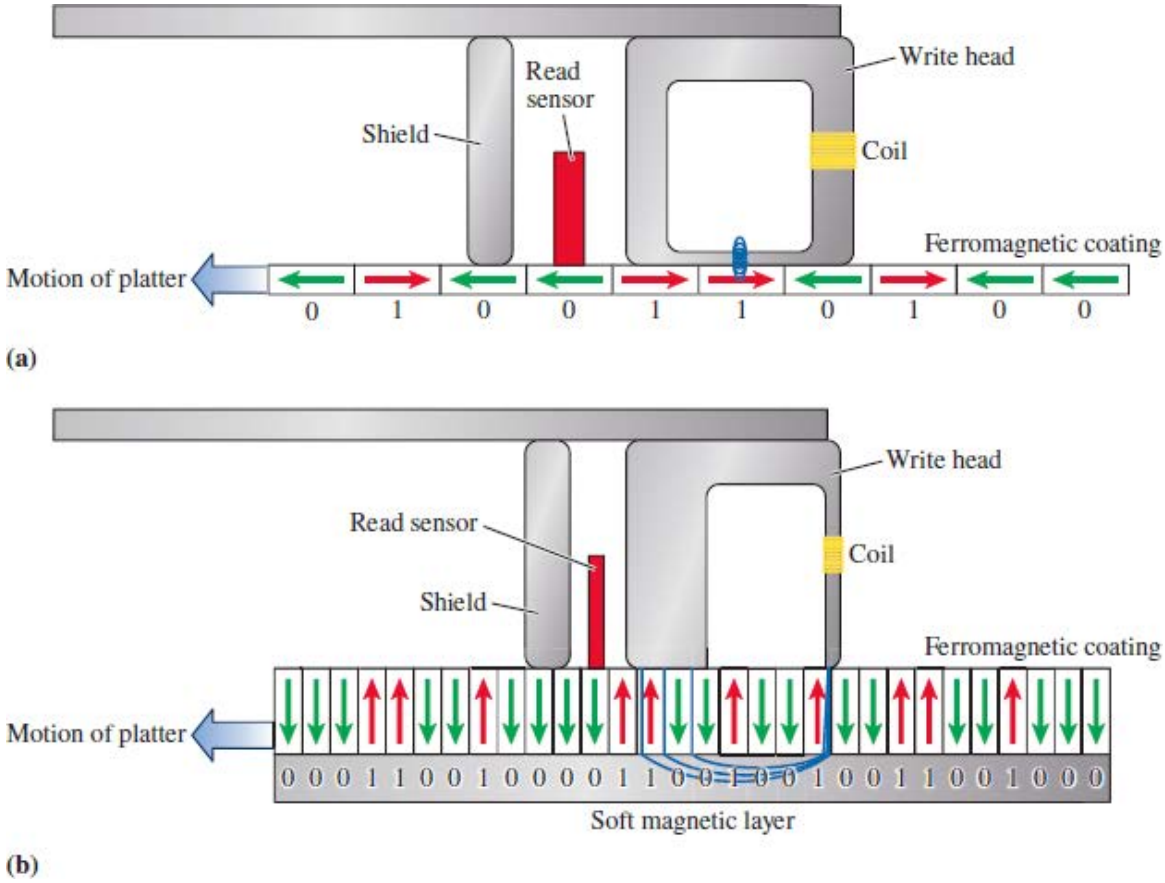

FIGURE 29.32 The read/write head of a computer hard drive. (a) Longitudinal encoding of information on the spinning platter. (b) Perpendicular encoding of information on the spinning platter.

Recently, the technique of *perpendicular encoding* of data has been developed, illustrated in Figure 29.32b. Again, a read/write head is used above a spinning platter coated with a ferromagnetic substance. However, in this case, the magnetic fields are

perpendicular to the surface of the platter, which allows a tighter packing of the bits and increases the capacity of the hard drive. The platter is constructed with a thicker ferromagnetic coating and a soft magnetic material on the bottom that acts to contain the magnetic field lines. Note that the magnetic field lines at the pointed end of the write head are very close together, whereas the magnetic field lines returning to the blunt end of the write head are widely spaced. Thus, the ferromagnetic coating of the platter is strongly magnetized in the up or down direction, depending on the direction of the current pulse through the coil of the write head, while the bits closer to the read sensor are not affected.

Hard drives using perpendicular encoding also incorporate the phenomenon called *giant magnetoresistance (GMR),* which allows the construction of a very small and sensitive read sensor. The French physicist Albert Fert and the German physicist Peter Grünberg received the Nobel Prize in Physics in 2007 for the discovery of this effect. Hard drives with information storage capacities of up to 18 terabytes or more that use perpendicular encoding and GMR read sensors are widely available. As research in nanoscience and nanotechnology continues to produce exciting results for technological applications, the amazing growth in the capabilities of consumer electronics devices will continue for the foreseeable future.

WHAT WE HAVE LEARNED | EXAM STUDY GUIDE

- According to Faraday's Law of Induction, the induced potential difference, ΔV_{ind}, in a conducting loop is given by the negative of the time rate of change of the magnetic flux passing through the loop: $\Delta V_{\text{ind}} = -\dfrac{d\Phi_B}{dt}$.
- The magnetic flux, Φ_B, is given by $\Phi_B = \iint \vec{B} \cdot d\vec{A}$, where $\vec{B}$ is the magnetic field and $d\vec{A}$ is the differential area element defined by a vector normal to the surface through which the magnetic field passes.
- For a constant magnetic field, $\vec{B}$, the magnetic flux, Φ_B, passing through an area, A, is given by $\Phi_B = BA\cos\theta$, where θ is the angle between the magnetic field vector and a normal vector to the area.
- Lenz's Law states that a changing magnetic flux through a conducting loop induces a current in the loop that opposes the change in magnetic flux.
- A magnetic field that is changing in time induces an electric field given by $\oint \vec{E} \bullet d\vec{s} = -\dfrac{d\Phi_B}{dt}$, where the integration is done over any closed path in the magnetic field.
- The inductance, L, of a device with conducting loops is the flux linkage (the product of the number of loops, N, and the magnetic flux, Φ_B) divided by the current, i: $L = \dfrac{N\Phi_B}{i}$.
- The inductance of a solenoid is given by $L = \mu_0 n^2 \ell A$, where n is the number of turns per unit length, ℓ is the length of the solenoid, and A is the cross-sectional area of the solenoid.

- The self-induced potential difference, $\Delta V_{\text{ind},L}$, for any inductor is given by $\Delta V_{\text{ind},L} = -L\dfrac{di}{dt}$, where L is the inductance of the device and $\dfrac{di}{dt}$ is the time rate of change of the current flowing through the inductor.
- A single-loop circuit with an inductance L and a resistance R has a characteristic time constant of $\tau_{\text{RL}} = \dfrac{L}{R}$.
- The energy, U_B, stored in the magnetic field of an inductor with an inductance L and carrying a current i is given by $U_B = \dfrac{1}{2}Li^2$.

ANSWERS TO SELF-TEST OPPORTUNITIES

29.1
$$\frac{dB}{dt} = -\frac{0.500\ \text{T}}{0.250\ \text{s}} = -2.00\ \text{T/s}$$
$$\Delta V_{\text{ind}} = -\frac{d\Phi_B}{dt} = -\frac{d(BA)}{dt} = -\pi r^2 \frac{dB}{dt}$$
$$r = \sqrt{\frac{|\Delta V_{\text{ind}}|}{\pi\,|dB/dt|}} = \sqrt{\frac{1.24\ \text{V}}{\pi(2.00\ \text{T/s})}} = 0.444\ \text{m}.$$

29.2 As the loop enters the magnetic field, the magnetic flux is increasing. The current induced in the loop will be in the counterclockwise direction to oppose the increase in the flux. As the loop exits the magnetic field, the magnetic flux is decreasing. The current induced in the loop will be in a clockwise direction to oppose the decrease in the flux.

29.3 If the induced potential difference were equal to the change in the magnetic flux, then any increase in the flux going through a coil (perhaps from just a minute random fluctuation in the ambient magnetic field in the room) would lead to an induced potential difference, which would produce a current in the coil, which would act to increase the flux, which would lead to a larger induced potential difference, a larger current, and an even larger increase in flux. In other words, a runaway situation would result, which clearly violates energy conservation.

29.4 a) true

b) false

c) true

d) true

PROBLEM-SOLVING GUIDELINES

1. To solve a problem involving electromagnetic induction, first ask: What is making the magnetic flux change? If the magnetic field is changing, you need to use equation 29.9; if the area through which the flux passes is changing, you need to use equation 29.10; and if the orientation between the magnetic field and the area is changing, you need to use equation 29.11. You don't need to memorize these equations, as long as you remember Faraday's Law (equation 29.5) and the definition of magnetic flux (equation 29.1).

2. Once you know which elements of the problem situation are constant and which are changing, use Lenz's Law to determine the direction of the induced current and the locations of higher and lower potential. Then, you can pick a direction for the differential area vector, $d\vec{A}$, of the flux and calculate the unknown quantities.

MULTIPLE-CHOICE QUESTIONS

29.1 A solenoid with 200 turns and a cross-sectional area of 60 cm^2 has a magnetic field of 0.60 T along its axis. If the field is confined within the solenoid and changes at a rate of 0.20 T/s, the magnitude of the induced potential difference in the solenoid will be

a) 0.0020 V.

b) 0.02 V.

c) 0.001 V.

d) 0.24 V.

29.2 The rectangular loop of wire in Figure 29.9 is pulled with a constant acceleration from a region of zero magnetic field into a region of a uniform magnetic field. During this process, the current induced in the loop

a) will be zero.

b) will be some constant value that is not zero.

c) will increase linearly with time.

d) will increase exponentially with time.

e) will increase linearly with the square of the time.

29.3 Which of the following will induce a current in a loop of wire in a uniform magnetic field?

a) decreasing the strength of the field

b) rotating the loop about an axis parallel to the field

c) moving the loop within the field

d) all of the above

e) none of the above

29.4 Faraday's Law of Induction states that

a) a potential difference is induced in a loop when there is a change in the magnetic flux through the loop.

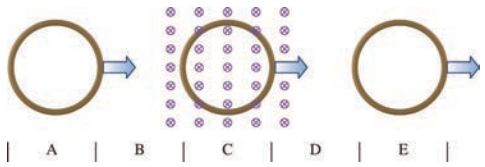
b) the current induced in a loop by a changing magnetic field produces a magnetic field that opposes this change in magnetic field.

c) a changing magnetic field induces an electric field.

d) the inductance of a device is a measure of its opposition to changes in current flowing through it.

e) magnetic flux is the product of the average magnetic field and the area perpendicular to it that it penetrates.

29.5 A conducting ring is moving from left to right through a uniform magnetic field, as shown in the figure. In which region(s) is there an induced current in the ring?



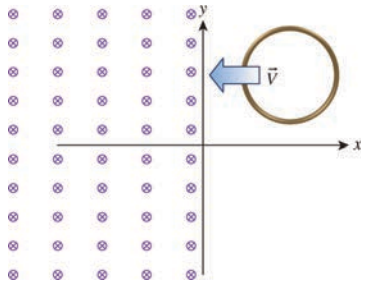
a) regions B and D

b) regions B, C, and D

c) region C

d) regions A through E

29.6 A circular loop of wire moving in the *xy*-plane with a constant velocity in the negative *x*-direction enters a uniform magnetic field, which covers the region in which $x < 0$, as shown in the figure. The surface normal vector of the loop points in the direction of the magnetic field. Which of the following statements is correct?



a) The induced potential difference in the loop is at a maximum as the edge of the loop just enters the region with the magnetic field.

b) The induced potential difference in the loop is at a maximum when one fourth of the loop is in the region with the magnetic field.

c) The induced potential difference in the loop is at a maximum when the loop is halfway into the region with the magnetic field.

d) The induced potential difference in the loop is constant from the instant the loop starts to enter the region with the magnetic field.

29.7 Which of the following statements regarding self-induction is correct?

a) Self-induction occurs only when a direct current is flowing through a circuit.

b) Self-induction occurs only when an alternating current is flowing through a circuit.

c) Self-induction occurs when either a direct current or an alternating current is flowing through a circuit.

d) Self-induction occurs when either a direct current or an alternating current is flowing through a circuit as long as the current is varying.

29.8 You have a light bulb, a bar magnet, a spool of wire that you can cut into as many pieces as you want, and nothing else. How can you get the bulb to light up?

a) You can't. The bulb needs electricity to light it, not magnetism.

b) You cut a length of wire, connect the light bulb to the two ends of the wire, and pass the magnet through the loop that is formed.

c) You cut two lengths of wire and connect the magnet and the bulb in series.

29.9 Calculate the potential difference induced between the tips of the wings of a Boeing 747-400 with a wingspan of 64.67 m when it is in level flight at a speed of 913 km/h. Assume that the magnitude of the downward component of the Earth's magnetic field is $B = 5.00 \cdot 10^{-5}\ \mathrm{T}$.

a) 0.820 V

b) 2.95 V

c) 10.4 V

d) 30.1 V

e) 225 V

29.10 A long solenoid with a circular cross section of radius $r_1 = 2.80$ cm and $n = 290$ turns/cm is inside of and coaxial with a short coil that has a circular cross section of radius $r_2 = 4.90$ cm and $N = 31$ turns. Suppose the current in the short coil is increased steadily from zero to $i = 2.80$ A in 18.0 ms. What is the magnitude of the potential difference induced in the solenoid while the current in the short coil is changing?

a) 0.0991 V

b) 0.128 V

c) 0.233 V

d) 0.433 V

e) 0.750 V

29.11 A long solenoid has a circular cross section of radius $r = 8.10$ cm, a length $\ell = 0.540$ m, and $n = 2.00 \cdot 10^4$ turns/m. The solenoid is carrying a current of magnitude $i = 4.04 \cdot 10^{-3}$ A. How much energy is stored in the magnetic field of the solenoid?

a) $2.11 \cdot 10^{-7}$ J

b) $8.91 \cdot 10^{-6}$ J

c) $4.57 \cdot 10^{-5}$ J

d) $6.66 \cdot 10^{-3}$ J

e) $4.55 \cdot 10^{-1}$ J

29.12 Suppose the current in the short coil in Solved Problem 29.2 is increased steadily from zero to $i = 2.80$ A in 18.0 ms. What is the magnitude of the potential difference induced in the solenoid while the current in the short coil is changing?

a) 0.0991 V

b) 0.128 V

c) 0.233 V

d) 0.433 V

e) 0.750 V

29.13 Suppose the length of the rotating rod in Solved Problem 29.1 is increased by a factor of 2. By what factor does the power dissipated in the resistor change?

a) $\frac{1}{2}$

b) 2

c) 4

d) 8

e) 16

29.14 Suppose the resistance of the resistor in Solved Problem 29.1 is increased by a factor of 2. By what factor does the power dissipated in the resistor change?

a) $\frac{1}{2}$

b) 2

c) 4

d) 8

e) 16

CONCEPTUAL QUESTIONS

29.15 When you plug a refrigerator into a wall socket, on occasion, a spark appears between the prongs. What causes this?

29.16 People with pacemakers or other mechanical devices as implants are often warned to stay away from large machinery or motors. Why?

29.17 Chapter 14 discussed damped harmonic oscillators, in which the damping force is velocity dependent and always opposes the motion of the oscillator. One way of producing this type of force is to use a piece of metal, such as aluminum, that moves through a nonuniform magnetic field. Explain why this technique is capable of producing a damping force.

29.18 In a popular lecture demonstration, a cylindrical permanent magnet is dropped down a long aluminum tube as shown in the figure. Neglecting friction of the magnet against the inner walls of the tube and assuming that the tube is very long compared to the size of the magnet, will the magnet accelerate downward with an acceleration equal to g (free fall)? If not, describe the eventual motion of the magnet. Does it matter if the north pole or south pole of the magnet is on the lower side?

29.19 A popular demonstration of eddy currents involves dropping a magnet down a long metal tube and a long glass or plastic tube. As the magnet falls through a tube, the magnetic flux changes as the magnet moves toward or away from each part of the tube.

a) Which tube has the larger voltage induced in it?

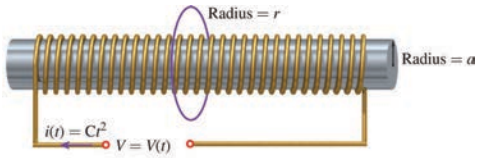
b) Which tube has the larger eddy currents induced in it?

29.20 The current in a very long, tightly wound solenoid with radius a and n turns per unit length varies over time according to the equation $i(t) = Ct^2$, where the current i is in amps and the time t is in seconds, and C is a constant with appropriate units. Concentric with the solenoid is a conducting ring of radius r, as shown in the figure.

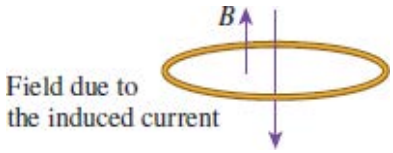
a) Write an expression for the potential difference induced in the ring.

b) Write an expression for the magnitude of the electric field induced at an arbitrary point on the ring.

c) Is the ring necessary for the induced electric field to exist?



29.21 A circular wire ring experiences an increasing magnetic field in the upward direction, as shown in the figure. What is the direction of the induced current in the ring?



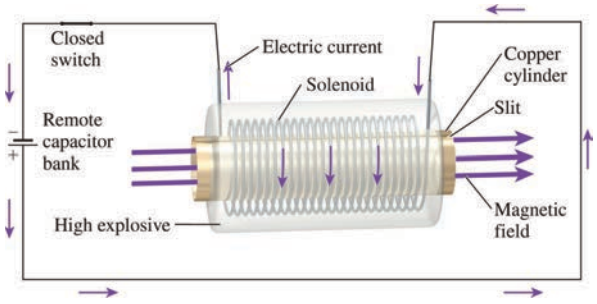
29.22 A square conducting loop with sides of length L is rotating at a constant angular speed, ω, in a uniform magnetic field of magnitude B. At time $t = 0$, the loop is oriented so that the direction normal to the loop is aligned with the magnetic field. Find an expression for the potential difference induced in the loop as a function of time.

29.23 A solid metal disk of radius R is rotating around its center axis at a constant angular speed of ω. The disk is in a uniform magnetic field of magnitude B that is oriented normal to the surface of the disk. Calculate the magnitude of the potential difference between the center of the disk and the outside edge.

29.24 Large electric fields are certainly a hazard to the human body, as they can produce dangerous currents, but what about large

magnetic fields? A man 1.80 m tall walks at 2.00 m/s perpendicular to a horizontal magnetic field of 5.0 T; that is, he walks between the pole faces of a very big magnet. (Such a magnet can, for example, be found in the National Superconducting Cyclotron Laboratory at Michigan State University.) Given that his body is full of conducting fluids, estimate the potential difference induced between his head and feet.

29.25 At Los Alamos National Laboratories, one means of producing very large magnetic fields is the *EPFCG (explosively-pumped flux compression generator)*, which is used to study the effects of a high-power electromagnetic pulse (EMP) in electronic warfare. Explosives are packed and detonated in the space between a solenoid and a small copper cylinder coaxial with and inside the solenoid, as shown in the figure. The explosion occurs in a very short time and collapses the cylinder rapidly. This rapid change creates inductive currents that keep the magnetic flux constant while the cylinder's radius shrinks by a factor of r_i/r_f. Estimate the magnetic field produced, assuming that the radius is compressed by a factor of 14 and the initial magnitude of the magnetic field, B_i, is 1.0 T.

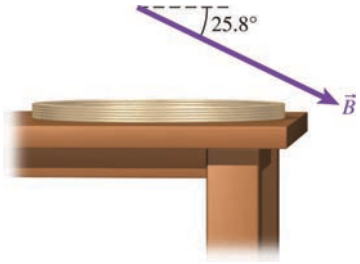


29.26 A metal hoop is laid flat on the ground. A magnetic field that is directed upward, out of the ground, is increasing in magnitude. As you look down on the hoop from above, what is the direction of the induced current in the hoop?

29.27 The wire of a tightly wound solenoid is unwound and then rewound to form another solenoid with double the diameter of the first solenoid. By what factor will the inductance change?

EXERCISES

A blue problem number indicates a worked-out solution is available in the Student Solutions Manual. One • and two •• indicate increasing level of problem difficulty.



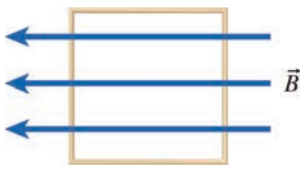
Sections 29.1 and 29.2

29.28 A circular coil of wire with 20 turns and a radius of 40.0 cm is laying flat on a horizontal tabletop as shown in the figure. There is a uniform magnetic field extending over the entire table with a magnitude of 5.00 T and directed to the north and downward, making an angle of 25.8° with the horizontal. What is the magnitude of the magnetic flux through the coil?

29.29 When a magnet in an MRI is abruptly shut down, the magnet is said to be *quenched*. Quenching can occur in as little as 20.0 s. Suppose a magnet with an initial field of 1.20 T is quenched in 20.0 s, and the final field is approximately zero. Under these conditions, what is the average induced potential difference around a conducting loop of radius 1.00 cm (about the size of a wedding ring) oriented perpendicular to the field?

29.30 An 8-turn coil has square loops measuring 0.200 m along a side and a resistance of 3.00 Ω. It is placed in a magnetic field that makes an angle of 40.0° with the plane of each loop. The magnitude of this field varies with time according to $B = 1.50t^3$, where t is measured in seconds and B in teslas. What is the induced current in the coil at $t = 2.00$ s?

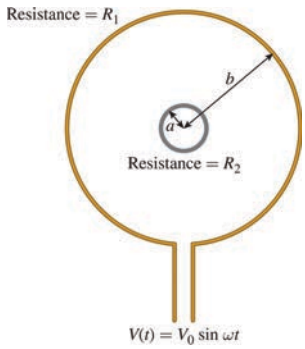
29.31 A metal loop has an area of $0.100\ \text{m}^2$ and is placed flat on the ground. There is a uniform magnetic field pointing due west, as shown in the figure. This magnetic field initially has a magnitude of 0.123 T, which decreases steadily to 0.075 T during a period of 0.579 s. Find the potential difference induced in the loop during this time.



•**29.32** A respiration monitor has a flexible loop of copper wire, which wraps about the chest. As the wearer breathes, the radius of the loop of wire increases and decreases. When a person in the Earth's magnetic field (assume $0.426 \cdot 10^{-4}$ T) inhales, what is the

average current in the loop, assuming that it has a resistance of 30.0 Ω and increases in radius from 20.0 cm to 25.0 cm over 1.00 s? Assume that the magnetic field is perpendicular to the plane of the loop.

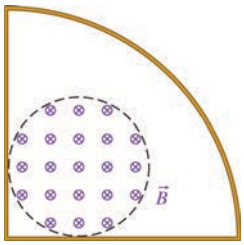
•29.33 A circular conducting loop with radius a and resistance R_2 is concentric with a circular conducting loop with radius $b \gg a$ (b much greater than a) and resistance R_1. A time-dependent voltage is applied to the larger loop; its slow sinusoidal variation in time is given by $V(t) = V_0 \sin \omega t$, where V_0 and ω are constants with dimensions of voltage and inverse time, respectively. Assuming that the magnetic field throughout the inner loop is uniform (constant in space) and equal to the field at the center of the loop, derive expressions for the potential difference induced in the inner loop and the current i through that loop.



•• 29.34 A long solenoid with cross-sectional area A_1 surrounds another long solenoid with cross-sectional area $A_2 < A_1$ and resistance R. Both solenoids have the same length and the same number of turns. A current given by $i = i_0 \cos\omega t$ is flowing through the outer solenoid. Find an expression for the magnetic field in the inner solenoid due to the induced current.

Section 29.3

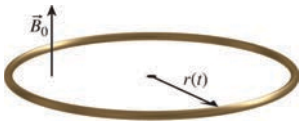
29.35 The conducting loop in the shape of a quarter-circle shown in the figure has a radius of 10.0 cm and a resistance of 0.200 Ω. The magnetic field strength within the dotted circle of radius 3.00 cm is initially 2.00 T. The magnetic field strength then decreases from 2.00 T to 1.00 T in 2.00 s. Find (a) the magnitude and (b) the direction of the induced current in the loop.



29.36 A supersonic aircraft with a wingspan of 10.0 m is flying over the north magnetic pole (in a magnetic field of magnitude 0.500 G oriented perpendicular to the ground) at a speed of three times the speed of sound (Mach 3). What is the potential difference between the tips of the wings? Assume that the wings are made of aluminum.

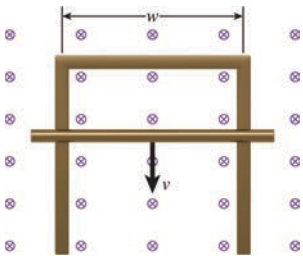
•**29.37** A helicopter hovers above the north magnetic pole in a magnetic field of magnitude 0.426 G and oriented perpendicular to the ground. The helicopter rotors are 10.0 m long, are made of aluminum, and rotate about the hub with a rotational speed of $1.00 \cdot 10^4$ rpm. What is the potential difference from the hub to the end of a rotor?

•**29.38** An elastic circular conducting loop expands at a constant rate over time such that its radius is given by $r(t) = r_0 + vt$, where $r_0 = 0.100$ m and $v = 0.0150$ m/s. The loop has a constant resistance of $R = 12.0\ \Omega$ and is placed in a uniform magnetic field of magnitude $B_0 = 0.750$ T, perpendicular to the plane of the loop, as shown in the figure. Calculate the direction and the magnitude of the induced current, i, at $t = 5.00$ s.

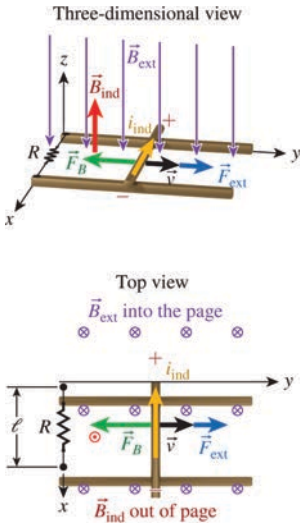


•**29.39** A rectangular frame of conducting wire has negligible resistance and width w and is held vertically in a magnetic field of

magnitude B, as shown in the figure. A metal bar with mass m and resistance R is placed across the frame, maintaining contact with the frame. Derive an expression for the terminal velocity of the bar if it is allowed to fall freely along this frame starting from rest. Neglect friction between the wires and the metal bar.



•**29.40** Two parallel conducting rails with negligible resistance are connected at one end by a resistor of resistance R, as shown in the figure. The rails are placed in a magnetic field $\vec{B}_{\text{ext}}$, which is perpendicular to the plane of the rails. This magnetic field is uniform and time independent. The distance between the rails is ℓ. A conducting rod slides without friction on top of the two rails at constant velocity $\vec{v}$.



a) Using Faraday's Law of Induction, calculate the magnitude of the potential difference induced in the moving rod.

b) Calculate the magnitude of the induced current in the rod, i_{ind}.

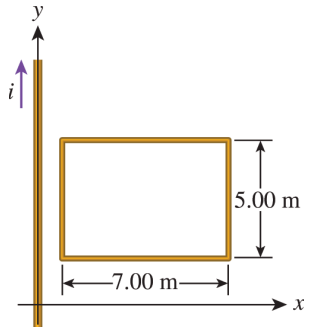
c) Show that for the rod to move at a constant velocity as shown, it must be pulled with an external force, $\vec{F}_{\text{ext}}$, and calculate the

magnitude of this force.

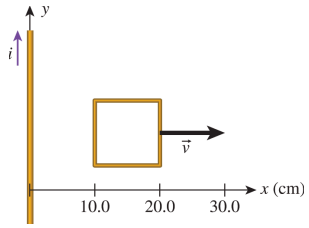
d) Calculate the work done, W_{ext}, and the power generated, P_{ext}, by the external force in moving the rod.

e) Calculate the power used (dissipated) by the resistor, P_{R}. Explain the correlation between this result and those of part (d).

•29.41 A long, straight wire runs along the y-axis. The wire carries a current in the positive y-direction that is changing as a function of time according to $i = 2.00\ \text{A} + (0.300\ \text{A/s})t$. A loop of wire is located in the xy-plane near the y-axis, as shown in the figure. The loop has dimensions 7.00 m by 5.00 m and is 1.00 m away from the wire. What is the induced potential difference in the wire loop at $t = 10.0$ s?



•• 29.42 The long, straight wire in the figure has a current $i = 1.00$ A flowing in it. A square loop with 10.0-cm sides and a resistance of 0.0200 Ω is positioned 10.0 cm away from the wire. The loop is then moved in the positive x-direction with a speed $v = 10.0$ cm/s.



a) Find the direction of the induced current in the loop.

b) Identify the directions of the magnetic forces acting on all sides of the square loop.

c) Calculate the direction and the magnitude of the net force acting on the loop at the instant it starts to move.

Section 29.4

29.43 A simple generator consists of a loop rotating inside a constant magnetic field (see Figure 29.19). If the loop is rotating with frequency f, the magnetic flux is given by $\Phi_B(t) = BA\cos(2\pi ft)$. If $B = 1.00\,\text{T}$ and $A = 1.00\,\text{m}^2$, what must the value of f be for the maximum induced potential difference to be 110. V?

•29.44 A motor has a single loop inside a magnetic field of magnitude 0.870 T. If the area of the loop is 300. cm^2, find the maximum angular speed possible for this motor when connected to a source of emf providing 170. V.

•29.45 Your friend decides to produce electrical power by turning a coil of $1.00 \cdot 10^5$ circular loops of wire around an axis perpendicular to the Earth's magnetic field, which has a local magnitude of 0.300 G. The loops have a radius of 25.0 cm.

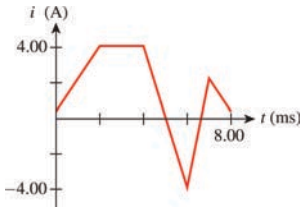
a) If your friend turns the coil at a frequency of 150. Hz, what peak current will flow in a resistor, $R = 1.50\,\text{k}\Omega$, connected to the coil?

b) The average current flowing in the coil will be 0.7071 times the peak current. What will be the average power obtained from this device?

Sections 29.6 and 29.7

29.46 Find the mutual inductance of the solenoid and the coil described in Example 29.1 and the induced potential difference in the coil at $t = 2.0$ s using the techniques described in Section 29.7. How do the results for the induced potential difference compare?

29.47 The figure shows the current through a 10.0-mH inductor over a time interval of 8.00 ms. Draw a graph showing the self-induced potential difference, $\Delta V_{\text{ind},L}$, for the inductor over the same interval.



•**29.48** A short coil with radius $R = 10.0$ cm contains $N = 30.0$ turns and surrounds a long solenoid with radius $r = 8.00$ cm containing $n = 60$ turns per centimeter. The current in the short coil is increased at a constant rate from zero to $i = 2.00$ A in a time of $t = 12.0$ s. Calculate the induced potential difference in the long solenoid while the current is increasing in the short coil.

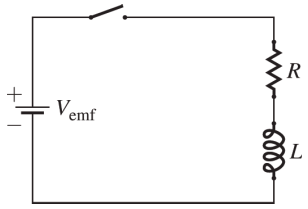
Section 29.8

29.49 Consider an RL circuit with resistance $R = 1.00\ \text{M}\Omega$ and inductance $L = 1.00\ \text{H}$, which is powered by a 10.0-V battery.

a) What is the time constant of the circuit?

b) If the switch is closed at time $t = 0$, what is the current just after that time? After 2.00 μs? When a long time has passed?

29.50 In the circuit in the figure, $R = 120.\ \Omega$, $L = 3.00\ \text{H}$, and $V_{\text{emf}} = 40.0\ \text{V}$. After the switch is closed, how long will it take the current in the inductor to reach 300. mA?



29.51 The current is increasing at a rate of 3.60 A/s in an RL circuit with $R = 3.25\ \Omega$ and $L = 440.\ \text{mH}$. What is the potential difference across the circuit at the moment when the current in the circuit is 3.00 A?

•**29.52** In the circuit in the figure, a battery supplies $V_{\text{emf}} = 18.0\ \text{V}$ and $R_1 = 6.00\ \Omega$, $R_2 = 6.00\ \Omega$, and $L = 5.00\ \text{H}$. Calculate each of the following *immediately* after the switch is closed:

a) the current flowing out of the battery

b) the current through R_1

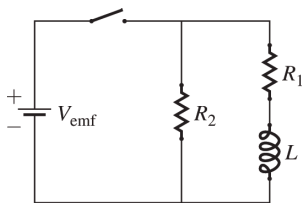
c) the current through R_2

d) the potential difference across R_1

e) the potential difference across R_2

f) the potential difference across L

g) the rate of current change across R_1



•29.53 In the circuit in the figure, a battery supplies $V_{\text{emf}} = 18.0\ \text{V}$ and $R_1 = 6.00\ \Omega$, $R_2 = 6.00\ \Omega$, and $L = 5.00\ \text{H}$, Calculate each of the following a *long time* after the switch is closed:

a) the current flowing out of the battery

b) the current through R_1

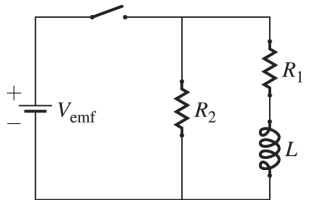
c) the current through R_2

d) the potential difference across R_1

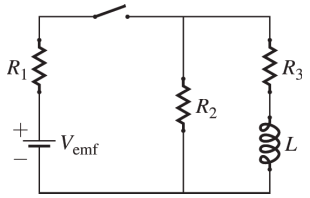
e) the potential difference across R_2

f) the potential difference across L

g) the rate of current change across R_1



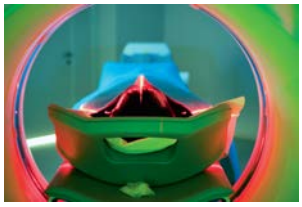
•29.54 A circuit contains a battery, three resistors, and an inductor, as shown in the figure. What will be the current through each resistor (a) immediately after the switch is closed and (b) a long time after the switch is closed? (c) Suppose the switch is reopened a long time after it has been closed. What is the current in each resistor? After a long time?



Section 29.9

29.55 Having just learned that there is energy associated with magnetic fields, an inventor sets out to tap the energy associated with the Earth's magnetic field. What volume of space near Earth's surface contains 1.00 J of energy, assuming the strength of the magnetic field to be $5.00 \cdot 10^{-5}$ T?

29.56 A clinical MRI (magnetic resonance imaging) superconducting magnet can be approximated as a solenoid with a diameter of 1.00 m, a length of 1.50 m, and a uniform magnetic field of 3.00 T. Determine (a) the energy density of the magnetic field and (b) the total energy in the solenoid.



baranozdemir/E+/Getty Images

29.57 A *magnetar* (magnetic neutron star) has a magnetic field near its surface of magnitude $4.00 \cdot 10^{10}$ T

a) Calculate the energy density of this magnetic field.

b) The Special Theory of Relativity associates energy with any mass m at rest according to $E_0 = mc^2$ (more on this in Chapter 35). Find the rest mass density associated with the energy density of part (a).

•**29.58** An emf of 20.0 V is applied to a coil with an inductance of 40.0 mH and a resistance of 0.500 Ω.

a) Determine the energy stored in the magnetic field when the current reaches $\frac{1}{4}$ of its maximum value.

b) How long does it take for the current to reach this value?

•**29.59** A student wearing a 15.0-g gold band with radius 0.750 cm (and with a resistance of 61.9 μΩ and a specific heat capacity of $c = 129$ J/kg °C) on her finger moves her finger from a region having a magnetic field of 0.0800 T, pointing along her finger, to a

region with zero magnetic field in 40.0 ms. As a result of this action, thermal energy is added to the band due to the induced current, which raises the temperature of the band. Calculate the temperature rise in the band, assuming that all the energy produced is used in raising the temperature.

•**29.60** A coil with N turns and area A, carrying a constant current, i, flips in an external magnetic field, $\vec{B}_{\text{ext}}$, so that its dipole moment switches from opposition to the field to alignment with the field. During this process, induction produces a potential difference that tends to reduce the current in the coil. Calculate the work done by the coil's power supply to maintain the constant current.

•• **29.61** An electromagnetic wave propagating in vacuum has electric and magnetic fields given by $\vec{E}\left(\vec{x},t\right) = \vec{E}_0 \cos\left(\vec{k}\cdot\vec{x} - \omega t\right)$ and $\vec{B}\left(\vec{x},t\right) = \vec{B}_0 \cos\left(\vec{k}\cdot\vec{x} - \omega t\right)$ where $\vec{B}_0$ is given by $\vec{B}_0 = \vec{k}\times\vec{E}_0/\omega$ and the wave vector $\vec{k}$ is perpendicular to both $\vec{E}_0$ and $\vec{B}_0$. The magnitude of $\vec{k}$ and the angular frequency ω satisfy the dispersion relation, $\omega/\left|\vec{k}\right| = \left(\mu_0\varepsilon_0\right)^{-1/2}$, where μ_0 and ϵ_0 are the permeability and permittivity of free space, respectively. Such a wave transports energy in both its electric and magnetic fields. Calculate the ratio of the energy densities of the magnetic and electric fields, u_B/u_E, in this wave. Simplify your final answer as much as possible.

Additional Exercises

29.62 A wire of length $\ell = 10.0$ cm is moving with constant velocity in the xy-plane; the wire is parallel to the y-axis and moving along the x-axis. If a magnetic field of magnitude 1.00 T is pointing along the positive z-axis, what must the velocity of the wire be in order for a potential difference of 2.00 V to be induced across it?

29.63 The magnetic field inside the solenoid in the figure changes at the rate of 1.50 T/s. A conducting coil with 2000 turns surrounds the solenoid, as shown. The radius of the solenoid is 4.00 cm, and the radius of the coil is 7.00 cm. What is the potential difference induced in the coil?

29.64 An ideal battery (with no internal resistance) supplies V_{emf} and is connected to a superconducting (no resistance!) coil of inductance L at time $t = 0$. Find the current in the coil as a function of time, $i(t)$. Assume that all connections also have zero resistance.

29.65 A 100-turn solenoid of length 8.00 cm and radius 6.00 mm carries a current of 0.400 A from right to left. The current is then reversed so that it flows from left to right. By how much does the energy stored in the magnetic field inside the solenoid change?

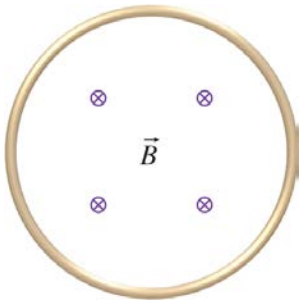
29.66 The electric field near the Earth's surface has a magnitude of 150. N/C, and the magnitude of the Earth's magnetic field near the surface is typically 50.0 μT. Calculate and compare the energy densities associated with these two fields. Assume that the electric and magnetic properties of air are essentially those of a vacuum.

29.67 What is the inductance in a series RL circuit in which $R = 3.00\ \text{k}\Omega$ if the current increases to $\frac{1}{2}$ of its final value in 20.0 μs?

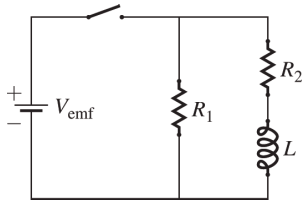
29.68 A 100.-V battery is connected in series with a 500.-Ω resistor. According to Faraday's Law of Induction, current can never change

instantaneously, so there is always some "stray" inductance. Suppose the stray inductance is 0.200 μH. How long will it take the current to build up to within 0.500% of its final value of 0.200 A after the resistor is connected to the battery?

29.69 A single loop of wire with an area of $5.00\ \text{m}^2$ is located in the plane of the page, as shown in the figure. A time-varying magnetic field in the region of the loop is directed into the page, and its magnitude is given by $B = 3.00\ \text{T} + (2.00\ \text{T/s})t$. At $t = 2.00\ \text{s}$, what are the induced potential difference in the loop and the direction of the induced current?



29.70 A 9.00-V battery is connected through a switch to two identical resistors and an ideal inductor, as shown in the figure. Each of the resistors has a resistance of 100. Ω, and the inductor has an inductance of 3.00 H. The switch is initially open.



a) Immediately after the switch is closed, what is the current in resistor R_1 and in resistor R_2?

b) At 50.0 ms after the switch is closed, what is the current in resistor R_1 and in resistor R_2?

c) At 500. ms after the switch is closed, what is the current in resistor R_1 and in resistor R_2?

d) After a long time (> 10.0 s), the switch is opened again. Immediately after the switch is opened, what is the current in resistor R_1 and in resistor R_2?

e) At 50.0 ms after the switch is opened, what is the current in resistor R_1 and in resistor R_2?

f) At 500. ms after the switch is opened, what is the current in resistor R_1 and in resistor R_2?

•29.71 A long solenoid with length 3.00 m and $n = 290.$ turns/m carries a current of 3.00 A. It stores 2.80 J of energy. What is the cross-sectional area of the solenoid?

•29.72 A rectangular conducting loop with dimensions a and b and resistance R is placed in the xy-plane. A magnetic field of magnitude B passes through the loop. The magnetic field is in the positive z-direction and varies in time according to $B = B_0\left(1 + c_1 t^3\right)$, where c_1 is a constant with units of $1/\text{s}^3$. What is the direction of the current induced in the loop, and what is its value at $t = 1$ s (in terms of a, b, R, B_0, and c_1)?

•29.73 A circuit contains a 12.0-V battery, a switch, and a light bulb connected in series. When the light bulb has a current of 0.100 A flowing in it, it just starts to glow. This bulb draws 2.00 W when the switch has been closed for a long time. The switch is opened, and an inductor is added to the circuit, in series with the bulb. If the light bulb begins to glow 3.50 ms after the switch is closed again, what is the magnitude of the inductance? Ignore any time needed to heat the filament, and assume that you are able to observe a glow as soon as the current in the filament reaches the 0.100-A threshold.

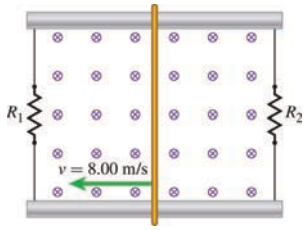
•29.74 A circular loop of area A is placed perpendicular to a time-varying magnetic field of magnitude $B(t) = B_0 + at + bt^2$, where B_0, a, and b are constants.

a) What is the magnetic flux through the loop at $t = 0$?

b) Derive an equation for the induced potential difference in the loop as a function of time.

c) What are the magnitude and the direction of the induced current if the resistance of the loop is R?

•29.75 A conducting rod of length 50.0 cm slides over two parallel metal bars placed in a magnetic field with a magnitude of 1.00 kG, as shown in the figure. The ends of the rods are connected by two resistors, $R_1 = 100.\ \Omega$ and $R_2 = 200.\ \Omega$ The conducting rod moves with a constant speed of 8.00 m/s.

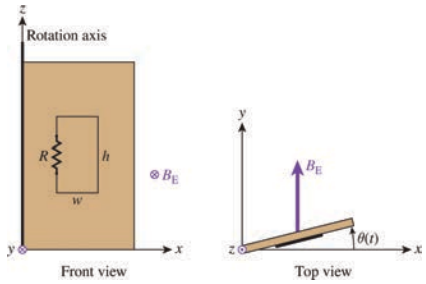


a) What are the currents flowing through the two resistors?

b) What power is delivered to the resistors?

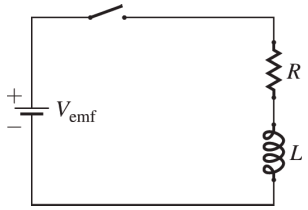
c) What force is needed to keep the rod moving with constant velocity?

•**29.76** A rectangular wire loop (dimensions of $h = 15.0$ cm and $w = 8.00$ cm) with resistance $R = 5.00\ \Omega$ is mounted on a door, as shown in the figure. The Earth's magnetic field, $B_{\mathrm{E}} = 2.60 \cdot 10^{-5}$ T, is uniform and perpendicular to the surface of the closed door (the surface is in the xz-plane). At time $t = 0$, the door is opened (right edge moves toward the y-axis) at a constant rate, with an opening angle of $\theta(t) = \omega t$, where $\omega = 3.50$ rad/s. Calculate the direction and the magnitude of the current induced in the loop, $i(t = 0.200\ \mathrm{s})$.



•**29.77** A steel cylinder with radius 2.50 cm and length 10.0 cm rolls without slipping down a ramp that is inclined at 15.0° above the horizontal and has a length (along the ramp) of 3.00 m. What is the induced potential difference between the ends of the cylinder as the cylinder leaves the bottom of the ramp, if the downward slope of the ramp points in the direction of the Earth's magnetic field at that location? (Use 0.426 G for the local strength of the Earth's magnetic field.)

•29.78 The figure shows a circuit in which a battery is connected to a resistor and an inductor in series.



a) What is the current in the circuit at any time t after the switch is closed?

b) Calculate the total energy provided by the battery from $t = 0$ to $t = L/R$.

c) Calculate the total energy dissipated in the resistor over the same time period.

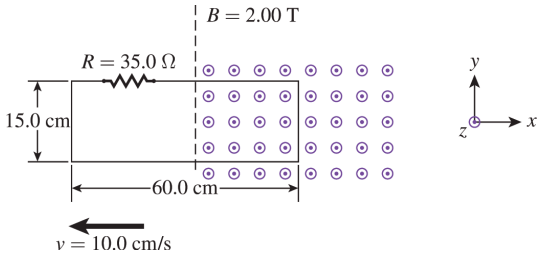
d) Is energy conserved in this circuit?

•29.79 As shown in the figure, a rectangular (60.0 cm long by 15.0 cm wide) circuit loop with resistance 35.0 Ω is held parallel to the xy-plane with one half inside a uniform magnetic field. A magnetic field given by $\vec{B} = 2.00\hat{z}$ T is directed along the positive z-axis to the right of the dashed line; there is no external magnetic field to the left of the dashed line.

a) Calculate the magnitude of the force required to move the loop to the left at a constant speed of 10.0 cm/s while the right end of the loop is still in the magnetic field.

b) What power is expended to pull the loop out of the magnetic field at this speed?

c) What is the power dissipated by the resistor?



MULTI-VERSION EXERCISES

29.80 What is the resistance in an RL circuit with $L = 33.03\ \text{mH}$ if the time required for the current to reach 75% of its maximum value is 3.350 ms?

29.81 What is the inductance in an RL circuit with $R = 17.88\ \Omega$ if the time required for the current to reach 75% of its maximum value is 3.450 ms?

29.82 For an RL circuit with $R = 21.84\ \Omega$ and $L = 55.93\ \text{mH}$, how long does it take the current to reach 75% of its maximum value?

29.83 A wedding ring (of diameter 1.95 cm) is tossed into the air and given a spin, resulting in an angular velocity of 13.3 rev/s. The rotation axis is a diameter of the ring. If the magnitude of the Earth's magnetic field at the ring's location is $4.77 \cdot 10^{-5}\ \text{T}$, what is the maximum induced potential difference in the ring?

29.84 A wedding ring is tossed into the air and given a spin, resulting in an angular velocity of 13.5 rev/s. The rotation axis is a diameter of the ring. The magnitude of the Earth's magnetic field is $4.97 \cdot 10^{-5}\ \text{T}$ at the ring's location. If the maximum induced voltage in the ring is $1.446 \cdot 10^{-6}\ \text{V}$, what is the diameter of the ring?

29.85 A wedding ring of diameter 1.63 cm is tossed into the air and given a spin, resulting in an angular velocity of 13.7 rev/s. The rotation axis is a diameter of the ring. If the maximum induced voltage in the ring is $6.556 \cdot 10^{-7}\ \text{V}$, what is the magnitude of the Earth's magnetic field at this location?

Almost all the devices in our homes operate on electricity. For example, Figure 30.1 shows a small sample of the consumer electronics devices (a notebook computer, a laser printer, a desk lamp, a smartphone, and headphones) that make our lives easier and more enjoyable by turning electricity into light and sound and by allowing us to communicate with the world. Refrigerators, televisions, washing machines, microwave ovens, air conditioners, hair dryers, and many other devices on which we rely also operate on electricity.

FIGURE 30.1 Almost all of the devices typically found on a student's desk are driven by alternating current.

W. Bauer and G. D. Westfall

Worldwide, approximately 3 terawatts (TW) of electric power are consumed, with one-quarter of the total used in North America. World electric power use has doubled in the last quarter-century (see Figure 5.20), driven mostly by very strong growth in East Asia. Almost all of this electricity is delivered to consumers via alternating current, which is the main topic of this chapter.

In Chapters 24 through 26 and 29, we examined direct current (DC) circuits, in which current flows in one direction. In this chapter, we study alternating current (AC) circuits, which use time-varying emf. AC circuits contain the same circuit elements (resistors, capacitors, and inductors) as DC circuits but show interesting physical

phenomena of tremendous importance for technological applications. In this chapter, we will learn what produces oscillations in currents and voltages, how the effective resistance in a circuit depends on the oscillation frequency, how this dependence is used in filters, and how alternating voltages and currents are transformed and rectified.

WHAT WE WILL LEARN

- Voltages and currents in single-loop circuits containing an inductor and a capacitor oscillate with a characteristic frequency.
- Voltages and currents in single-loop circuits containing a resistor, an inductor, and a capacitor also oscillate with a characteristic frequency, but these oscillations are damped over time.
- A single-loop circuit containing a time-varying source of emf and a resistor has currents and voltages that are in phase and time-varying.
- A single-loop circuit containing a time-varying source of emf and a capacitor has a time-varying current and voltage that are out of phase by $+\pi/2$ rad $(+90^\circ)$, with the current leading the voltage. The voltage and the current in such a circuit are related by the capacitive reactance.
- A single-loop circuit containing a time-varying source of emf and an inductor has a time-varying current and voltage that are out of phase by $-\pi/2$ rad (-90°), with the voltage leading the current. The voltage and the current in such a circuit are related by the inductive reactance.
- A single-loop circuit containing a time-varying source of emf and a resistor, a capacitor, and an inductor has a time-varying current and voltage. The phase difference between the current and voltage depends on the values of the resistance, the capacitance, and the inductance and on the frequency of the emf source.
- A single-loop circuit containing a time-varying source of emf and a resistor, a capacitor, and an inductor has a resonant frequency determined by the values of the inductance and the capacitance.
- The impedance of an alternating-current circuit is similar to the resistance of a direct-current circuit, but the impedance

depends on the frequency of the time-varying source of emf.

- Transformers can raise (or lower) alternating voltages while lowering (or raising) alternating currents.
- Rectifiers convert alternating current to direct current.

30.1 LC Circuits

Previous chapters introduced three circuit elements: capacitors, resistors, and inductors. We have examined simple single-loop circuits containing resistors and capacitors (RC circuits) or resistors and inductors (RL circuits). Now we'll consider simple single-loop circuits containing inductors and capacitors: **LC circuits.** We'll see that LC circuits have currents and voltages that vary sinusoidally with time, rather than increasing or decreasing exponentially with time, like currents and voltages in RC and RL circuits. These variations of voltage and current in LC circuits are called **electromagnetic oscillations.**

To understand electromagnetic oscillations, consider a simple single-loop circuit containing an inductor and a capacitor (Figure 30.2). Recall that the energy stored in the electric field of a capacitor with capacitance C is given by (see Chapter 24)

$$U_E = \frac{1}{2}\frac{q^2}{C},$$

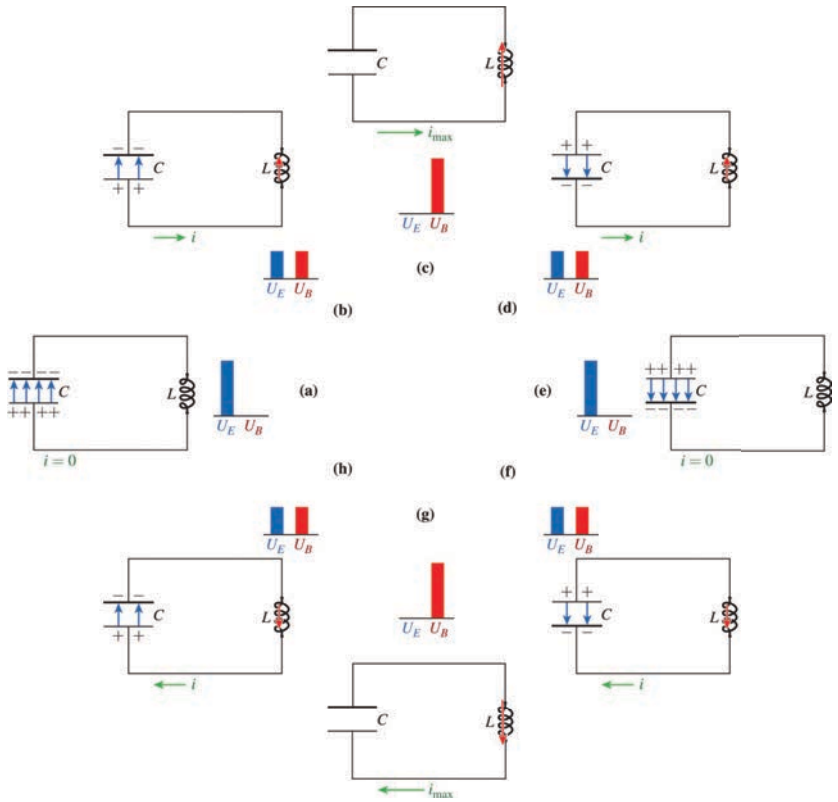

FIGURE 30.2 A single-loop circuit containing a capacitor and an inductor. (a) The capacitor is initially completely charged when it is connected to the circuit. (b)–(h) The current and the voltage in the circuit oscillate over time.

where q is the magnitude of the charge on the capacitor plates. The energy stored in the magnetic field of an inductor with inductance L is given by (see Chapter 29)

$$U_B = \frac{1}{2}Li^2,$$
